To decide which action to perform, the inputs to the basal ganglia must compute the utility of the two actions. For the first action, this is a function that outputs a 1 if there is a noun in vision, and a 0 otherwise. The second action is similar, but for identifying verbs. This is a simple classifier and can again be expressed as a function whose connection weights are computed with Equations 3 and 4.

The resulting system is capable of taking a stream of visual stimulus as input and keeping track of the most recent noun and the most recent verb seen. This verb and noun are then combined into a single vector representing that pair.

Figure 3: Routing information from vision to the correct noun and verb populations, depending on whether the visual stimulus is categorized as a noun or a verb. Once routed, the correct combined phrase is computed as in Figure 2.

\section*{Responding to Commands}

Once the model has formed a single representation of the command itself, we also need to show that it can execute that command correctly. That is, not only can the representation be encoded by spiking neurons, but it can also be decoded by spiking neurons to perform a task.

Since the focus of this paper is the parsing of a command, we use a very simple system for executing commands. In other work we show how to process significantly more complex commands, (Choo \& Eliasmith, submitted), but those commands are directly injected into the brain model, rather than being presented visually and parsed.

In this case, performing a command occurs via a new action added to the basal ganglia. It has a high utility when there is no visual input and when the phrase is similar to VERB \(\circledast\) WRITE. When selected, this action routes the information from phrase to motor while convolving it with the inverse of NOUN. Thus, if the phrase is VERB \(\circledast\) WRITE+NOUN \(\circledast\) FOUR, the semantic pointer \(\operatorname{inv}(\) NOUN \() \circledast(\) VERB \(\circledast\) WRITE+NOUN \(\circledast\) FOUR) will be routed to the motor area. Since NOUN and inv(NOUN) approximately cancel, the value set to the motor area will be close to the ideal vector for FOUR. This is mapped to a series of hand positions using the same method as Eq. 5.

The behaviour of the model is shown in Figure 5. The visual input is shown in the top row, and the written responses are shown in the bottom row. The other rows show the spiking behaviour of 50 neurons from each of the key brain areas in the model.

The first thing to note is that the model performs accurately. The correct response is given for each case. Furthermore, it should be noted that the two words in the command can be given in either order (WRITE FIVE versus TWO WRITE). This is because we have not imposed a particular grammatical order. While it would be possible to do so, we note that English speakers are quite capable of

Figure 4: Executing a WRITE action
correctly interpreting TWO WRITE as a command. However, as demonstrated in the section on Conditional Statements, word order does matter for complex commands.

The spike patterns shown in Figure 5 provide some insight into the performance of the model. In the vision row, we can see different patterns of activity for each visual input, as expected. The pattern for "W" and the pattern for seeing nothing at all are quite distinct. Similarly, the spike patterns in the noun and verb populations change depending on which term is currently being memorized, and these patterns in turn affect the phrase population.

Another feature that can be seen in Figure 5 is the cognitive reaction time. Each symbol is shown for 0.5 seconds, but the motor output is clearly delayed slightly. For example, the visual input is cleared at \(\mathrm{t}=1.0 \mathrm{~s}\), but the spiking behaviour in motor doesn't change until \(\mathrm{t}=1.05 \mathrm{~s}\). This is the time required for the model to notice the change in visual input, perform action selection in the basal ganglia, release the inhibition in the thalamus, and allow the information from the phrase neurons to pass to the motor neurons. The exact amount of time required is a function of the connectivity and neurotransmitter time constants, all of which are taken from neurological data (so they are not free parameters). For more analysis of this feature of the basal ganglia model, see (Stewart, Choo, \& Eliasmith, 2010).

\section*{Memory}

To demonstrate that this system can parse commands other than WRITE <number>, we add a memory action. If the model is told to REMEMBER 4 ("R 4"), the phrase will be similar to VERB \(\circledast\) REMEMBER. We add an action for this condition that routes the phrase information to the memory while transforming it by inv(NOUN). As with the WRITE action, this extracts the FOUR from the phrase. For this action, the output vector is routed to a working memory area. This is a group of neurons that stores a vector (like every other group of neurons in the model), but that has a communication channel back to itself. This recurrent connection causes the neurons to maintain their own state after the input is removed. This structure has been shown to match neural behaviour of visual working memory (Singh and Eliasmith, 2006), and is stable over long periods of time (tens of seconds).

Finally, we show that we can extract information from working memory by adding a special write action WRITE NUMBER ("W \#"). This action has a high utility when the phrase is VERB \(\circledast\) WRITE+NOUN \(\circledast\) NUMBER and causes the information in working memory to be routed to the motor system.

The result (Figure 6) is a system that can respond correctly to two different verbs and ten nouns (only ZERO through NINE were implemented). Importantly, adding the new action did not require any modifications to the phrase population. This is due to the fact that the semantic pointers used to represent the phrase are simply fixed-length vectors, and the phrase population is capable of storing any vector. No modifications to that population are needed to let it store a new vector like VERB \(\circledast\) REMEMBER+NOUN \(\circledast\) THREE, even if it has never seen it before.

In other words, the model does not require an exponential growth in numbers of neurons in order to handle the exponential growth in possible phrases that it can correctly interpret. Adding new actions only requires adding the neural populations needed to perform that action (in this case, the working memory population) and new connections between existing populations (in this case, phrase) and the basal ganglia and thalamus.

Figure 6: A model with REMEMBER and WRITE actions. Given an input REMEMBER SIX <long pause> WRITE NUMBER it will write the number 6.

\section*{Model Performance}

The behaviour of this model in a variety of conditions is shown in Figure 7. For each condition, new neurons (with preferred direction vectors, gains, and background currents) were generated, and Equations 3 and 4 were used to solve for all the synaptic connection weights.

First, the maximum vocabulary size (the largest number of nouns such that there is still a \(95 \%\) chance of correctly responding) scales exponentially as the number of neurons per population increases. This is an expected consequence of vector representations (e.g., Plate, 2003), as the number of dimensions accurately represented scales linearly with the number of neurons, while the volume of a hypersphere scales exponentially with the number of dimensions.

Second, the model is robust to destruction of neurons. To simulate neural death, we randomly delete neurons from every population, and then re-use Equations 3 and 4 to compute new connection weights between the remaining neurons. Performance decreases, but remains above well above chance until less than \(40 \%\) of the neurons remain. This shows a gradual degradation in behaviour, rather than catastrophic failure.

Finally, we show the model performs well for varying stimulus presentation times, but poor performance when symbols are seen for less than 250 milliseconds.

Figure 7: Model performance for varying vocabulary sizes, neural destruction, and display times. Input is of the form "R <number>, W \#", and an output is judged correct if the model writes the correct number. Shaded area is the \(95 \%\) bootstrap confidence interval over 50 trials.

\section*{Conditional Statements}

The method used to add the REMEMBER action can be used to add many new actions. For instance, an INCREMENT action can be added which increases the number stored in memory. However, to show that this method extends to more complex rules, we now consider the parsing of a conditional rule such as "if you see a six, write a one". Using " \(S\) " to as the symbol for SEE, we can present this to the model as "S 6 W 1". We then add actions to the basal ganglia such that a phrase of VERB \(\circledast\) SEE will cause that phrase to be routed to a new condition group of neurons. A global state population is created, which gets inputs from all cortical areas that could be used as part of a condition (in this case, just vision), so that if vision is TWO then the value TWO®SEE will be added to state. The state and condition vectors are then compared (by computing the dot product) in a similarity population. Finally, the go/nogo population uses the similarity and condition values to compute a penalty to be applied to the utilities of actions in the basal ganglia. That is, it decreases the utility if there is a condition but condition does not match the current state.

Importantly, once the condition is stored in a separate neural population, we can now combine the condition and the phrase into a single semantic pointer. For this case, the resulting vector would be CONDITION \(\circledast(S E E \circledast\) SIX) +VERB \(\circledast\) WRITE+NOUN \(\circledast\) ONE. This is a single vector representing a complex, syntactically structured command that can be successfully executed by this model. In (Choo \& Eliasmith, submitted), we develop a model capable of following a collection of rules of this form, but the model presented here is the first biologically realistic spiking model capable of taking the sequential input "S 6 W 1" and parsing it to create the correct semantic pointer vector.

Interestingly, the model supports some syntactic variation, such as "6 S 1 W " or "6 S W 1". However, it will not perform correctly when one phrase is embedded in the center of the other ("S W 61 ", for example). This difficulty with center embedding is a well-studied feature of natural languages, and appears naturally in this model from the processing available to neural populations.

Finally, in order to successfully respond to a condition instruction in the other order ("W 1 S 6"), we must also add an extra action rule which stores the initial phrase (VERB \(\circledast\) WRITE+NOUN \(\circledast\) ONE) in memory before processing the conditional phrase. This extra cognitive load indicates this model finds it easier to process "If you see a six, write a one" than "Write a one if you see a six".

Figure 8: Additions needed for conditional instructions.

\section*{Conclusion}

We have shown how a model consisting of spiking leaky-integrate-and-fire neurons with properties and connection patterns that match the human brain can take a visually presented input command, parse it, and perform the correct action. This works for simple verb-noun commands and for more complex conditional commands, and also scales up to a vocabulary size of hundreds of thousands of terms. The majority of the neural components are identical those in our previous models (e.g. Eliasmith et al., 2012).

To perform this parsing, the model builds a single combined vector representation of the command. This resulting structured representation is of exactly the same form as those we have used in other neural models. As such, this model provides a potential explanation as to how brains can form and manipulate these symbol-like structures that are found throughout cognition.

That said, the current model has many limitations. It does not impose particular grammatical rules (other than avoiding center embedding). Perhaps relatedly, it does not address the problem of ambiguous classifications. It also does not perform token separation, as it requires that the input be already sequentially arranged. Fortunately, these problems have been addressed by other researchers, and our ongoing work is to adapt their solutions to the constraints of a biologically realistic spiking model. In particular, Ball (2011) provides an extensive project to process natural language speech using the ACT-R cognitive architecture, which may be adaptable to our neural framework.

\title{
Complex Mental Time Travel
}

\author{
Kurt Stocker (kurt.stocker@psychologie.uzh.ch) \\ Department of Psychology, Binzmühlestrasse 14/22 \\ 8050 Zürich, Switzerland
}

\begin{abstract}
This article argues that investigating the conceptual structure underlying the use of the pluperfect and the future perfect reveals a new complex type of nested dual mental time travel: mental time travel into posteriority embedded into mental time travel into "anteriority in the past" (underlying the pluperfect) versus mental time travel into posteriority embedded into mental time travel into "anteriority in the future" (underlying the future perfect). Additionally this article also offers the following novel notions for temporal cognition: a mental time line where past/anteriority and future/posteriority have become nondispersible; dual temporal direct viewings at the present moment; and looking into the future from the past (rather than the more typical looking into the future from the present moment). Implications for cognitive modeling are discussed.
\end{abstract}

Keywords: mental time travel; tense system; Talmyan concept structuring; Talmyan perspective point (PP); mental time line; models

\section*{Introduction}

Until recently mental time travel has mainly been characterized as mentally construing oneself as looking forward or backward in time from the present moment (e.g., Addis et al., 2009; Schacter \& Addis, 2007; Tulving, 1972, 2002). By synthesizing findings from cognitive psychology and cognitive linguistics and by additionally applying cognitivelinguistic methodology, Stocker (2012a) then introduced the idea-based on a sketch by Talmy (2000, pp. 86-87)—that in addition to this basic type of mental time travel there might also be more complex types of mental time travel. For instance: a person may mentally construe herself as looking back from the present moment to a particular point in time in the past, but may additionally also conceptualize herself as mentally looking forward from this past point to a "later time" that is still in the past. Such examples have been referred to as examples of nested dual mental time travel ("mental time travel embedded within mental time travel") (Stocker, 2012a, p. 408). Investigating the conceptual structure underlying the linguistic use of before/after sentences that additionally are set in the past or future tense, Stocker (2012a) has thus far basically identified one form of nested dual mental time travel: mental time travel into anteriority or posteriority (underlying before/after) embedded in mental time travel into the past or future (underlying past/future tense). It is important to distinguish anteriority/posteriority ("earlierness/laterness") from past/future since the former is more generic and does not depend upon the present moment as a reference point (e.g., Núñez \& Sweetser, 2006, p. 404). For instance: One event may have occurred later in time
than another event (say my first day at school versus my birth), but both events have occurred in the past.

This article investigates how this anteriority/posteriority versus past/future distinction can help us to reveal the tem-poral-conceptual structure underlying the pluperfect and future perfect. The theoretical strategy I adopt is the same as used in Stocker (2012a): using language as an entree to a conceptual level that seems deeper than language itself (Pinker, 2007; Talmy, 2000). This strategy is supported by recent findings that many conceptualizations observed in relation to our use of language also exist in mental representations that are more basic than language itself (e.g., Boroditsky, 2000; Casasanto \& Boroditsky, 2008; McGlone \& Harding, 1998; Núñez, Motz, \& Teuscher, 2006). In the present investigation language can assist us to identify complex forms of mental time travel-complex forms of how we can mentally project through time.

The basic theoretical framework used is Talmyan concept structuring (Talmy, 2000), with the further refinement for temporal cognition by Stocker (2012a). There are many other basic theoretical frameworks that one could adopt when investigating the conceptual structure underlying the tense system or the conceptual structure of mental time in general-for example: formal accounts of tense (e.g., Comrie, 1985; Declerck, 1986; Jespersen, 1924; Reichenbach, 1947), conceptual semantics (Jackendoff, 1987, pp. 398402; cf. also Pinker 1989, pp. 205-206), formal semantics (e.g., Bennett \& Partee, 1978; Montague, 1973; Pendlebury, 1992), or temporal (tense) logic (e.g., Allen, 1984; Kowalski \& Sergot, 1986; Lichtenstein \& Pnueli, 2000; Prior 1967). While the current investigation is basically set in a Talmyan framework, it also, as we will see, benefits greatly from the formal-tense analysis of Comrie (1985).

One of the main motivations for choosing Talmyan concept structuring as a basic theoretical framework for the present investigation is that it offers a ready means to incorporate mental temporal perspective (Stocker, 2012a; Talmy, 2000, pp. 68-76+86-87). In the other above-mentioned approaches (formal tense, conceptual semantics, formal semantics, temporal logic), mental perspective is usually not considered or is only mentioned marginally, without incorporating it into the formal descriptive apparatus (e.g., in Jackendoff, 1987, p. 399). In contrast, in Talmyan concept structuring, perspective is an integral part of the overall theoretical descriptive system.

The present investigation will reveal several basic novel notions in relation to temporal cognition (as summarized in the discussion section). It will also be discussed if the current account of complex mental time travel could be used to refine modeling approaches which have incorporated mental
temporal perspective into their models (Brown, Neath, \& Chater, 2007).

\section*{Mental time travel underlying the pluperfect}

Undertaking an extensive cross-linguistic investigation, the linguist Bernard Comrie characterizes the temporalrelational structure of the pluperfect (I had already eaten when ...) in the following way:
"The meaning of the pluperfect is that there is a reference point in the past, and that the situation in question is located prior to that reference point, i.e. the pluperfect can be thought of as 'past in the past'" (1985, p. 65).

As we will see later on in this section, a still more refined characterization of the meaning of the pluperfect-rather than saying that it signifies "past in the past"-is to characterize it as "anteriority in the past." To start investigating the temporal-conceptual structure underlying the pluperfect, we use one of Comrie's own examples for illustration (1985, p. 66):
(1) John had already left when Mary emerged from the cupboard.

According to Comrie the temporal relations underlying the use of the pluperfect can be formalized in the following terms (1985, p. 125):

\section*{(2) pluperfect: E before R before S}

E stands for the event which is to be located in time. In Comrie's example, the event of John's leaving is the event to be located prior to Mary's emerging from the cupboard. Hence the event in the pluperfect clause (John's leaving) is E . R stands for the temporal reference point in relation to which E is defined. Thus Comrie's formula correctly predicts that E (John's leaving) occurs before R (Mary's emerging from the cupboard). S stands for moment of speech (i.e., the present moment). Comrie's formula again correctly predicts that R (Mary's emerging from the cupboard) occurs before \(S\) (the present moment). \({ }^{1}\)

\footnotetext{
\({ }^{1}\) Comrie's (1985) ERS notation for the pluperfect represents a further development-and major departure-from the famous tense formulations of Reichenbach (1947, pp. 287-298; cf. also Jespersen, 1924, pp. 262-264). Comrie's formulations are mainly taken over because it is Comrie's analysis that allows one to characterize the pluperfect as involving "anteriority in the past" and the future perfect as involving "anteriority in the future"-which has major implications when one adds mental perspective to the pluperfect and future perfect constructions, as shall be demonstrated in this article. Taken over from Prior in the analysis in this paper, is the argumentation that there is no need to-as Reichenbach does-"make such a sharp distinction between the point or points of reference and the point of speech" (1967, p. 13). This is so, as also pointed out by Prior, because the present moment ("the point of speech") itself can function as a reference point. This argumentation of Prior is taken over by allowing the present moment to function as a Ground (see below in this article). "Ground" is the Talmyan technical term for what one might also refer to as a "ref-
}

As has just been demonstrated, (2) can correctly predict all temporal-relational structure of the pluperfect. The question we now turn to is: How could mental temporal perspective (Stocker, 2012a; Talmy, 2000, pp. 72-76+86-87) be added to this basic account of the temporal-relational structure of the pluperfect? One theoretical solution to this question, the one to be adopted in this article, is to integrate Comrie's findings into the theoretical framework of Talmyan concept structuring-because Talmyan concept structuring can describe temporal relations and temporal perspective in one coherent theoretical framework (Stocker, 2012a; Talmy, 2000). As a starting point, let us reformulate Comrie's pluperfect formula in Talmyan terms. In Talmyan concept structuring spatial or temporal relations are captured with the notions of Figure (F) and Ground (G) (Talmy, 2000). In temporal Figure/Ground, one event serves as temporal reference point-G-in relation to which the temporal location of the other event-F-is defined. Thus (2) can be captured in the following way in Talmyan terms:
(3) pluperfect: \(F_{1}\) before \(G_{1} ; F_{2}\left(G_{1}\right)\) before \(G_{2}\left(G_{2}=\right.\) present moment)

We again exemplify the formalized temporal relationship with (1). Now it is \(\mathrm{F}_{1}\) which stands for the event which is to be located in time (John's leaving). \(\mathrm{G}_{1}\) stands for the temporal reference point (Mary's emerging from the cupboard) in relation to which \(F_{1}\) is defined. Thus (3) correctly predicts that \(F_{1}\) (John's leaving) occurs before \(G_{1}\) (Mary's emerging from the cupboard). However, \(G_{1}\) also functions as another \(F\), since the temporal position of \(G_{1}\) is also defined in relation to the present moment. Hence, one is in a position to postulate that \(\mathrm{G}_{1}\) (Mary's emerging from the cupboard) also functions as an F (a second F in the overall temporal complex: \(F_{2}\) ) whose temporal position is defined in relation to the present moment (which functions as a second \(G: \mathrm{G}_{2}\) ). Thus, (3) also correctly predicts that \(\mathrm{F}_{2}\) (Mary's emerging from the cupboard) occurs before \(\mathrm{G}_{2}\) (the present moment).

Thus far, Comrie's pluperfect (2) and the Talmyan pluperfect (3) formalization are equipotent in terms of theoretical explanatory power: they both correctly predict the complex temporal relations that underlie our use of the pluperfect. But having it phrased in Talmyan terms allows us now to add mental temporal perspective (Stocker, 2012a; Talmy, 2000, pp. 72-76+86-87) to the temporal-relational description. Both Talmy and Stocker have cognitive-linguistically argued in detail that a complex temporal sentence (a temporal sentence with a main and a subordinate clause) underlies a temporal direct viewing of the F event in relation to the content of the main clause and a temporal indirect (prospective or retrospective) viewing of the \(G\) event in relation to the content in the subordinate clause. Taking over this analysis (see Stocker, 2012a; Talmy, 2000, pp. 72-76+8687 for argumentation), we derive at the (perspective-

\footnotetext{
erence point." For a different theoretical approach to the notion of
} a temporal perspective point see Declerck (1986, pp. 320-321).
including) temporal-conceptual structure underlying our use of the pluperfect as it is depicted in Fig. 1.

Figure 1: Mental time travel into posteriority (to \(G_{1}\) ) embedded into mental time travel into anteriority in the past (to the \(\mathrm{F}_{1}\)-co-located PP), a nested dual form of mental time travel underlying the pluperfect. This temporal-conceptual structure (and the cognition thereof) is in many respects identical to the one proposed by Stocker (2012a) for be-fore/past-tense constructions (p. 408). However, the crucial difference is that in before/past-tense constructions there are two distinct temporal Reference Frames (anteriority/posteriority and past/future RFs) whereas in constructions containing a pluperfect these two RFs have fused into one larger, more complex anteriority-past/posteriority-future RF.

When taking a look at this figure, the temporal structure (and perspectival cognition thereof) might at first glance seem identical to the conceptual structure underlying our use of a temporal complex sentence containing before and the past tense (a before/past-tense construction like \(I\) shopped at the store before I went home; cf. with Fig. 9 in Stocker, 2012a, p. 408). This is also not surprising: Comrie's characterization of the pluperfect clause as the "past in the past" could also be paraphrased as "past event before another past event." We should also note that Comrie's pluperfect characterization of "the past in the past" just serves him as a first rough characterization of the pluperfect (he uses the phrase to introduce the pluperfect). Crucially, Comrie notes that in relation to (2):
"Since the relation before is transitive (i.e. if X is before Y and Y is before Z , then necessarily X is before Z ), one can deduce \(E\) before \(S\) from the representation of the pluperfect, but this is not part of the formal representation of the pluperfect; the importance of this observation will become clear when we discuss the future perfect" (1985, p. 125).

In other words, what Comrie is saying is that the pluperfect is basically speaking not "a past in the past" (i.e., this can only be deduced), but anteriority in the past (since he says that S-the present moment-is in no way directly related to E). All that is inherent in (2)-or (3)-is that the event in the pluperfect must occur earlier than its reference event in the past. As with Comrie, we examine the importance of this observation when we examine the temporalconceptual structure underlying the future perfect (see next section). The observation that the pluperfect signifies "anteriority in the past" also leads us to the basic temporalconceptual difference between before/past-tense construc-
tions and complex sentences containing a pluperfect in the main clause and the simple past in the subordinate clause. In a before/past-tense construction, one can identify two distinct temporal Reference Frames (RFs): an anteriority/posteriority RF (underlying before) that is embedded in a past/future RF (underlying past/future-tense; as examined in Stocker, 2012a, where the term RF is also technically defined). But in a pluperfect construction, one cannot disentangle the anteriority/posteriority RF and the past/future RF. The observation that the pluperfect stands for "anteriority in the past" means that the temporal conceptual structure underlying the pluperfect has fused these two RFs into a larger complex whole: the pluperfect carries components of both these RFs within it. Trying to tease them apart would result in the dissolving of the sine qua non of the pluperfect: that it refers to an event that must occur earlier than another event in the past. It is in this sense that a pluperfect construction is more complex than a before/past-tense construction: underlying a pluperfect structure is a more complex RF (a mental time line) where components of two separate RF-systems have formed a new complex whole.

Additionally cognitive-linguistic analysis of complex temporal sentences in relation to Talmyan mental perspective points (PPs) suggests that \(F\) and \(G\) are cognized as points (punctual events) on the mental time line and they are mentally cognized from a distal PP (as detailed in Stocker 2012a; Talmy 2000, pp. 61-62). A distal PP means mentally zooming out as much from an event as to collapse the entire duration of an event to a single temporal point. The self needs to zoom out this much in order to be able to cognize two events-that is the relationship between the two events -from one perspective point. Note also that the observation that the pluperfect indicates that self travels back from the present moment to a point in time prior to another past event (to \(F_{1}\) ) means that the reference point in the past \(\left(G_{1}\right)\) can only be located in a prospective (later) direction when viewed from the perspective of \(\mathrm{F}_{1}\). Thus the self at the point in the past that is prior to another event in the past must mentally travel forward in order to establish the posterior reference point (in order to establish \(\mathrm{G}_{1}\) ). That the self travels from temporal F co-location to G (to establish a reference point at the temporal G point) has been examined in detail for before/after temporal constructions (Stocker, 2012a).

Stocker (2012a) also argues in detail (by providing cogni-tive-linguistic evidence) that the schematic geometric representations, as for instance shown in Fig. 1, are not merely a didactic aid that allows us to illustrate the underlying cogni-tive-temporal structure. Rather it is proposed that such geometry is actually construed in our mind when we conceptualize time. For instance: the depicted time line is proposed to be an actual, mentally construed spatial structure in our mind that allows for mental time travel-for instance in relation to the pluperfect by projecting one's mental gaze along this mentally construed line once in a retrospective direction (to "anteriority in the past") and once in a prospective direction (to the reference point in the past). The pro-
posal that the "mental time line" is mentally construed when we engage in mental time travel is also supported by a growing number of recent experimental behavioral findings. The mental time line is for instance frequently conceptualized in relation to the cognizer's body along the sagittal (back to front) or transversal (left to right) axis (e.g., Hartmann \& Mast, 2012; Miles, Nind, \& Macrae, 2010; Ulrich \& Maienborn, 2010).

\section*{Mental time travel underlying the future perfect}

Drawing-as in the pluperfect-extensively on crosslinguistic data, Comrie concludes that the temporalconceptual structure underlying the future perfect (I will have eaten when ...) differs to the one underlying the pluperfect in only one way: the reference point \(\left(G_{1}\right.\) in the Talmyan framework) is set in the future rather than in the past (Comrie 1985, p. 69-74). Accordingly, Comrie (p. 126) formalizes the temporal-relational structure underlying the pluperfect in the following way (cf. with (2)):

\section*{(4) future perfect: E before R after S}

Reformulation in Talmyan concept structuring (cf. with (3)); this will again enable us to integrate PP into the temporal cognition:
(5) future perfect: \(F_{1}\) before \(G_{1} ; F_{2}\left(G_{1}\right)\) after \(G_{2}\left(G_{2}=\right.\) present moment)

Both formulations-(4) and (5)-encode a remarkable finding of Comrie about the pluperfect (a finding that holds true cross-linguistically): that all that the future perfect indicates is that there must be a reference point \(\left(\mathrm{G}_{1}\right)\) in the fu-ture-but while the event referred to ( \(\mathrm{F}_{1}\) ) most typically also occurs in the future, it can also occur in the present or even in the past. Comrie:
"Let us start with the example John will have finished his manuscript by tomorrow. Let us suppose moreover that I do not know whether or not John has already finished his manuscript (or at least do not wish to reveal this knowledge), but I know (and am prepared to divulge) that he will have finished it by tomorrow - say, because he made a promise to this effect several days ago, and is judged by me to be reliable. Then there are three sets of circumstances in which I can felicitously and truthfully utter this statement. One set of circumstances is where John finishes his manuscript between the moment of my uttering this sentence and the reference point 'tomorrow'. The second is where John is in fact finishing his manuscript at this very moment, but I am unaware (or wish to give the impression that I am unaware) of this fact. The third is where John has already finished his manuscript, but I am unaware (or wish to appear unaware) of the fact. Thus the time reference of John's finishing his manuscript is left open as to whether it is future, present, or past relative to the present moment, the only stipulation
being that it must be prior to the reference point in the future, the sine qua non of the future perfect" \((1985\), p. 71).

This leads to three kinds of temporal relations that can underlie our use of the perfect: future perfect with future interpretation, future perfect with present interpretation, and future perfect with past interpretation (Comrie, 1985, p. 70). It is in this context where the anteriority/posteriority versus past/future distinction becomes highly relevant: whereas the structure underlying the pluperfect (by deduction) can be characterized as a "past in the past" (but is more precisely "anteriority in the past"; cf. previous section), this is no longer true for the structure underlying the future perfect. As the analysis of Comrie demonstrates, the temporal relations underlying the future perfect could not (also not by deduction) be characterized as "past in the future" (since this would only correctly characterize the future perfect with past interpretation). The only characterization that can capture the sine qua non of the future perfect is "anteriority in the future"-that is, a reference point \(\left(\mathrm{G}_{1}\right)\) in the future in relation to which an earlier event \(\left(\mathrm{F}_{1}\right)\) is defined, an event that can be located in the future, present, or past.

If we now add-as we did with the temporal-conceptual structure underlying the pluperfect-mental temporal perspective (Stocker, 2012a; Talmy, 2000, pp. 72-76+86-87), then these three possible interpretations of the future perfect naturally lead to three different kinds (subtypes) of nested dual mental time travel, as illustrated in Figs. 2-4.

Figure 2: Mental time travel into posteriority (to \(\mathrm{G}_{1}\) ) embedded into mental time travel into anteriority in the future (to the \(\mathrm{F}_{1}\) co-located PP), where the anterior event is also set in the future-a nested dual form of mental time travel underlying the future perfect with future interpretation.

The temporal-conceptual structure and cognition underlying the future perfect with future interpretation (Fig. 2) is largely identical to complex before-sentences that would additionally be marked as occurring in the future (cf. Stocker, 2012a). However, the vital difference is again-as in before-past-tense constructions (cf. previous section)-that in a before-relation where both events are set in the future there are two distinct temporal Reference Frames (anteriority/posteriority and past/future RFs) whereas in a construction containing a future perfect these two RFs have fused to one larger, more complex anteriority/past-posteriority/future RF where the two RFs can no longer be disentangled.

Figure 3: Mental time travel into posteriority (to \(G_{1}\) ) embedded in "mental time travel" into anteriority in the future (to the \(\mathrm{F}_{1}\) co-located PP ), where the anterior event is set at the present moment, a nested dual form of mental time travel underlying the future perfect with present interpretation.

The novel finding in the temporal-conceptual structure and cognition underlying the future perfect with present interpretation (Fig. 3) is that computational logic requires us to place the self twice at the present moment: the self must be located at the present moment in order to look out at the embedded self that is a distal distance removed from the time line (cf. previous diagrams); the second (embedded) self a distal distance away from the time line (but still colocated with the present moment) needs to look at the present moment on the time line so that \(\mathrm{F}_{1}\) can be cognized in a temporally direct way (cf. also previous diagrams). More technically speaking, the novel proposal is the existence of a dual form of temporal direct viewing, where both viewings are located at or co-located at the present moment. Note also that "mental time travel" into anteriority in the future is not really mental time "travel" in the present-interpretation case-since the anterior point happens to be at the present moment, the self at the present moment must cognize an embedded self a distal distance away from the timeline (but since this all happens at the present moment, the self does not really "travel" anywhere, at least not in a "forward/backward in time" sense).

The major novel observation in the temporal-conceptual structure and cognition underlying the future perfect with past interpretation (Fig. 4) is a looking forward from a past point (from the PP that is co-located with \(\mathrm{F}_{1}\) ) to a future point (to \(\mathrm{G}_{1}\) )-that is, a prospective projection through mental time that starts off in the past and extends (passing by the present moment as it were) right into the future.

Figure 4: Mental time travel into posteriority (to \(\mathrm{G}_{1}\) ) embedded in mental time travel into anteriority in the future (to the \(\mathrm{F}_{1}\) co-located PP ), where the anterior event is set in the past-a nested dual form of mental time travel underlying the future perfect with past interpretation.

\section*{Discussion}

The current investigation has-in addition to the findings of Stocker (2012a)—identified one more complex form of mental time travel: mental travel into posteriority embedded into mental time travel into "anteriority in the past" (underlying the pluperfect) versus mental time travel into posteriority embedded into mental time travel into "anteriority in the future" (underlying the future perfect). Additional novel notions include: a mental time line where past/anteriority and future/posteriority have become nondispersible; dual temporal direct viewings at the present moment; and looking into the future from the past (rather than the more typical looking into the future from the present moment). The last two of these novel notions have only been possible to identify because the current investigation uses a basic theoretical approach (Talmyan concept structuring for time: Stocker, 2012a; Talmy, 2000) that inherently incorporates temporal mental perspective into the explanatory framework.

One advantage for cognitive science in general that comes out of the current work (and of Stocker 2012a, 2012b) is that it offers a systematic and detailed explanatory framework how mental perspective can be included in a theory of temporal cognition. The relevance of this can for instance be illustrated in relation to cognitive models of memory retrieval. Brown et al. (2007) have introduced a retrieval model they call SIMPLE (scale independent memory, perception, and learning):
„... memory traces can be seen as located and individuated at least partly in terms of their position along a temporal continuum receding from the present into the past. This time line is logarithmically compressed, such that recent locations are more easily discriminable from one another than are more temporally distant locations" (p. 541).

As in SIMPLE, the current investigation has also identified a self who is looking back from the present moment along a mental time line to multiple temporal points (locations) in the past. Furthermore, the current investigation (see also Stocker, 2012a; Tulving, 1972, 2002) suggests that the
self at the present moment also mentally cognizes an additional (remembered) self in the past itself (in Figs. 1-4 this is always the self at the \(\mathrm{F}_{1}\)-co-located PP, a distal distance away from the time line). In the current framework, it is this remembered embedded self that looks out at the actual past events. In addition, Stocker (2012b) has reviewed findings that suggest how this embedded distal self in the past can take on an embodied (field) or disembodied (observer) mental perspective. Future research could address the question, whether it might be fruitful for temporal-perspectiveincluding models (like SIMPLE) to incorporate this ,,additional self" in the past. This then would allow such models to investigate if this embedded self (i) cognizes the memory items in the past in a temporally direct or temporally indirect (prospective or retrospective) way and (ii) if it cognizes the items in an embodied (field) or disembodied (observer) perspective. Such refinements are likely to be relevant for a recall model. For instance: In field (embodied) memories one is known to retrieve richer accounts of affective reactions, physical sensations, and psychological states whereas in observer (disembodied) memories one is known to retrieve richer accounts of the external environment, such as where things were located in the remembered surroundings (e.g, McIsaac and Eich, 2002).

\title{
Representation and Criterion Differences between Men and Women in Semantic Categorization
}

\begin{abstract}
Gender differences are not widely studied in the categorization literature and the studies that did focus on gender differences generally investigated processing differences or differences in the use of particular categorization answers (absolute versus continuous). In the following study we looked at differences in the likelihood that men or women consider an item to be part of a category. The objective of the study was twofold: we wanted to introduce a model that is able to determine whether there are meaningful differences in categorization between groups and that is able to identify the sources of these differences. Secondly with this model we wanted to show that there were meaningful categorization differences between men and women: these differences are located at the level of the representation and/or the criterion.
\end{abstract}

Keywords: semantic categorization, threshold theory, gender differences, typicality, similarity, differential item functioning

\section*{Introduction}

Are men more likely than women to consider fishing a sport? And are women more likely than men to consider a dollhouse a member of the category toys? Or in other words are there, for some items, differences between men and women in the likelihood that they would consider an item to belong to a particular category? And if so what is/are the source(s) of this gender difference? In the following study we addressed this question by gathering categorization judgments for 23 exemplars from eight categories, and by analyzing these data with a model that is able to detect differences between men and women in the strictness of the criterion they use to judge an item to be part of the category and differences in the representation that men and women use. The model is a random item mixture model proposed by Frederickx, Tuerlinckx, De Boeck, and Magis (2010), henceforth referred to as the RIM model.

\section*{RIM model}

The RIM model is an item response theory model, Such models assume that the probability that a person endorses an item can be derived from the relative position of the item and the person towards each other on a common latent scale. The more an item's position exceeds the position of the person on the scale the more likely that the person will give a positive answer to the item. Verheyen, Hampton, and Storms (2010) claimed that these models therefore provide
an excellent formalization of the threshold theory proposed by Hampton \((1995,2007)\) in which it is assumed that an item is judged to be part of a category if the similarity of the item to the category exceeds a certain threshold criterion. In this case the item's position on the latent scale represents the item's similarity to the category and the person's position is the threshold criterion the person uses to judge whether the item-category similarity is sufficient for the item to belong to the category.

The RIM model extends this approach in that it is able to account for group differences in two different ways. First of all, the RIM model estimates an average threshold criterion for each group. If the average threshold criterion estimated for women differs from the average threshold criterion for men, women have, depending on the sign of the difference, either a more liberal threshold criterion (they require a smaller item-category similarity than men to judge items as belonging to the category) or a more strict threshold criterion (they require a larger item-category similarity than men to judge an item to be part of the category). Thus the model allows us to detect whether the categorization differences between men and women are due to differences in the threshold criterion that they use to determine whether an item belongs to the category.

Secondly, the model is able to detect differential item functioning (DIF). An item demonstrates DIF when men and women who employ the same threshold criterion, nevertheless are found to have a different probability of endorsing an item. The RIM model allows the positions of these items on the latent scale to differ for different groups of people. The model is thus able to detect whether the position of an item on the latent scale should be different for men and women. The different position of the item indicates that the similarity of the item to the category differs between men and women and thus that men and women, given that they use the same threshold criterion, will have a different probability in judging this item to be part of the category. Different item positions for men and women thus imply representation differences between men and women. The RIM model is thus able to detect whether categorization differences between men and women are due to a difference in the representation and/or in the criterion between men and women.

The model is formally implemented by assuming that a categorization decision for item \(i\) by categorizer \(j\) from group \(g\) is the outcome of a Bernoulli trial with the
probability that the item is judged to belong to the category equal to:
\[
\operatorname{logit}\left(\operatorname{Pr}\left(\mathrm{Y}_{\mathrm{ijg}}==1\right)\right)=\beta_{\mathrm{i}}-\theta_{\mathrm{jg}}
\]

In which \(\beta_{i}\) represents the item i's position on the latent scale and \(\theta_{\mathrm{jg}}\) represents the threshold criterion of categorizer \(j\) from group \(g\). In a categorization context \(\beta_{i}\) can be taken to represent the similarity of item i to the category; \(\theta_{\mathrm{jg}}\) can be taken to represent the required level of item-category similarity to consider an item a category member (Verheyen, Hampton, \& Storms, 2010). The model makes furthermore use of an indicator variable that indicates for each item, whether the item should be considered a DIF item. If so the model estimates a different \(\beta\) for that item for the two groups. If not the model estimates the same \(\beta\) for both groups.

\section*{Gender differences}

Several studies showed that men and women differ in the processing of natural and artificial categories. Women tend to name and recognize members of natural categories faster, while men have an advantage over women in naming and recognizing artificial categories (Barbarotto, Laiacona, Macchi, \& \& Capitani, 2002; Capitani, Laiacona, \& Barbarotto, 1999; Laws, 1999). Based on these studies Pasterski, Zwierzynska, and Estes (2011) argued that women and men might differ in the vagueness of their category judgments since natural and artificial categories tend to differ in vagueness. While membership in many natural categories is considered all-or-none, membership in most artifact categories is found to be graded (Diesendruck \& Gelman, 1999; Estes, 2003, 2004; Verheyen, Heussen, \& Storms, 2011).

Contrary to their initial hypotheses Paterski et al. showed that women provided more vague judgments than men (regardless of category type). They also showed that men, relative to women, gave more inclusive judgments for the artifact categories and tended to give more exclusive judgments for the natural categories.

Our study differs from these studies in that we are not focusing on differences between men and women in the processing of different types of categories or in the type of judgments that men or women give. We are interested in the question of whether or not there are differences in the likelihood/probability that men and woman judge an item to be part of the category. We argue that since men and women are known to be raised differently, to dress differently, to play with different toys, and to engage in different hobbies and professions, we expect that for some items men and women might differ in the likelihood that they consider the item as part of a particular category. To our knowledge this is the first study that looks at gender differences in the likelihood/probability that individual items are part of a category and allows to determine whether these differences reside at the level of the criterion or at the level of the representation.

\section*{Method}

\section*{Materials}

Eight natural language categories were studied (Addictions, Clothing, Diseases, Furniture, Professions, Sports, Toys, Weapons). The categories were selected based on the intuition of the researchers that they might contain items that have a different likelihood of membership in men and women. For each category we included 23 exemplars in the study. The items were selected based on previously collected typicality ratings to make sure that each category contained candidate exemplars that were generally considered typical of the category, atypical of the category, and borderline (items for which people in general are not always sure of whether they belong to the category or not). The typicality ratings were gathered as part of a larger norming project comprising 1276 items from 24 categories. Twenty-nine students ( 23 women, 6 men) provided typicality ratings for half of the categories using a seven point Likert scale ranging from very atypical to very typical. The reliability of these ratings for the \(23 \times 8\) items in our study varied between 0.86 for addictions and 0.96 for clothing with a mean of 0.93 .

\section*{Categorization task}

In total 287 men and 568 women participated in the study. They filled in a questionnaire in which they were, for each item, asked to indicate (yes or no) whether it belonged to the corresponding target category. Participants were, for example, asked whether or not a cold was part of the category diseases. To prevent order effects, we administered 4 different versions of the task with a different order for items and categories. The participants were randomly assigned to one of the 4 versions of the task. The age of the participants ranged between 17 and 64 with an average of 20.

\section*{Model analyses}

Each category's categorization data were analyzed separately using the RIM model. This was done using WinBUGS (Lunn, Thomas, Best, \& Spiegelhalter, 2000) according to the details and code provided by Frederickx et al. (2010). For every analysis 5 chains were run of 10,000 iterations each, with a burn-in sample of 800 .

\section*{Results}

\section*{Typicality}

For every category we calculated the correlation between the items' positions on the scale (the posterior means for the \(\beta_{\mathrm{i}}\) 's) and the items' average typicality to verify whether people were categorizing items by the use of similarity. We calculated the correlation between the items' positions and typicality because it was previously suggested that typicality and item-category similarity are strongly linearly related
(Hampton, 2007; Verheyen, Hampton, \& Storms, 2010). A high correlation between typicality and the items' positions thus also implies a high correlation between the items' positions and the similarities of the items towards the category. We calculated the correlations between typicality and the items' positions for men and women separately. The correlations can be found in Table 1. The correlations were invariably high, suggesting that our participants were indeed using item-category similarity when they judged whether the items belonged to the category.

Table 1
For each category the correlation between item positions and typicality for men and women separately
\begin{tabular}{lll}
\hline Category & Men & Women \\
\hline Addictions & 0.92 & 0.92 \\
Clothing & 0.98 & 0.98 \\
Diseases & 0.92 & 0.95 \\
Furniture & 0.95 & 0.95 \\
Professions & 0.91 & 0.93 \\
Sports & 0.87 & 0.96 \\
Toys & 0.93 & 0.93 \\
Weapons & 0.94 & 0.94 \\
\hline
\end{tabular}

Also note that the correlations of typicality with the items' positions of men and women can hardly be distinguished. Looking at categorization tendencies across the entire typicality range might not be the most fruitful manner to identify differences between groups of categorizers. For natural language categories, whose meaning is to a considerable extent determined by the environment the language community shares, one does not expect pronounced reorganizations of the representation from one group to the other. This would seriously hamper the communication between the group members. Rather, the differences might be more subtle, residing in individual items or in the severity of the employed categorization criterion.

\section*{Criterion differences}

To check whether there were any gender differences in the threshold criterion that participants used to make category judgments, we plotted the posterior distribution of the difference in the average threshold criterion between men and women. If there is a reliable difference in the average threshold criteria, the credibility intervals of this distribution (the region around the mean that contains \(95 \%\) of the mass of the distribution) may not include 0 . As can be seen from Figure 1, this is the case for two categories: professions and toys. In these categories the average differences were 0.34 and 0.74 respectively, indicating that women had a more liberal threshold criterion and require less item-category similarity to judge items to be part of the category than men. For the other categories there is no credible difference in
average threshold criterion indicating that women and men on average require equal levels of item-category similarity for category membership.

\section*{Representation differences}

The RIM model gives an indication of the DIF-status of items by means of latent indicator values that can take one of two values (either DIF or no DIF) on every iteration, resulting in a difference in the estimated item position when required. Following Frederickx et al. (2010) we term an item a DIF item if in more than half of the iterations it was classified as DIF. Table 2 gives an overview of the number of items that were identified as DIF items and the number of items for which men seemed to be more inclined/likely to consider the item to be part of the category and the number of items for which women seemed to be more likely to judge the item to be part of the category. There was one category for which no DIF items were found, the category furniture. For one category, the category clothing, we found only one DIF item: belt was categorized differently by men and women with the same threshold criterion (men were more likely than women to indicate that belt was part of the category). For the other categories the number of DIF items ranged between 2 and 16 and for most of these categories there were both DIF items for which men were more likely to indicate that they were part of the category and DIF items for which women were more likely to indicate that they were part of the category. The categories professions and weapons were the only categories that contained only DIF items for which women were more likely to indicate that they were part of the category. For professions these items were diver, magician, explorer, parachutist, pirate, and inventor. For weapons these were catapult and harpoon.
DIF items were found across the entire range of typicality. Within the DIF items there were items for which people generally agree that it belongs to the category (for example: dollhouse for the category toys), items for which it is not sure whether or not they belong to the category (snooker for the category sports) and items for which it is generally agreed that they do not belong to the category (pirate for the category professions). Thus women and men do not only disagree on items for which there is uncertainty about whether or not they belong to the category, but also on items for which there is general agreement about whether or not they belong to the category.
First of all remember that for the category clothing the RIM model indicated that there is no reliable difference in mean threshold criterion between men and women. So any gender differences in categorization proportions are representation differences according to the model. The model considers only one of these differences meaningful. The model detected only one DIF item (belt, with an average typicality of 4.53).

Figure 1: The posterior distributions of the difference in mean threshold between men and women for the eight categories. The \(95 \%\) credibility interval is represented by the red bars.

Table 2
Overview of the number of DIF items in the categories
\begin{tabular}{lccc}
\hline Category & \# DIF items & Men \(^{\mathbf{1}}\) & Women \(^{\mathbf{1}}\) \\
\hline Addictions & 4 & 1 & 3 \\
Diseases & 10 & 8 & 2 \\
Clothing & 1 & 1 & 0 \\
Furniture & 0 & 0 & 0 \\
Professions & 6 & 0 & 6 \\
Sports & 16 & 5 & 11 \\
Toys & 6 & 4 & 2 \\
Weapons & 2 & 0 & 2 \\
\hline ' \({ }^{\text {' }}\) ? & & & \\
\hline
\end{tabular}
\({ }^{1}\) columns 'Men' and 'Women' represent the number of DIF items for which respectively men and women are more inclined to consider it as part of the category

For the category toys there were several items for which the difference in proportion was determined meaningful after controlling for the threshold criterion. The RIM model indicated that the items pin-ball machine, gocart, coloured pencil, and chalk (manly items); and dollhouse and skipping rope (womanly items) are DIF items. That is, according to the model, the categorization differences one observes for these items are representational in nature. Interesting here are the items comic book and music box, that at first glance have a large and meaningful difference in the categorization proportion between men and women ( 0.60 versus 0.73 and 0.46 versus 0.62 at average typicalities of 4.23 and 5.08 , respectively). The RIM model nevertheless indicates that these are not DIF items. After controlling for the threshold criterion there no longer is a meaningful difference between men and women for these items, indicating that the difference in proportion for these items is entirely caused by the difference in threshold criterion for this category. Indeed, the category of toys was one of the categories for which the RIM model indicated there was a credible criterion difference between men and women.
It is therefore also able to identify items for which at first glance there are no differences when one looks only at the differences in proportions between the groups/sexes. The item, go-cart (average typicality: 5.15), for example, has a very small difference in categorization proportion between men and women ( 0.78 versus 0.76 ), but after controlling for the threshold criterion the item is identified by the model as a DIF item.

These examples should make it clear that it does not suffice to look at categorization proportions alone to determine whether there are group/gender differences in categorization, and that the main contribution of the model is that it is able to disentangle two main causes of differences in categorization proportions: criterion differences and representation differences.

Figure 2: Categorization proportion for men and women as a function of typicality for the categories clothing and toys

\section*{Discussion}

This is, to our knowledge, the first study that looks at differences in the likelihood/probability with which men and women would judge items to be part of the category. We have shown that for some items categorization differences were due to representational differences between men and women and for other items these differences were due to the differences in threshold criterion that men and women use.

The study described above fits in a recent group of studies in which it is shown that item response theory models can be used to analyze data from categorization tasks (Verheyen, Hampton, \& Storms, 2010; Verheyen, De

Deyne, Dry, \& Storms, 2011). It has previously been shown that variations of these models can reveal differences in the threshold criterion between different groups (Verheyen, Ameel, \& Storms, 2011) and reveal latent groups of categorizers who employ a different representation (Verheyen \& Storms, 2013). The RIM model is another valuable approach in that it can not only reveal criterion differences between existing groups, but also representation differences between these groups. It therefore opens up new ways of investigating group differences in semantic categorization.

For instance, a study by Hampton, Dubois, \& Yeh (2006) that investigated categorization differences between groups of categorizers who were categorizing items in different contexts, compared the correlation between categorization proportions and typicality, and the percentage positive responses between the different groups. In our study there were only minor differences in the correlation between the categorization proportions and typicality between men and women, but the model did indicate that there were differences between the two sexes. Furthermore, looking at the percentage positive responses to see whether some groups are using a stricter threshold criterion, might give an imprecise picture of what is going on, since we showed that not all differences in categorization proportions are due to the use of a more or less strict categorization criterion. It should be clear from our results that the RIM model allows for the detection of more subtle but important differences between groups. The implementation of the model is also not limited to two groups. It can easily be extended to investigate data from multiple groups, such as the pragmatic, technical, and neutral context groups in Hampton, Dubois, \& Yeh (2006), cultures (Medin \& Atran, 2004), or age groups (Ameel, Malt, \& Storms, 2008). The RIM model can also be easily adjusted to account for continuous categorization data.

\title{
A delayed discrimination task yields categorical perception of color not only in the right but also in the left visual field

\begin{abstract}
Whether categorical perception of color is lateralized in the left cerebral hemisphere (e.g., Gilbert, Regier, Kay, \& Ivry, 2006) or not (e.g., Witzel \& Gegenfurtner, 2011) is still controversial. This ongoing debate, however, has been studied with visual search tasks, which seemed to produce residual laterality effects. The present study assessed whether a delayed discrimination task with divided visual field method, rather than visual search tasks, yields lateralized or bilateral categorical perception of color. The results showed an advantage for between-category discrimination relative to within-category discrimination. Such an advantage, importantly, was obtained in the left visual field as well as in the right visual field. These results suggest categorical perception of color is bilateral and not lateralized. Combining recent studies with visual search tasks (e.g., Witzel \& Gegenfurtner, 2011), our results would provide further evidence for bilateral categorical perception, and thus throw doubt on the laterality effects of categorical perception.
\end{abstract}

Keywords: categorical perception; color perception; delayed discrimination task

\section*{Introduction}

A growing number of studies have shown that categorical perception (better discrimination of the stimuli from adjacent categories than those from the same category) of color (e.g., Roberson \& Davidoff, 2000; Suegami \& Michimata, 2010; Wiggett \& Davis, 2008; Winawer et al., 2007). In a seminal study, Gilbert, Regier, Kay, and Ivry (2006) employed a visual search task, where a colored target was detected faster when the target and distracters belonged to different color categories than when the target was in the same color category as the distracters (i.e., categorical perception). However, such a categorical perception of color was observed only when the target appeared in the right visual field (RVF) but not in the left visual field (LVF). Some successive studies, either behavioral studies (e.g., Drivonikou, et al., 2007) or imaging study with fMRI (Siok et al., 2009), obtained a stronger categorical perception in the RVF relative to LVF. Since the RVF is projected to the left cerebral hemisphere (LH), which is thought to be a center of verbal processing, the results would apparently
reflect the fact that categorical perception is verbally mediated.

Meanwhile, some other studies suggested that lateralized categorical perception in the RVF could be interpreted in terms of other general cognitive mechanisms supported by the LH, rather than simply verbal or language-related processing. Holmes and Wolff (2012), for instance, showed that not only labeled objects but also unlabeled objects produced categorical perception in the RVF on a visual search task. They attributed such a categorical perception in the RVF to an LH's advantage in qualitative or "categorical" processing (cf, Hellige \& Michimata, 1989; Kosslyn et al., 1989; Laeng, Chabris, \& Kosslyn, 2003).

The debate about the origin of the LH-lateralized categorical perception is ongoing and resolving such a debate may be of importance for the understanding of the nature of categorical perception. It should be noted, however, that such laterality effects could also result from some other residual factors. Some recent studies (Brown, Lindsey, \& Guckes, 2011; Witzel \& Gegenfurtner, 2011), for instance, showed that when using the same visual color search tasks as the previous studies but correcting some methodological weakness of previous studies, such as color production or eye movements, yielded categorical perception of color in the LVF as well as RVF.

Another concern could be brought in regard to the tasks; the LH-lateralized categorical perception was predominantly obtained with visual search tasks (e.g., Brown et al., 2011; Drivonikou et al., 2007; Gilbert et al., 2006; Gilbert et al., 2008; Holmes \& Wolff, 2012; Roberson, Pak, \& Hanley, 2008; Siok et al., 2009; Witzel \& Gegenfurtner, 2011). Visual search tasks seem to be suitable for examining categorical "perception," since this kind of tasks would have little memory demands. In the visual search tasks, however, one can also find some factors that might confound the results. In all of the visual search tasks we reviewed, participants were asked to judge which side (i.e., left or right) did the target appear in, and made their responses by hitting the keys associated with target's position (i.e., left or right key). Since judging left or right side is in the nature of
the "categorical" spatial relation processing, which is better processed in the LH (Hellige \& Michimata, 1989; Hellige, Laeng, \& Michimata, 2010; Jager \& Postma, 2003; Kosslyn et al., 1989; Laeng, Chabris, \& Kosslyn, 2003), this kind of tasks would produce residual laterality effects. The visual search tasks, moreover, seem to consist of detection of the target among distractors. Kitterle, Christman, and Hellige (1990) argued that laterality for the spatial frequency processing could be obtained in an identification task (or a delayed discrimination task) but not in a detection task. Although it is not clear whether laterality for categorical perception and these other types of "categorical" processing share the same mechanisms (c.f., Franklin, Drivonikou, Bevis, Davies, Kay, \& Regier, 2008; Holmes \& Wolff, 2012; Suegami \& Laeng, 2013), employing the visual search task, which seems to be another variation of a detection task, might diminish or cancel the lateralization of categorical perception. Thus, one could argue that some recent studies (Brown et al., 2011; Witzel \& Gegenfurtner, 2011) failed to replicate LH-lateralized categorical perception since laterality effects were cancelled out by residual factors.

Thus, the present study aimed to provide further evidence for either LH-lateralized or bilateral categorical perception of color by means of a delayed discrimination task with divided visual field method, rather than the visual search tasks (e.g., Drivonikou et al., 2007; Gilbert et al., 2006). The delayed discrimination task employed here was the classical method for exploring an LH's advantage in categorical processing of spatial relations and patterns (e.g., Hellige \& Michimata, 1989; Kosslyn et al, 1989; Saneyoshi \& Michimata, 2009; Suegami \& Laeng, 2013). Following previous studies (e.g., Siok et al., 2009), four colors with a constant color difference in CIE L* \(\mathrm{u}^{*} \mathrm{v}^{*}\) perceptually uniform color space were emulated. The experiment consisted of an initial training for eye-fixation (GuzmanMartinez, Leung, Franconeri, Grabowecky, \& Suzuki, 2009) and two main tasks: a delayed discrimination task and a color categorization task.

In the delayed discrimination task, moreover, two different lengths of delays ( 500 ms or 5000 ms ) were employed since both theories for the LH-lateralized categorical perception expected that such a LH-lateralized pattern should be enhanced by longer delays. A 5000 ms or longer delay in the delayed discrimination task would enhance using verbal codes rather than visual codes (Posner \& Keele, 1967), and also enhance an LH's advantage in "categorical" spatial relation processing (Postma, Huntjens, Meuwissen, \& Laeng, 2006).

After the delayed discrimination task, the participants also took part in a color categorization task to validate the categories of the four colors. The color categorization task was conducted after the delayed discrimination task in order to avoid any biases to the discrimination task.

\section*{Method}

\section*{Participants}

Thirty participants were recruited as volunteers for an experiment on color perception. Each participant received a gift card for 200 Norwegian Crowns (i.e., about 35 U.S. dollars). Edinburgh Handedness Inventory (Oldfield, 1971) and Farnsworth-Munsell 100-Hue test were conducted for screening out left-handers and individuals with abnormal color vision.

\section*{Apparatus}

All the stimuli were presented on a \(21-\mathrm{in}\). CRT monitor with 75 Hz refreshing rate (EIZO Flex Scan T961), connecting with Apple MacBook Pro ( 2.8 GHz Intel Core 2 Duo ). The distance between the CRT monitor and participant's eyes was fixed in 85.5 cm . The experiment was operated by MATLAB 2008b with Psychophysics Toolbox 3 (Brainard, 1997). A 10-key pad was connected to the computer and served as a response console. Both the training and two main tasks were conducted in a dark room.

\section*{Stimuli}

Eye-fixation training The stimuli in the original training task (Guzman-Martinez et al., 2009) were closely duplicated. Two circles of \(17.27^{\circ}\) (visual angle) diameter, filled with black and white random-dot pattern or its contrast-reversed pattern, were created. Each of the two circle had \(1.00^{\circ}\) by \(1.00^{\circ}\) of a black fixation cross at its center.

Delayed discrimination task Four colors used in the previous studies (e.g., Siok et al., 2009) were emulated. Each adjacent pair had approximately constant distance in the CIE L* \(u^{*} v^{*}\) color space. Two of them ought to belong to blue category and other two to green (hereafter, the four colors were termed as Blue 1, Blue 2, Green 2, and Green 1 respectively). The CIE L* \(\mathrm{u}^{*} \mathrm{v}^{*}\) coordinates for each color were measured by means of Datacolor Spyder 4 ELITE (CIE L* \(\mathrm{u}^{*} \mathrm{v}^{*}\) coordinates for each color were listed on Table 1). The mean color difference ( \(\Delta E\) in CIE L* \(\mathrm{u}^{*} \mathrm{v}^{*}\) space) of within-category pairs was 17.76 , and slightly larger than the \(\Delta E\) for the between-category pair (17.10).

Four color patches of \(2.00^{\circ}\) by \(2.00^{\circ}\) and a hairline fixation cross of \(1.00^{\circ}\) by \(1.00^{\circ}\) were created as the stimuli. Each color patch had one of the 4 colors, and the fixation cross was depicted by the neutral orange color which had approximately constant distance from all of the 4 colors in terms of CIE L* \(u^{*} v^{*}\) coordinates.

Color categorization task The same color patches as the delayed discrimination task were employed as the stimuli.

\section*{Procedure}

Eye-fixation training The procedure was based on the original work by Guzman-Martinez et al. (2009). Each
participant was seated in front of the CRT monitor, and fixed her/his eyes into the fixation cross. Participant's hitting the appropriate key led to 5000 ms of 37.5 Hz flickering presentation of the two random-dots circles. The participant was instructed that random-dots circles would turn into an uniform gray circle if her/his eyes were fixed into the fixation cross. After 5000 ms of flickering presentation, the participant could take a short break, and was allowed to start next trial by her/his own pace. The training had 30 trials and took approximately 5 min .

Delayed discrimination task After the eye-fixation training, the participant took part in the delayed discrimination task. The apparatus was identical to those for the eye-fixation training.

Typical trial sequence was shown in the Figure 1. Each trial began with 200 ms of a fixation cross against black background. Then two identical color patches filled with one of the 4 colors appeared \(3.9^{\circ}\) left and right from the center as probes \({ }^{1}\), and a blank screen followed for 300 ms or 4800 ms . After the blank, a fixation cross appeared again for 200 ms (therefore, the ISI was 500 ms or 5000 ms ), and then target color patch was presented \(3.9^{\circ}\) left or right from the center for 200 ms . The target could have an adjacent color or the same color as the probes. The participant judged if the color of the target was identical to that of the probes by hitting the left or right key as quickly as s/he could. A half of the participants hit the left key if the target and probes had the same color, and the other half hit the right key instead. Response times (RTs) were recorded from the onset of the target. If no response occurred until 2000 ms had elapsed from the onset, the trial was classified as an error. After a response had been made or 2000 ms had elapsed, the next trial started through a 1500 ms of inter trial interval. Twenty trials constituted an experimental block. The length of the ISI was manipulated between the experimental blocks. Half of the participants performed 10 blocks with 500 ms of ISI first, and then another 10 blocks with 5000 ms of ISI second. Another half of the participants performed each 10 blocks in reversed order.

For both ISI conditions, a practice block was held before starting each task. In the practice block, each trial had instant feedback, and another block was repeated if the accuracy rate of the block had not reached \(65.0 \%\).

Color categorization task After the delayed discrimination task, a color categorization task took place. In each trial, a color patch filled with one of the 4 colors appeared in the center. The participant judged if the color was blue or green by manual response. The color patch was presented until the response had been made (with no time limitation). The participant could take a short break after each 20 trials, and the whole task consisted in a total of 100 trials.

\footnotetext{
\({ }^{1}\) The probes were presented left and right from the center of the screen simultaneously, ensuring that the probes and the target had identical retinal eccentricity.
}

Figure 1: Illustration of a trial sequence of the delayed discrimination task.

\section*{Results}

Eight participants were excluded from the analysis. One of them did not get a score above +50 on the Edinburgh Handedness Inventory and therefore was ruled out for excluding potential left-handed or mix-handed (see Dragovik, 2004). Another showed significant positive correlation between accuracies and RTs ( \(\boldsymbol{r}=+.91\) ), suggesting a speed-accuracy trade-off. Three participants were screened out due to their abnormal scores on the Farnsworth-Munsell 100-Hue test. Other three showed atypical categories of color; the boundary between blue and green category did locate at between blue 1 and blue 2, instead of between blue 2 and green 2 (see Gilbert et al., 2006). Thus, the data from the remaining 22 participants were employed for the statistical analysis. Six of them were native Norwegian speakers, five were Lithuanian speakers, two were Chinese and two were English, and each of the other participants spoke, respectively, Bosnian, French, Italian, Persian, Portuguese, Spanish, and Swedish as a native language. Fifteen of them were female, and the mean age of the participants was 27.76 years \((S D=5.32)\). The mean score on the Edinburgh Handedness Inventory was \(91.57(S D=9.06)\).

\section*{Color categorization task}

The rates of the trials in which the color was categorized "blue" were calculated for all of the four colors (Table 1). One-sample \(t\)-tests for each rate revealed that all the rates were significantly different form the chance level of \(50.0 \%\), \(p \mathrm{~s}<.001\). That is, both of blue 1 and blue 2 were categorized as "blue" robustly, and likewise both of green 2 and green 1 were categorized as "green." These results confirmed that blue 1 and blue 2 indeed belonged to "blue" category, and likewise green 2 and green 1 were belonged to "green" category.

Table 1: CIE L* \(\mathrm{u}^{*} \mathrm{v}^{*}\) coordinates and rate of categorized "blue" in the color categorization task for each color.
\begin{tabular}{lcccc} 
Color & \(\mathrm{L}^{*}\) & \(\mathrm{u}^{*}\) & \(\mathrm{~V}^{*}\) & Rate of "blue" response (\%) \\
\hline Blue 1 & 56.655 & -41.973 & -27.120 & \(99.6(0.3)\) \\
Blue 2 & 62.963 & -48.252 & -10.988 & \(86.6(2.9)\) \\
Green 2 & 62.141 & -50.880 & 6.534 & \(1.6(0.7)\) \\
Green 1 & 62.432 & -52.346 & 23.564 & \(0.2(0.2)\) \\
Neutral orange & 27.004 & 40.084 & 16.971 & -- \\
\hline \multicolumn{4}{l}{ Note Standard errors for the rates of "blue" responses are within parentheses. }
\end{tabular}

\section*{Delayed discrimination task}

Accuracy As indices of accuracies, \(A\) 's (Aaronson \& Watts, 1987; Pollack \& Norman, 1964) were employed instead of error rates, so as to exclude possible participants' response bias (see also Pilling et al., 2003). A's for within- and between-category pairs with two ISI conditions were calculated for each visual field (panel \(a\) and \(b\) in Figure 2).

The \(A\) 's were analyzed by a three-way analysis of variance (ANOVA), with category (within-category or between-category), visual field (LVF or RVF), and ISI (500 ms of ISI or 5000 ms of ISI) as within-participants factors. As the most important result, a significant effect of category was obtained, \(F(1,21)=28.40, M S E=0.06^{-1}, p<\) \(.001, \eta_{p}^{2}=.58\), reflecting that the \(A^{\prime}\) for the betweencategory discrimination was larger than that for the withincategory discrimination (i.e., categorical perception of color). A main effect of visual field was also significant, \(F(1,21)=11.12, M S E=0.03^{-1}, p=.003, \eta_{p}^{2}=.35\), revealing that the \(A^{\prime}\) in the LVF was larger than that in the RVF. An interaction between category and visual field, moreover, was significant. Post hoc \(t\)-tests revealed the \(A^{\prime}\) for the between-category discrimination was larger than that for the within-category discrimination in the RVF, \(t(21)=3.75, p=.001, d=0.60\), and also in the LVF as well, \(t(21)=5.53, p<.001, d=1.06\). The \(A^{\prime}\) for the between-category discrimination was larger in the LVF than that in the RVF, \(t(21)=3.90, p=.001, d=0.63\), whereas no significant difference was found between in the \(A^{\prime}\) for the within-category discrimination in the LVF and RVF, \(t(21)=1.01, p=.326, d=0.12\). These results suggest that the categorical perception of color was obtained not only in the RVF but also in the LVF, and, unexpectedly, such a category perception was observed stronger in the

LVF instead of the RVF. Neither any other main effects nor interactions was significant, \(p>.175, \eta_{p}^{2}<.09\).

Response Time Median RTs for correct responses were also calculated for within- and between-category pairs with two ISI conditions in both visual fields (panel cand din Figure 2).

The RTs were also analyzed by the same three-way ANOVA as the accuracies. In line with the results in the accuracies, a main effect of category was again significant, \(F(1,21)=12.78, M S E=9104.76, p=.002, \eta_{p}^{2}=.38\). This main effect reflects that the RTs for the betweencategory discrimination were shorter than that for the within-category discrimination. Post hoc \(t\)-tests revealed the RTs for the between-category discrimination were significantly shorter than that for the within-category discrimination in the RVF, \(t(21)=2.80, p=.011, d=\) 0.28 , and also in the LVF, \(t(21)=2.43, p=.024, d=\) 0.32 . These results, in accordance with the results in the accuracies, suggest that categorical perception of color was found in the LH as well as in the RH. A significant main effect of ISI was also found, not surprisingly, \(F(1,21)=\) \(36.45, M S E=25739.96, p<.001, \eta_{p}^{2}=.63\), revealing that the RTs with 500 ms of ISI were shorter than those with 5000 ms of ISI. Any other effects or interactions failed to be significant, \(p>.203, \eta_{p}^{2}<.08\).

Figure 2: \(A\) 's (two panels on upper line) and RTs (two panels on lower line) for within- and between-category pairs. The left panels show \(A\) 's and RTs with 500 ms of ISI (panel a and \(c\), respectively), whereas the right panels show those with 5000 ms of ISI (panel b and d, respectively). Each error bar shows \(\pm 1\) standard error.

\section*{Discussion}

The present study aimed to assess whether, by means of a delayed discrimination task, one would observe a LH-
lateralized categorical perception of color (e.g., Drivonikou et al., 2007; Gilbert et al., 2006; Siok et al., 2009) or bilateral categorical perception (Brown et al., 2011; Witzel \& Gegenfurtner, 2011). In such a delayed discrimination task, we found evidence for bilateral but not LH-lateralized categorical perception. We employed the same color set as some of the previous studies that had found a LH-lateralized categorical perception (e.g., Siok et al., 2009). The results from the categorization task confirmed that both of blue and green categories in the present study were well established. Thus, such bilateral categorical perceptions could not be attributed to the color difference itself, and they confirm recent studies also showing bilateral categorical perception of color (Brown et al., 2011; Witzel \& Gegenfurtner, 2011). Interestingly, an unexpected RH-lateralized categorical perception was obtained in terms of accuracies. A possible account for this "reversed" laterality effects could be the RH's advantage in color processing (e.g., Levy \& Trevarthen, 1981; Pennal, 1977). Importantly, this result presents another example of counter evidence for the hypothesis of a LH-lateralized categorical perception.

One could argue that the present study failed to replicate the LH-lateralized categorical perception merely due to employing a different task than the typical visual search. This is plausible, but this reasoning contradicts the idea that either an LH's advantage in verbal processing or a hemispheric specialization in "categorical" processing underlies the LH-lateralized categorical perception effect. In fact, an LH's advantage in both verbal (Posner \& Keele, 1967) and categorical spatial processing (Postma, et al., 2006) is typically enhanced with longer time intervals, as in a delayed discrimination task. Moreover, a delayed discrimination task would seem more suitable for obtaining laterality effects than the tasks with no memory demands, like the visual search tasks (Kitterle et al., 1990). Therefore it could be argued that the present task should have been more likely to yield laterality effects on categorical perception than the previous visual search tasks. However, we failed to observe any sign of a LH-lateralized categorical perception in the current study. Thus, the present results are best interpreted as supporting the conclusion that categorical perception of color is represented bilaterally in the brain.

One possible weakness of the present study may be due to the large variety of participants' mother languages in our sample. Several studies have reported that people may possess different color categories in their native languages and consequently this could yield different patterns of categorical perception of color (e.g., Winawer et al., 2007) or its lateralization (e.g., Roberson et al., 2008). However, we took care to confirm that all of our participants shared the same color categories, and we found evidence that only three participants showed atypical categorical structures. Moreover, the native languages of all participants (except excluded three participants) distinguish between green and blue at the lexical level. According to the previous studies (e.g., Roberson, Davies, \& Davidoff, 2000), it is when the native languages do not distinguish, for example, blue from
green that these individuals would also show different patterns of category effects. As mentioned in the Results section, moreover, three participants were excluded since their categorical boundary located at between blue 1 and blue 2, instead of blue 2 and green 2. For these participants, two of them were Russian and the other was Turkish. Previous studies showed that Russian (Winawer et al., 2007) and Turkish (Özgen \& Davies, 1997) have different structures of blue category relative to native English speakers. The fact that those participants with different color structures in their native languages indeed showed different categorical structures in the categorization task indicates that the results of the categorization task adequately reflect participants' categorical structures. Thus, these results could provide another moderate support for that the participants employed in current analysis shared the same category structures to a satisfactory extent.

In conclusion, the present study revealed bilateral categorical perception with a delayed discrimination task. Although the delayed discrimination task has memory components and therefore could be less appropriate for examining "perception," such a task has the advantage to exclude residual laterality effects caused by previous visual search tasks (e.g., residual categorical spatial processing caused by left/right judgments). Combining recent studies employed visual search tasks with correcting some other methodological flaws (Brown et al., 2011; Witzel \& Gegenfurtner, 2011), our results provide further evidence for bilateral categorical perception, and thus throw doubt on the laterality effects of categorical perception.

\begin{abstract}
Studies on the effects of pronunciation variants on spoken word recognition have seemingly contradictory results - some find support for a lexical representation that contains a frequent variant, others, an infrequent (but idealized) variant. We argue that this paradox is resolved by appealing to the phonetics of the overall word. In two phoneme categorization studies, we examined the categorization of the initial sounds of words that contain either tap or [ t ]. Listeners identified the initial sound of items along a voiced-voiceless continuum (e,g, bottom-pottom, produced with word-medial [ t ] or tap). No preference for wordforming responses for either variant was found. But, a bias toward voiced responses for words with [t] was found. We suggest this reflects a categorization bias dependent on speaking style, and claim that the difference in responses to words with different variants is best attributed to the phonetic composition of the word, not to a particular pronunciation variant.
\end{abstract}

Keywords: phonetic variation, pronunciation variation, speech perception, phoneme categorization, lexical representation

\section*{Introduction}

As listeners, we face a speech signal that is riddled with variation, with countless acoustic realizations of any given word. Words stream by listeners at a rate of about 5-7 syllables per second, further complicating the listener's task. How listeners understand spoken words despite this variation is an issue central to linguistic theory.

The finding that lexical representations are rich with phonetic detail along with associated theories of representation and lexical access have greatly advanced our understanding of this process (e.g., Goldinger, 1998; Johnson, 2006). Incorporating variation into theory was a major step toward a full explanation of spoken language understanding. \({ }^{1}\) But, claims made by lexical-representationbased accounts are becoming increasingly difficult to validate or falsify.

Studies that examine the effects of pronunciation variants on spoken word recognition highlight this point. Two different realizations of a sound are considered pronunciation variants. For example, one can produce the word baiting with a [ t\(]\), sounding like bay-ting or with a tap [r], sounding more like bay-ding. Or, one can produce the word center with a [ t ], sounding like sen-ter, or without [ n ] (though some acoustic residue is likely to remain), sounding like sen-ner. Studies that examine the recognition of words

\footnotetext{
\({ }^{1}\) This is a move often discussed, but still largely absent from theories of spoken word recognition; see McLennan \& Luce (2005) for related discussion.
}
with pronunciation variants typically compare a frequent (commonly produced) variant (e.g., [r] or [n_]) to an canonical, but infrequent variant (e.g., [t] or [nt]). Interestingly, in this area of research, two conceptuallyidentical studies have found evidence for lexical representations that are specified for a particular pronunciation variant. In one case, though, the data suggest that the frequent variant is stored (Connine, 2004). In the other case, the data suggest that the canonical variant is stored (Pitt, 2009). We call this the representation paradox. Specifically, these studies found:
(1) Frequency bias: A cost for words produced with [t], like baiting produced like bay-ting, (Connine, 2004) compared to those produced with the more common tap ([r]) variant, and
(2) Canonical bias: A benefit for words with [t], like center produced sounding like sen-ter (Pitt, 2009) compared those produced with the more common postnasal deletion variant ([n_]) (sounding like sen-ner).

In this paper, we suggest that this paradox has resulted for two reasons. First, pronunciation variants are typically examined independent of the phonetic composition of the entire word (see also Andruski et al., 1994). While it is true that we may produce [ t ] or [ r\(]\) in a word like baiting, it is also true that each variant co-varies with a different set of acoustic correlates across the word. Second, in the examples in (1) and (2), it is not clear that listener responses are driven by stored lexical forms in this task, and not by these co-present acoustic cues.

It is undoubtedly the case that detailed representations exist. But, it is also the case that (1) listeners are highly sensitive to acoustic fluctuations in speech (Clayards, Tanenhaus, Aslin, \& Jacobs, 2008; Green, Tomiak, \& Kuhl, 1997; McMurray \& Aslin, 2005; McMurray, Tanenhaus, \& Aslin, 2009), (2) low-level acoustic mismatches result in major perceptual costs either from manipulations resulting in incongruent cues (Gaskell \& Marslen-Wilson, 1996) or from intentionally mispronounced sounds (Gow, 2001, 2003; Sumner \& Samuel, 2005), and (3) acoustic cues inform a listener not only about linguistic units, but provide expectations about the style of a speech event (Labov, 1966; among many others)

In this paper, we ground ourselves broadly in a phonetic perspective and make two suggestions. First, we suggest that different pronunciation variants are processed equally
well when presented in a congruent phonetic word frame. Note that this is not inconsistent with an exemplar account, but suggests only that these representations are not at play here, and the canonical bias in (2) results from an artificial bias toward the canonical variant. Second, we suggest that once we accept that all variants are processed equally well by listeners, we need to reconsider the exaplanatory burden placed on exemplars for theories accommodating variation during spoken word recognition.

\section*{Categorization and pronunciation variants}

As mentioned, current studies diverge on how listeners respond to words with different pronunciation variants in spoken word recognition. The frequent variant is the one uttered by speakers with the highest frequency, and is often regarded as a reduced form, (i.e., [r] and [n_]; see Patterson \& Connine, 2001). The canonical variant is less common in casual conversation, but is more likely to be produced in careful speech, and may be more faithful to orthography (e.g., [t] and [nt]).

Through a series of phoneme categorization studies, Connine (2004) examined the perception of the initial sounds of words that contain either tap or [ t ]. Creating voiced-voiceless continua for words like baiting (baitingpaiting, produced either with word-medial [ t\(]\) or tap), listeners were asked to identify the initial sound of items along the continuum. Listeners made more word-forming responses (in this case, " \(B\) " responses) to items with the frequent tap than to items with canonical \([t]\). She argued that in words like baiting, the tap is stored in the lexical form. Consistent with exemplar accounts of lexical access (Goldinger, 1998; Johnson, 1997, 2006; Pierrehumbert, 2001, 2002), the cost associated with [ t ] is argued to result from access to a frequency-based lexical representation (see also LoCasto \& Connine, 2002).

Through his own series of phoneme categorization studies, Pitt examined post-nasal [t]-deletion in words like center. Comparing responses to items along a centershenter continuum ([nt]) to those along a cenner-shenner ([n_]) continuum, he found that listeners made more wordforming responses (in this case, " S " responses) to items with the canonical [nt] than to items with the frequent [n_]. In this case, the benefit associated with \([\mathbf{t}]\) is argued to result from access to a canonical representation.

Maybe differences encoding words or word forms exist, and there is no paradox at all. One would need to argue that baiting and center are treated differently, and that experience with one yields a surface-based representation and experience with another yields a canonical representation. In this case, tapping and post-nasal [t] deletion are different processes which affect representations differently (e.g. the former could be viewed as an altered form, and the latter a phonological deletion (though a nasal tap may be a residual phonetic cue to the t-deletion process)). Here we offer another alternative explanation: The apparent paradoxical dissolves when we consider the
phonetic composition of the word frame that houses a particular pronunciation variant.

\section*{The phonetic perspective}

Consider again the example of baiting. The use of the [t]variant is constrained by speech style, occurring (though rarely) in extra careful speech (Shockey, 2003). When [t] is used, the entire word (word-level phonetic variation) is hyperarticulated, so that [ t ] co-occurs with other predictable acoustic values (longer stop closure, longer duration of the previous vowels, de Jong, 1998, p. 293). In contrast, the tap, when produced in casual speech, co-occurs with cues common to casual speech (short, centralized vowels, shorter overall duration, reduced amplitude).

Interestingly, the usage patterns of each pronunciation variant pair ([t]-[r]; [nt]-[n_]) differ greatly. The production of tap is nearly categorical in American English (AE), produced nearly \(97 \%\) of the time in running speech (Patterson \& Connine, 2001), typically uttered in a casual frame with approximant-like characteristics, but is so often pronounced that it can occur in a careful phonetic frame (Tucker, 2011). The [t] variant is virtually never uttered, but when uttered, it is paired with a careful phonetic frame. In contrast, the same is not true for post-nasal t-deletion. While rampant in AE, it is less likely as the onset of a prominent syllable (Raymond et al., 2006), so as one shifts to a careful speaking style, post-nasal t-deletion becomes less likely. Critically, the stimuli used in both studies involved different pronunciation variants uttered in controlled, careful phonetic frames, biasing a listener against the frequent-variant in the Pitt study. \({ }^{2}\)

Consider Figure 1, which illustrates 6 different productions of the word beating. Along a hyper-tohypoarticulation continuum (Lindblom, 1991), half of these productions include the phonological variant [ t ], the other half include the phonological variant [ r\(].{ }^{3}\)

\footnotetext{
\({ }^{2} \operatorname{Pitt}(2009\), page 903) mentions that the with-[t] production and deleted-[t] production differ by 55 msec ( 605 vs .550 ), which, when carefully-articulated, is the approximate time needed to produce a voiceless alveolar stop, including release. Connine (2004) mentions that the two were phonetically-controlled, as she spliced the variants into a single token that served as the base form.
\({ }^{3}\) These examples were created by asking a naïve speaker to produce the word beating (extremely carefully; carefully; casually; extremely casually). We created spectrograms for the longest and shortest productions that contained [t] (1, 3; left column) and for those that contained \([r](3,5\); right column). We chose one of many productions in between the endpoints to represent the gradient productions along the continuum.
}

Figure 1. Sample productions of the word beating produced with [t] (left column) or [r] (right column). The schema represents a categorical view of the pronunciation variants, with co-varying phonetic patterns, but also shows that a variant may be natural or forced in a particular phonetic frame.

Figure 1 illustrates the wide-range of variation that appears not only in different productions of each pronunciation variant, but also in the variation across word utterances. The spectrograms in row 3 likely illustrate the stimuli used in the studies discussed, as they are phonetically similar independent of the variant examined.

We are interested in comparing variants, like [t] or [r], in different phonetic frames. In Figure 1, the spectrograms in the middle of each variant-specific continuum reflect the types of phonetic patterns we find in words uttered with one variant or another. We investigate listener responses to words with \([\mathrm{t}]\) that have a more carefully-articulated phonetic word frame to words with [ \([\mathrm{r}\) ] that have a more casually-articulated word frame. The stimuli that exemplify this comparison are marked with black tabs.

Across two experiments, we examine the perception of words with pronunciation variants dependent on the phonetic composition of critical words and fillers. Replicating the methods of prior studies, we examine the perception of word-initial stops of words with either [ t ] or [r], but show that the effects can be attributed more to the phonetic composition of words and fillers (and the expectations and information those provide) than to the pronunciation variants themselves.

\section*{Experiment 1}

In Exp. 1, we investigate responses to words with [t] and tap when the variants are embedded in phonetic frames that
typically co-vary with each variant. We do this for two reasons: First, while this task is based on work by Ganong (1980) showing that lexical status drives categorization responses (listeners make more " T " responses on a taskdask continuum than a tesk-desk continuum), it is not immune to low-level perceptual responses that may also drive categorization (McMurray, et al., 2009; Sumner, 2011). Second, replicating within task as a first step enables us to better interpret past work.

\section*{Methods}

Participants Thirty-five native monolingual speakers of AE participated in this experiment for credit. All were Stanford University undergraduate students. No participants reported any hearing-related issues.
Materials Eight critical words were used in this study. Four words were b-initial (e.g., bottom) and four were p-initial (e.g., pattern). In addition to the critical words, we included seven b-initial fillers, and seven p-initial (three for each onset without \(/ \mathrm{t} /\), believe, police; four for each onset with final /t/, bait, put). Critically, the voiced/voiceless counterpart of all words (critical and filler) resulted in a pseudoword (e.g., bottom/*pottom, believe/*pelieve). The inclusion of fillers served two purposes (1) to control for response bias (Exp. 1) and to include word-external phonetic support for a casual or careful speaking style (Exp. 2). Each word was recorded, along with its voiced/voiceless pseudoword counterpart in two articulation types: Casual speech and Careful speech. This resulted in eight Careful/[t] and eight 1 Casual/[r] critical words. A continuum was created for each word, as described below.
Stimuli Creation From our recordings, we created b-p continua, resulting in a word-pseudoword continuum for each item. To avoid naturalness differences across onsets, all items were manipulated from the nonword base. Using PSOLA in Praat (Boersma \& Weenink, 2008), we then created a 10 -step continuum for each item (from 0 to 45 msec in five msec steps) by increasing or decreasing the amount of aspiration in each word. We should note here that we expect an overall bias toward "P" responses, as on this continuum, there are more responses that typically fall within the English voiceless category.
Design This experiment was designed to examine the proportion of word-forming responses (e.g., "B" for bottompottom continua; " P " for pattern-battern continua) resulting from listening to Careful/[t] words and Casual/[r] words. The design was a \(2 \times 2\) within-subjects design, where the main factors were onset ( \(p, b\) ) and variant/articulation type ([t]/Careful, [r]/Casual).
Procedure Participants completed the task individually or in groups of two or three in a sound-attenuated booth. All 160 critical items ( 8 critical words X 2 articulation types X 10 continuum steps) were randomized with 140 filler items and presented to participants one at a time in isolation over Sennheiser 390 Pro headphones at a comfortable listening level using E-Prime experimental presentation software. Participants were instructed to listen carefully to each word
presented, to decide whether the token they heard began with a P or B , and then press the corresponding button. Response categories were held constant for each participant, but randomized across participants, so the "B" button appeared equally on the right and in the left across participants. A new trial began one second after a response was recorded, and three seconds if no response was made.
Predictions Evidence for the frequency bias should result in more word-forming responses to words with tap than to words with [ t\(]\). Evidence for the canonical bias should result in more word-forming responses for words with [t] than words with tap. Evidence that this task better reflects pre-lexical responses independent of specified lexical representations should yield some pattern that reflects an influence of the phonetic frame of the words.

\section*{Results and Discussion}

A mixed logit regression analysis was employed to predict the participants' word-forming responses. We report the results for the model with maximum random effect structure justified by the data based on model comparison (Jaeger, 2008), which contained random by-subject and by-item intercepts. Initial analyses were based on the proportion of word-forming responses, following past work, and show no main effect of articulation type ( \(\beta=.11 p>.47\) ). A closer look revealed that responses to b-initial words differed dramatically from those to p-initial words. Specifically, binitial words resulted in a higher proportion of wordforming responses for Careful/[t] words than for Casual/[r] words ( \(\beta=1.1 p<.002\) ). Mean proportions of word-forming responses are provided in Figure 2. The onset-based differences suggest that when collapsing across onset, the effects cancel each other out.

Figure 2. Two plots for resulting data depending on response label: Proportion word-forming responses (left); Proportion voiced responses (right).

The data pattern is unexpected if responses are driven by the pronunciation variant. Were these effects due to the activation of a lexical representation with one pronunciation variant or the other, we would expect the Careful/[t] and Casual/[r] items to behave similarly for each onset with respect to word-forming responses. This is not the case. Here, a " B " response to b-initial words is consistent with
both a "word" response and a "voiced" response (e.g., I heard a [b] not a [p]). For p-initial words, a "P" response corresponds with a word-forming response, but not a "voiced" response.

The right panel of Figure 2 plots the data by proportion voiced responses. Any influence of co-varying phonetic cues present in the congruent word frames is likely to surface independent of the lexicon-as a phonetic bias. Analyzing the data in terms of proportion voiced responses reveals that Careful [ t ] items result in a higher proportion of voiced responses (" \(B\) " regardless of lexical status) than Casual/[r] items ( \(\beta=-.5 p<.003\) ). This suggests that listener responses depend on the phonetics, not on access to a stored lexical representation. A higher proportion of " B " responses reflects a different categorization boundary between the two articulation types, with more aspiration (longer VOT) required to prompt a " P " response in careful speech, resulting in a higher proportion of " B " responses.

One implication is that the pronunciation variants have little to do with the response patterns in this paradigm. The high number of " \(P\) " responses for p -initial words likely reflects combined influences of the asymmetrical breakup of the VOT continuum in English, and lexical status. In order for the variant effects to be attributed to lexical representations, the patterns of responses to words with [t] and words with tap must behave similarly across onsets, predicted by a view where the most accessible lexical representation is the best match to the incoming signal (Johnson, 2006). We would expect results analogous with the lexical effect; which we do not find.

If this paradigm is capturing phonetic responses rather than lexical responses, then we should reconsider claims made about the nature and activation of variant-dependent lexical representations more broadly. Certainly, it is now fact that listener memory for auditory events is detailed. But, this does not imply that all accommodation of variation is handled at the level of the lexicon. One prediction a phonetic account makes is that as the articulation type becomes more predictable, the phonetic categorization bias should be more robust. For example, if item presentation were to be blocked by articulation type, listeners would have information about the speech style well before each critical item. We cast the effect as a category boundary difference mediated by word-level phonetic variation. Therefore, the effects are not due to lexical activation. We predict, then, an increase in evidence of a speech style will reinforce the different VOT thresholds, and will result in a greater difference between the two articulation types.

\section*{Experiment 2}

Our goal in Exp. 2 was to increase the predictability of a particular articulation type. One prediction of our claim that the basic effects are driven by the phonetic composition of the words and not by the pronunciation variant is that effects should fluctuate as evidence of a particular speech style increases. Blocking the stimuli by articulation type enabled us to test this prediction.

\section*{Methods}

Participants Thirty-four native monolingual speakers of AE participated in this experiment for credit. All were Stanford University undergraduate students. No participants reported any hearing-related issues.
Materials The stimuli from Exp. 1 were used.
Design The design was identical to Exp. 1 with one exception: Stimuli were blocked by articulation type (careful vs. casual). Block order was randomized, as was the presentation order of items within a block.
Procedure The procedure was identical to Exp. 1.

\section*{Results and Discussion}

Using the same statistical approach as in Experiment 1, we analyzed the data to predict proportions of voiced responses. Proportions of voiced responses by condition are provided in Table 1.

Table 1. Proportion of voiced responses from Exp. 2.
\begin{tabular}{|c|c|c|c|c|c|c|}
\hline Typ e & Condition & N & Prop or tion Voiced Responses & Stan dar d Deviation & Standard Error & Confidence Interval \\
\hline \multirow[t]{2}{*}{B-initial} & Cas ual /[] & 1119 & 0.235 & 0.424 & 0.012 & 0.024 \\
\hline & Careful/[t] & 1117 & 0.286 & 0.452 & 0.013 & 0.026 \\
\hline \multirow[t]{2}{*}{P-initial} & Cas ual /[] & 1141 & 0.105 & 0.306 & 0.009 & 0.017 \\
\hline & Car eful/[t] & 1141 & 0.175 & 0.380 & 0.011 & 0.022 \\
\hline
\end{tabular}

We find that participants are more likely to respond " \(B\) " in the Careful/[t] condition than in the Casual/[r] condition ( \(\beta\) \(=-.76 p<.002\) ). To investigate the phonetic effects across experiments, we conducted an additional analysis on the first 100 items for all conditions across Exp. 1 and Exp. 2. The first 100 trials were examined to minimize the influence of learning throughout the experiment. The first 100 trials give us the best picture of participant responses dependent on the nature of the filler items. The proportion of voiced responses for the first 100 items across experiments and conditions are provided in Figure 3

Figure 3. Proportion voiced responses to Careful/[t] items and Casual/[r] items collapsed across onset type for Exp. 1 (left) and Exp. 2 (right) for first 100 trials.

The difference suggests that the word-external information available serves to stabilize different categorization criteria, resulting in a higher rate of voiced responses in the Careful/ \([\mathrm{t}]\) condition than that found in Exp. 1.

\section*{General Discussion}

We began this study based on our observations that (1) effects of pronunciation variants are typically examined independently from the phonetic composition of the wordframe in which they are uttered and (2) accounts of opposite pronunciation variant effects that intuitively seem incompatible with each other are both viable under an exemplar-theoretic interpretation. While it is accepted and verified that lexical representations are rich with phonetic detail, we sought to investigate phonetic effects in speech perception independent of the lexicon.

To do this, we investigated pronunciation variants that are embedded in congruent phonetic frames. We then examined the responses made to voiced- and voiceless-initial words when presented in a single block with careful and casual speech styles mixed (Exp.1). Finally, we strengthened the expectations based on speech style by blocking the stimuli by articulation type (Exp.2).

In Exp. 1, considering responses made by listeners as word-forming caused some difficulty. The data are more easily accounted for by considering the responses as voicedvoiceless, not as word-forming or pseudoword-forming. In a careful word frame, listeners require a longer VOT before they will switch to a "P" categorization than in a casual frame. Alternatively, this could be driven by an increased likelihood to press "P" at the slightest hint of aspiration in casual word frame. \({ }^{4}\) In Exp. 2, we found that increasing the likelihood of a carefully-articulated word (via critical items with phonetically-congruent fillers) increased voiced responses compared to Exp. 1.

One implication of this work is that the canonical bias is, in part, artificially bolstered by our comparisons. And, reconsidering past work, there is support for this notion. A number of studies that have found a canonical effect examine a frequent variant embedded in an incongruent phonetic frame (Andruski, et al., 1994; Gaskell \& MarslenWilson, 1996). Our data show that the effects here, and likely in some number of previous studies, are due more to congruence between a phonetic frame and a pronunciation variant and to expectation-based categorization than to the activation of a particular lexical representation (or of a more available lexical representation, if we assume there are within-word phonetic clouds). The next step is to consider how frequency-based accounts of lexical access are separate from and integrated with the pre-lexical processes listeners use to navigate a variable speech stream.

\footnotetext{
\({ }^{4}\) While we cannot distinguish the two here, both are compatible with a phonetic explanation of the data rather than one dependent on the pronunciation variants.
}

\section*{Conclusion}

We have discussed one limit of exemplar-accounts of variation effects, and have tailored our investigation to examine an apparent paradox in the literature in which two representative studies account for opposing data with the same broad representation-based interpretation. We highlighted both the ways in which phonetic variation might interact with pronunciation variants in speech production, and presented two experiments aimed at understanding the effects of this interaction. As listeners exhibited a strong bias toward voiced responses for Careful/[t] tokens, amplified by within-speech style blocking, we suggest that the difference between the conditions is entirely due to the phonetic composition of the word, absent the influence of detailed lexical representations.

\title{
Dyadic Cooperation Enhances Retrieval and Recall of Crossword Solutions
}

\author{

\begin{abstract}
The benefits of collaborative activities have been demonstrated in many domains, but there remain mixed results across several others as to whether collaborative groups can achieve greater performance than individuals, and can achieve greater performance than nominal group comparisons. Here we develop a task that is especially suited to testing collaborative gains. In a collaborative crossword game, two individuals solved puzzle questions either alone or collaboratively through discussion. When talking, participants solved more puzzle questions, solved them more quickly and accurately, and in general seemed to recall the words from collaborative contexts better than from matched independent contexts. By extracting the audio of their interaction, we also demonstrate interesting relationships between spoken interaction and performance on the collaborative tasks. This task environment further substantiates the notion that, in the context of knowledge retrieval, two heads are better than one.
\end{abstract}

Keywords: Dyadic cooperation; collaborative recall.

\section*{Introduction}

Knowledge can be thought of as a probabilistic distribution. As samples are repeatedly taken from this distribution, a more complete picture emerges of the underlying knowledge. Often, as is implied by the phrase "the wisdom of crowds", the probability distribution is quite accurate with respect to its information representation-so that as samples are collected, an increasingly accurate picture emerges. For example, when eight-hundred attendees of a stock and poultry exhibition were asked to estimate the weight of a large ox, the mean of their estimates was very accurate (Galton, 1907). The error of the mean estimate was in fact much lower than the mean error of each individual's estimate. This "wisdom of crowds" effect has continued to be demonstrated in a number of domains: aggregate financial forecasts tend to be better than individual forecasts (Clemen, 1989), polls of the audience in game shows tend to reveal correct answers (Surowiecki, 2004).

The probabilistic nature of knowledge is also apparent when an individual accesses his or her own knowledge over time. When individuals were asked to make quantitative estimates of worldly information on two separate instances, the average of their estimates tended to be more accurate than either individual estimate (Vul \& Pashler, 2008). When multiple individuals work interactively on a joint decision, however, the "two heads are better than one" intuition does not always hold. In general, the literature on group performance shows that groups rarely outperform their best members-the whole is rarely greater than the sum of its parts (Bahrami et al., 2010; Hastie \& Kameda, 2005; Kerr \&

Tindale, 2004). In fact, across a large number of contexts, individuals tend to remember less when they're working with others (Rajaram \& Pereira-Pasarin, 2010).

In these studies, subjects are usually presented with a list of items and must study and reproduce the items either individually or as a group. On average, groups tend to recall more items than individuals, but recall fewer items than nominal groups (consisting of the pooled, non-overlapping items recalled by individuals working alone; Barnier, Sutton, Harris \& Wilson, 2008). That is, individuals working in a group context don't perform at their full potential. The leading explanation for this observation is the retrieval disruption hypothesis (Basden, Basden, Bryner \& Thomas, 1997). According to this hypothesis, individuals use their own, idiosyncratic, strategies to organize and encode information. When recall takes place in an interactive context, the output of one member disrupts the retrieval strategies of the other(s), inhibiting recall performance.

The large body of empirical work providing evidence for the detrimental effects of collaboration on memory is unified by the term social contagion research (Barnier, Sutton, Harris \& Wilson, 2008; and see Rajaram \& PereiraPasarin, 2010, for a review). In addition to disrupting the recall of correct items, collaborators can even introduce the recall of incorrect items. When a confederate collaborator misleadingly recalled an incorrect item, participants later recalled that item themselves, as if it had been in the original recall list (Roediger, Meade \& Bergman, 2001). This effect extends beyond laboratory recall studies, as individuals can often misremember important life events. Loftus has worked extensively on issues surrounding the fallibility of memory, especially as it applies to false memories and eyewitnesses, showing that social context can significantly impact the accuracy of memory (Loftus, 1996).

A related example of the negative consequences of social context is groupthink-a phenomenon where groups of people may end up making poor decisions, generally because of a motivation to reduce conflict and reach consensus, therefore failing to continue the search for an optimal solution (see Esser, 1998). This collaborative inhibition may be related to both retrieval disruption or social loafing (reduced effort or motivation when in a group context; Weldon, Blair \& Huebesch, 2000).

Despite the abundance of theories and supporting evidence for social contagion, there exists an intuitive feeling that we should benefit from working with others. In addition to social contagion research, Barnier and colleagues (2008) define two other approaches to
investigating the effects of social context on memory: collaborative recall, and transactive memory. These approaches tend to seek out the beneficial effects of social context. In collaborative recall research, the social context is conceptualized as part of a broader environmental and situational context which can facilitate an individual's recall through priming. This priming could be detrimental, such as in retrieval disruption, or could be beneficial through cueing or triggering of correct information.

Bahrami and colleagues (2010) found that group performance interacted dynamically with social context. They designed a low-level perceptual decision-making task where members of a dyad reported their own decisions then agreed on a joint decision to report. When members of a dyad had unequal performance levels, the dyad tended to do worse overall than the better-performing member. However, performance exceeded aggregate individual performance when members had equal visual sensitivities and could communicate openly to discuss their observations (Bahrami et al., 2010), and when they used similar task-relevant linguistic forms (Fusaroli et al., 2012). In order to come to an agreement regarding an ambiguous low-level stimulus, members of a dyad must attempt to communicate subjective and graded confidence levels. The combination of information for higher-level decision-making tasks, such as those involving knowledge and memory, may be very different. For example, if two friends are attempting to recall the Spanish word for "countryside" from a long-ago language course, one may offer: "I think it was something like camping", which may trigger the other to remember the correct "campo." In this sense, members of a dyad can prime each other and iteratively build greater information.

Finally, in transactive memory research, the group is conceptualized as the unit of analysis: individuals are components of a coupled, distributed memory system (Wegner, 1987). In these transactive memory systems, group members may share the tasks of encoding, storing, or retrieving information in any combination. Wegner (1987) notes that memories are connected concepts-such as the concept "tomato" with the concept "red"-and these connections are formed through encoding, which can be done at the group level. As an example, consider a couple discussing the odd behavior of a mutual friend. The male partner mentions that their mutual friend seemed quiet at a recent party, while the female partner instead thought he seemed overly friendly. This reminds the man that their mutual friend had been thinking about splitting from his wife, which leads the couple to conclude that their mutual friend had been flirting with the female partner, and subsequently acted awkwardly around the male partner (from Wegner, Giuliano \& Hertel, 1985). Through collaboration (discussion), the couple in this example was able to bind information and encode a quantitatively and qualitatively different memory than either would have achieved individually. Conceptualizing the distributed storage of memories is more intuitive: We already store much of our information externally (books, to-do lists, smart
phones), and in much the same way we could rely on a partner to remember something for us (essentially 'outsourcing' the storage of that information to another person).

From the perspectives of both the collaborative recall and the transactional memory traditions, the performance of a group can come to be greater than the performance of its members. In this paper, we work from these intersecting perspectives to investigate the potential benefit of working with two minds instead of one on a knowledge-based trivia task. Individuals are randomly assigned to dyads and given trivia questions, which they solve either independently or collaboratively. These general knowledge trivia questions provided a set of stimuli on which subjects' knowledge varied widely, and allowed for rich discussions during collaborative sessions. Following four rounds of ten trivia questions, subjects were given individual recall tests for the answers to the preceding trivia questions.

As described by Hare (1976), research on social influence can be characterized by two factors: the "social climate", which could be either individuals collaborating or individuals working independently; and the "task completion", which is a measure of either the group product or the individual product. Consistent with previous work on joint performance measures (i.e., Hill, 1982), the current study design allowed us to first compare [1] the group product of collaborating individuals (group performance on collaborative trivia rounds) to [2] the individual product of individuals working alone (individual performances on independent trivia rounds). The recall task allowed us to compare [1] the individual product of collaborating individuals (individual recall of trivia items from collaborative rounds) to [2] the individual product of individuals working alone (individual recall of items from independent rounds).

By analyzing task performance and efficiency at the group and individual levels, and resultant memory at the individual level, we substantiate the beneficial gain of collaborative cognitive performance. Our results suggest that in knowledge-based tasks, two heads are indeed better than one.

\section*{Methods}

Sixty two participants were recruited from a subject pool of University of California, Merced, undergraduate students who participated for course credit. The participants had an average age of \(19.6(S D=1.7)\) and were mostly female (16 male; 46 female). The participants were grouped into thirtyone dyads. Each dyad participated in four rounds of a trivia game, where each round of ten questions was to be solved individually or collaboratively, followed by a surprise recall task after all four rounds.

Participants were seated directly across from each other at a small table with IBM ThinkPad laptop computers. This allowed each participant to have a private workspace during the independent tasks, but also enabled easy communication during the collaborative tasks. Participants wore Shure Beta

54 supercardiod microphone headsets, and their conversations were recorded using an M-Audio MobilePre recording interface and Audacity software.

Figure 1: Experimental setup.

\section*{Materials}

Trivia questions were collected from a variety of crossword puzzles from www.bestcrosswords.com. Questions were all straight-forward (i.e., not "cryptic") type clues. In total, 140 questions were collected with types that were categorized as culture ( \(n=23\) ), general knowledge ( \(n=21\) ), definitions ( \(n\) \(=27\) ), logic ( \(n=22\) ), fill-in-the-blank (FITB, \(n=20\) ), categories \((n=16)\), and sayings \((n=11)\). Table 1 gives examples of each type.

Table 1: Example trivia types.
\begin{tabular}{lll}
\hline Type & Question & Answer \\
\hline Culture & "Kill Bill" star Thurman & Uma \\
Knowledge & U.S. spy organization & CIA \\
Definition & Gift to charity & Donation \\
Logic & Hour subunits & Minutes \\
FITB & "If all fails" & Else \\
Categories & Tulips and irises, for example & Flowers \\
Sayings & "Rolling in dough" meaning & Rich \\
\hline
\end{tabular}

The trivia questions were normalized for difficulty. 449 University of California, Merced undergraduate students with an average age of 18.4 ( \(S D=1.4 ; 200\) male, 249 female) were given surveys containing trivia questions. There were 10 versions of the survey, each of which contained 14 trivia questions with lines indicating the number of letters the answers. Participants were allowed to leave answers blank, but were instructed to do the best they could to answer to each question, guessing when possible. Results showed that questions varied widely in difficulty (see Fig. 2). For the present study, 40 questions were chosen that were answered correctly about half of the time. As shown in Figure 2, these trivia questions were solved by 45\(77 \%\) of participants, and they contained all types: culture ( \(n\) \(=6\) ), general knowledge \((n=8)\), definitions \((n=4)\), logic ( \(n\)
\(=8\) ), fill-in-the-blank (FITB, \(n=8\) ), categories ( \(n=2\) ), and sayings \((n=4)\). The examples in Table 1 were each used.

Figure 2: Question norming. Potential questions are ranked by the percentage of participants who answered correctly.

Dotted lines show the question rankings we used.
Trivia Program The experimental interface was programmed by the authors using Adobe Flash CS5. The program led participants through four experimental blocks (rounds) containing ten questions each. For each round, the program instructed participants to work either individually (I) or collaboratively (C). During collaborative sessions, participants were asked to work together and discuss each answer as a team. Across all subjects, the order of questions and condition (I-C-I-C or C-I-C-I) was randomized and counterbalanced between dyads, but was kept the same within each dyad.

Each question was provided alone on the screen with a sequence of blank squares indicating the number of letters in the answer. The space-bar was used to submit answers, and subjects were given feedback about their submission. If correct, a green checkmark appeared briefly before moving on to the next question. If incorrect or missing, a red " X " marked the incorrect or blank boxes. Subjects were given 20 seconds to correctly answer each question (with as many tries as necessary) before being automatically moved on to the next question. Between blocks, subjects were given the new condition and asked to wait for their partners before moving on. Progress was indicated using flip cards with "Working" on one side, and "Ready when you are!" on the other (see Fig. 1).

\section*{Procedure}

Participants were given five minutes to introduce themselves at the beginning of the study, in order to facilitate comfort and camaraderie (consistent with previous findings that more familiar groups tend to perform better on collaborative tasks; Barnier et al., 2008). After this brief familiarization period, headsets were fitted and the Flash program was started. The program began with instructions, which the researcher read aloud and subjects read on their respective screens, then the researcher left the room. After
completion of the four trivia rounds, subjects removed their headsets and summoned the researcher. The trivia program was closed and each subject was given a blank text editor. Subjects were instructed to recall and type as many of the answers to the previous trivia questions as possible. They were given five minutes and asked to work individually.

\section*{Results}

Thirty-one dyads participated in the experiment, but one dyad's audio was not recorded due to equipment error. Thus, task performance results are given for thirty-one dyads, while the audio results reflect thirty dyads.

For each question, the Flash program recorded (1) whether a correct answer was submitted before time ran out. If a correct answer was achieved, it also recorded (2) how much time elapsed from the beginning of the trial to the submission of the correct answer, in milliseconds, and (3) the number of incorrect attempts before the final, correct submission. Because each participant worked on his own computer, two independent data sets were collected for each dyad. For purposes of data analysis, results for each trial were averaged over the members of the dyad. These aggregated results were used to compare each dyad's performance on individual versus collaborative rounds. Dyads are independently sampled (though, individual performance is not, as one is not independent of one's partner), and hence at the dyad level, conditions (I vs. C) can be compared using paired-samples \(t\)-tests (unless otherwise noted below). \({ }^{1}\)

\section*{Trivia Performance}

On all three aggregate measures, collaborative dyads outperformed their non-collaborative counterparts. Out of the twenty questions presented in each condition, the average correctly answered by collaborative dyads was \(14.94(S D=3.77)\), while the average correctly answered by non-collaborative dyads was \(12.35(S D=3.11)\). This difference was significant, \(t(30)=5.58, \mathrm{p}<.0001\). Dyads were also faster to submit correct answers while they were collaborating ( \(M=5527 \mathrm{~ms}, S D=1212 \mathrm{~ms}\) ) as compared to when they were not collaborating \((M=6611 \mathrm{~ms}, S D=\) 1181 ms ), and this difference was also significant, \(t(30)=\) 3.17, \(p<.005\). Finally, the number of incorrect attempts made before achieving a correct answer was smaller for collaborative dyads ( \(M=.26, S D=.16\) ) than for noncollaborative dyads \((M=.61, S D=.27)\), which is also significant, \(t(30)=7.19, p<.0001\).

Thus, working collaboratively conferred benefits on all three measures of task performance: it increased the number, speed, and accuracy of successful submissions. Figure 3 shows the performance gain results, where gain for each dyad is calculated as average performance on collaborative rounds, minus average performance on noncollaborative rounds.

\footnotetext{
\({ }^{1}\) We also examined individual-level performance across most measures, and results are consistent with the dyad-level analyses.
}

Figure 3: Collaboration gains for the following measures: (a) average number of correct answers, (b) average time taken to achieve a correct answer (ms), (c) average number of incorrect attempts, per question. Gain for each dyad is calculated as the difference between aggregate performance on collaborative versus non-collaborative rounds. All points above \(x=0\) show dyads benefitting from collaboration. For illustration, dotted lines show median ranked dyads.

\section*{Recall}

The list of recalled items for each participant was first checked for accuracy and incorrect recalls were removed. This was relatively rare, however, as incorrect recalls represented only \(5.7 \%\) of the total recalled items across participants (36 out of 629). Each recalled item was matched to the round and condition in which it was encountered. At the group level (i.e., averaged within dyads), the average number of items recalled from each round was, respectively, \(1.60(S D=.74), 2.27(S D=1.35)\), \(1.97(S D=.91), 3.71(S D=1.57)\). Items from the last round were recalled significantly more often than any other round, \(t(30)=4.25, p<.001\), indicating a serial position effect of recency. Although the mean recall from the first round was the lowest, there was also evidence of a serial position effect from primacy. This pattern is shown in Figure 4, which plots the number of recalled words from each round, binned by the number of individuals recalling each number of items. A generalized linear model, fit to the data, shows both the recency and the (more subtle) primacy effects.

In general, subjects tended to remember more items from the rounds in which they participated collaboratively. Figure 5 shows ranked, aggregated dyads' recall from each round, separated by condition. For each round there was a tendency towards enhanced recall from collaboration, but this difference was only significant in the fourth round, \(t(28.88)\), \(p<.05\) (Welch's two-sample \(t\)-test). Overall, group level
recall was not significantly better for items from collaborative rounds \((M=5.24, S D=2.35)\) compared to non-collaborative rounds \((M=4.31, S D=2.00)\). At the individual level, however, where dyad members are not aggregated and are instead treated as independent, there was a significant effect of condition. That is, individuals recalled more items they had encountered during collaborative rounds \((M=5.24, S D=2.63)\) than during independent rounds \((M=4.31, S D=2.47), t(61)=2.03, p<.05\). Thus, there appears to be a tendency for enhanced recall from collaboration. Admittedly, these effects are smaller than the performance measures, though more power may bear this out.

Figure 4: Binned individual-level recall per round. Circle sizes illustrate the number of individuals that recalled the corresponding number of items from each round. The line shows the fit of a generalized linear model with quadratic term.

\section*{Conversation Analysis}

In order to further quantify the effects of collaboration on performance, conversations during the collaborative sessions were recorded. A coarse analysis of these recordings allowed us to collect information on the total amount of time each dyad spent in the collaborative sessions, as well as the amount of this time that was spent talking. On average, dyads spent 241.13 seconds ( \(S D=\) 71.37) in the (summed) collaborative rounds, and used, on average, 109.29 of these seconds \((S D=34.72)\) conversing. Because the amount of time spent in the collaborative part of the task varied between dyads, a measure of percent talking was also calculated for each dyad. This percent talking measure varied from about \(27 \%\) to \(70 \%\) ( \(M=46.54\), \(S D=10.76\) ).

As in the previous analyses, results were aggregated over dyads and each data point represents the group-level mean, across a dyad's participants. The total amount of time each dyad spent talking was negatively correlated with their performance, as measured by the number of correct answers they submitted during the collaborative rounds, \(r(28)=-.77\), \(p<.0001\). That is, the more talking they did, the worse they performed. This negative correlation may reflect the fact

Figure 5: Recall for items from Rounds 1-4 for each dyad, ranked in order of performance. Dotted lines with empty circles show the aggregated number of items recalled by dyads working collaboratively; Solid lines with filled circles show recall by dyads working non-collaboratively.
that when uncertain of an answer, dyads spend more time in discussion in order to figure it out. Indeed, when considering the percentage of time spent talking, there was a positive correlation with performance, \(r(28)=.27\), although this trend did not achieve significance. Figure 6 shows the relationship between talking and performance, as measured by both absolute and percentage metrics of talking.

Figure 6: Relationship between talking and performance. The scatterplot on the left shows each dyad's performance (percentage of questions answered correctly) as a function of the total number of seconds spent talking (regression line \(m=-0.4229\) ). On the right, performance is shown as a function of the percentage of time spent talking (regression line \(m=0.4724\) ).

\section*{General Discussion}

On all measures of performance for the trivia task, there appeared to be a collaborative benefit. Aggregate dyads achieved more correct answers in the collaborative rounds than in the independent rounds, and they did so with greater accuracy. Interestingly, aggregate dyads were actually faster in the collaborative rounds than in the independent rounds, despite the fact that they had the added task of communicating with their partner for each question. With respect to the terminology described earlier (Hare, 1976), we observed that the group product, produced by collaborating individuals, was better than the individual product, produced by individuals working alone. The recall task also suggested a benefit from collaboration. Previous work has shown that participating collaboratively in recall enhances future independent recall (Basden, Basden \& Henry, 2000), but our results also suggest that collaborative encoding could enhance independent recall: the individual recall product of collaborating individuals was (slightly) greater than the individual recall products of individuals acting alone.

It must be noted, however, that the present study was specifically designed to enable us to look for evidence of a collaborative gain. The collaborative benefit apparent in this situation may not apply to other situations, as previous work described earlier has found that the degree of collaborative gain is highly influenced by social context. Future work is needed to elaborate on the specifics of the social, environmental and task contexts which allow for these collaborative gains. We would also like to address the current findings in the context of interpersonal alignment, in future work. It was noted earlier that the use of similar taskrelevant linguistic forms benefits dyadic cooperation, (Fusaroli et al., 2012), and a growing body of research addresses how interpersonal interactions can cause automatic alignment to spread between physical, linguistic, and other cognitive states (Tollefsen \& Dale, 2012). This begs the question of whether collaborative performance on knowledge-based and memory tasks can be influenced or indicated by various levels of behavioral, linguistic, and cognitive alignment.

\begin{abstract}
A novel computational cognitive model explains human procedural error in terms of declarative memory processes. This is an early version of a process model intended to predict and explain multiple classes of procedural error a priori. We begin with postcompletion error (PCE), a type of systematic procedural error that people are prone to commit when there is one step to perform after they have accomplished their main task goal. Participants in an experiment demonstrated increased PCE rates following an interruption in a realistic form-filling task. The model explains PCE as a consequence of two declarative retrieval processes, spreading activation and base-level activation, competing with each other because of features of task and working memory structure. Our intention is to generalize the model to other classes of procedural error in complex task environments.
\end{abstract}

Keywords: computational cognitive model; human error; human-computer interaction; interruption; long-term memory; working memory

\section*{Introduction}

If you have ever left an original document on a photocopier after walking away with the copies then you have committed a postcompletion error (PCE). PCE is one example of a systematic procedural error, an error people tend to commit in familiar tasks that follow a specific sequence of actions each time the task is performed. Systematic procedural errors seem to be products of a combination of stable human cognitive structures and processes as well as certain task environments. PCE, in particular, tends to have a much higher rate of incidence than chance slips and seems to be very resistant to training (Byrne \& Davis, 2006). Our goal is to understand the cognitive structures and processes underlying PCE and, ultimately, to extend that same model to account for other systematic procedural error types.

Studying human error is important because with increasing capability and complexity of our technological systems (e.g., transportation, power generation) the amount of damage that can result from error is magnified. While chance slips occur because humans are fundamentally stochastic, systematic error occurs when certain features of human cognition meet certain task environmental conditions. If we learn about those cognitive and environmental features then we can learn to avoid them in our technological systems such as by exclusion from designs (Chung \& Byrne, 2008) or prediction and prevention (Ratwani \& Trafton, 2011).

Studying human error is difficult because of the variability of error behavior. Furthermore, error often arises from the dynamic interactions of several cognitive processes
that normally perform with with very little error. Models of human error are often complex compared to models of other behavior because these models must capture these interactions in ways that lead to proper proportions of both correct and incorrect behaviors.
For PCE, Byrne and Bovair (1997) explained it as a function of limited-capacity working memory. They addressed high and low working memory demand as well as individuals' high and low working memory capacities. Their model assumed a hierarchical goal representational structure. This was based on a GOMS (Card, Moran, \& Newell, 1983) analysis of an experiment task also reported in their study. Their CAPS model (Just and Carpenter, 1992) propagated activation necessary for retrieval of step representations downward from the task supergoal to subgoals to individual steps. Subgoals had to have their activations maintained above a certain threshold in order for them to remain accessible. Crucially, the main goal of the procedure would be satisfied before it was time to perform the postcompletion step. The presence of other information to maintain in an active state, in this case a three-back memory task, taxed the system to capacity such that it failed to maintain the postcompletion subgoal above threshold.

Another account of systematic error, Memory for Goals (Altmann \& Trafton, 2002), posits that we encode episodic traces of our goals as we complete tasks. Each goal is encapsulated in an episodic memory, which sparsely represents a behavioral context at the time of its encoding. The strength of these memories decay over time such that it may be difficult to remember the correct point at which we resume a task after an interruption. Memory for Goals provides a process-level theory for why certain types of errors are made during a well-learned task as a consequence of retrospective, episodic memory (Altmann \& Trafton, 2007; Ratwani \& Trafton, 2010, 2011; Trafton, Altmann, \& Ratwani, 2009). Memory for Goals implies that people are able to retrieve suspended goals successfully if and only if there are cues that prime them (Altmann \& Trafton, 2002). Here decay is indexed by time, so postcompletion steps, being at the end of their tasks, have relatively more time to decay compared to other steps that come earlier in the task.

The model presented in this paper draws upon both previous works, predicting PCE to occur as a combination of goal decay and a limited-capacity to spread activation from working memory to long term memory. Ultimately what we want is a unified framework with which we can make predictions about PCE, and later, other types of human error. A unified framework is important because one cognitive system, i.e. the human mind, produces all error types. Getting the explanation correct for one type then acts as a constraint on getting the explanation correct for the next

Figure 1: The financial management task interface resembled a web form. Subgoals assumed for the model are grouped by dotted lines and labeled for purposes of illustration here, but were not so in the task.
type tackled by the theory. Furthermore, if we are to predict error in complex task environments multiple error types must fall naturally out of the theory.

\section*{Experiment}

Participants performed a version of Ratwani and Trafton's (2011) financial management task (Figure 1). This is a type of form-filling task wherein participants, using a graphical user interface, click a series of buttons in a specific order. The goal of the task is to fill out an order form according to information available within the display. An arithmetic task occasionally interrupted the financial management task for 15 seconds at a time.

The final step of the task consisted of a single button not placed within a box and placed above the right column of boxes. This arrangement broke with the Western reading convention followed by the progression of all of the other steps. This step was arranged this way because we intended it to serve as a postcompletion step.

\section*{Design and Procedure}

Each order on the financial management task constituted a single trial. Control and interruption trials were manipulated in a within participants design; participants performed 12 trials. Half of the trials were control trials with no interruption and half were interruption trials with two interruptions each. The order of trials was randomly generated and participants did not have prior knowledge as to which trials would be control or interruption trials.

There were eight possible interruption points in the financial management task. These points occurred after clicking the Confirm button following the first seven modules, including just prior to the postcompletion action. The location of the interruptions on a trial by trial basis was randomized with the constraint that exactly two interruptions occurred just prior to the postcompletion step and at least one interruption occurred at each of the other
seven possible locations. The were 12 postcompletion error opportunities, one during each trial. Six of these opportunities were during control trials with no interruptions, two opportunities were immediately following an interruption, and four opportunities were during interruption trials where an interruption occurred at a point that did not immediately precede the postcompletion step.

Participants were seated approximately 47 cm from the computer monitor. After the experimenter explained the financial management task and interrupting task to the participant, the participant completed two training trials (one trial with and one trial without interruptions) with the experimenter. Following these two training trials, participants had to perform two consecutive randomly selected trials on their own without making a postcompletion error before the participant could begin the experiment. Forcing participants to perform two consecutive error free trials was a method for ensuring that participants were proficient at the task before beginning the actual experiment. Each participant was instructed to work at his/ her own pace. When performing the interrupting task, participants were instructed to answer the addition problems as soon as the solution was known and to answer as many addition problems as possible in the time interval. Upon resumption of the financial management task, there was no information available on the interface to indicate where to resume.

For modeling purposes the important points about the financial management task were:
1. It featured a primary task that was occasionally interrupted by a secondary task,
2. Participants had to follow a specific procedure.
3. The spatial layout of the interface (working from top to bottom down the left column and then the right column of Figure 1) and the operations required to perform the task were quite intuitive.
4. After entering information in each module, the participant clicked the Complete Order button (upper right corner). Clicking the Complete Order button was the postcompletion step and failing to click the Complete Order button constituted a PCE.
5. The spatial layout of the task grouped steps by proximity. This encouraged use of an intuitive heuristic ("go down the column"), as well as having an isolated "clean-up" step at the end. This format followed the form of other tasks shown by GOMS analysis to lead to subgoaling (e.g., Byrne \& Bovair, 1997).

6 . No information remained on the interface after clicking the confirm button within each module (i.e. no global place keeping (Gray, 2002)).
7. Measures: A PCE was defined as failing to click the last step's button and instead making an action that was in service of the next order on the financial management task (e.g. attempting to start a new trial by clicking an Order Ticker). The PCE rate was the number of PCEs divided by the number of opportunities to make a PCE. Skipping the next correct step, at any other time, was classified as an anticipation error.

Figure 2: Base-level and spreading activation of the model's postcompletion step chunk in control (a) and interruption (b) trials. X-axes indicate the step to be performed, by step ordinal number. Interruptions occur for the interruption trial type between steps four and five and nine and ten in this example. Consequently the goal buffer chunk lacks task context representation in these two spots, indicated by dashes. The chunk encoding the main goal of the task is Do a Trial (DAT) and it is associated to subsequently performing the first step. Do a Trial, as well as each step's representation, acts as context to cue retrieval of the next step. Do a Trial's activation is depicted in panel c. Arrows indicate times at which Do a Trial receives activation boosts because the model retrieves it at the end of each subgoal. The model's behavior with regard to Do a Trial is the same in both control and interruption conditions. The model's internal context representations, encoded in the chunks referenced from the slots of the goal and imaginal buffer chunks, are depicted at each step of the task beneath panels a and \(b\). These are the procedure step representations the model had retrieved when performing previous steps. To conserve space task steps are indicated by procedure sequence order, so the first step of the task is 1 and so on.

\section*{Model}

A model constructed using the ACT-R 6 cognitive architecture (Anderson et al., 2004) performed an abstract version of the financial management task. ACT-R is a hybrid symbolic and subsymbolic computational cognitive architecture that takes as inputs knowledge (both procedural and declarative about how to do the task of interest) and a simulated environment in which to run. It posits several modules, each of which perform some aspect of cognition (e.g., long-term declarative memory, vision). Each module has a buffer into which it can place a symbolic representation that is made available to the other modules. ACT-R contains a variety of computational mechanisms and the ultimate output of the model is a time stamped series of behaviors including individual attention shifts, speech output, button presses, and the like. One of the benefits of embodying a theory in a computational architecture, such as

ACT-R, is that it allows researchers to develop and test concrete, quantitative hypotheses and it forces the theorist to make virtually all assumptions explicit. To the extent that the model is able to simulate human-like performance the model provides a sufficiency proof of the theory.

In essence, the model worked by cyclic, activation-based retrieval from long-term memory of the task step representations encoded as chunks. At each step there were two sources of retrieval activation: 1) spreading activation from the contents of the goal and imaginal representations (these constituted the model's working memory), and 2) each chunk's base-level activation. Sometimes these activation sources conflicted with each other, particularly for the postcompletion step. At such times the model was likely to commit an error.
Activation spreading from the model's working memory to the long-term memory encoding the postcompletion step
increases with advancing task context because of the inverse association strength function we used (Equation 1).
\[
\begin{equation*}
\left(\frac{1}{i-j}\right) \mathrm{m} \tag{1}
\end{equation*}
\]

That in turn is based on step co-occurrence. For the model, doing one step cues the next (Figure 2a). Do a Trial, the main goal of the task, gets retrieved at the end of every subgoal. With each retrieval its base-level activation gets a sharp increase that decays gradually over time (Figure 2c).

The difference at the postcompletion step between control and interruption is that in the interruption condition, the model lacks spreading activation from its working memory (Figure 2b). This is because when the interruption occurs, the model clears that resource of primary task representations so that secondary task representations may reside there. Then when the model resumes task execution, it restores only a part of its task context representation.

The model lacks context, and thus spreading activation, at resumption because the sparse representation of the episodic memory trace only records reference to one chunk encoding context (Altmann \& Trafton, 2002), in this case the imaginal buffer chunk. Consequently when the model resumes it has only the imaginal buffer contents and not the goal buffer contents available to it.

In the example depicted in Figure 2b, the model is shown as having been interrupted before steps five and ten. Because of the way the model encodes its episodic memory and uses that to resume task execution, the chunks encoding steps four and nine are not referenced from the goal buffer chunk when it is time for the model to retrieve from longterm memory the chunks encoding how to perform steps five and ten.

The model produces PCE at resumption because total activation for the postcompletion step chunk and Do a Trial are approximately equal. In that context and with transient retrieval activation noise, each has an approximately equal chance of being retrieved.

\section*{Spreading Activation and Strength of Association}

An architectural feature of ACT-R is that it uses a limited pool of spreading activation from sources-a chunk in a module's buffer-to associated chunks in declarative memory as one of its mechanisms of declarative retrieval. Our model used ACT-R's goal and imaginal buffers as sources of activation, each providing one unit of spreading activation.

Activation spreads from source chunks in ACT-R's buffers to chunks residing in ACT-R's declarative memory as a function of the strength of association between the value of each slot in source chunk \(j\) to chunk \(i\) in declarative memory (Anderson, 2007; Anderson et al., 2004). This gives ACT-R a way to adjust its behavior according to context as the strength of association indicates the probability that chunk \(i\) will be needed in context \(j\). The limited pool of activation is divided equally among all the slots of source chunk \(j\). This means that ACT-R implements a limited-capacity working memory.

Our model set strengths of association from each step's representation to the next at the beginning of each model
run according to Equation 1.Association strengths remained static for the duration of each model run. Here, \(j\) is the serial position within the financial management task of the step encoded by a chunk representing some part of the model's current context (i.e., the last step performed). \(I\) is the serial position within the financial management task of the step encoded by an associated chunk in declarative memory. \(M\) is for a global ACT-R parameter to set the maximum association strength, set to 3.5 for this model.

For example, if the model had just performed the first step, Order Ticker, the association strength to the chunk encoding the second step, Quantity, would be 3.5. The strength of association to the third step, Cost, would be 1.75 . This enabled associative chaining from the model's current context to the next procedure step. This produced a graded representation that decreased in strength with increasing psychological distance, a feature borrowed from Altmann and Trafton (2007).

\section*{Base-Level Activation}

Base-level activation is an estimate that a declarative chunk will be needed in the future, given how recently it has been needed and how often it has been needed. This is another architectural feature of ACT-R and the idea is that given a limited capacity to retain information, those chunks not retrieved for a long time are allowed to have their activation decay below a threshold beyond which their retrieval will become less likely. Conversely, chunks that are retrieved frequently will have a high base-level activation contribution to their total activation. The model used ACTR's default decay rate of 0.5 and activation noise of 0.2 .

We assume spatial grouping of steps leads to Millerian (Miller, 1956) chunking of steps into groups, or subgoals. Anderson et al. (Anderson, Bothell, Lebiere, \& Matessa, 1998), in their model of sequence memory, determined it crucial that sequence items be recalled in groups. Their model traversed a hierarchy of list item chunks, grouping chunks, and a chunk encoding the current list.

The financial management task model abstracted this process by adding a retrieval reference to the Do a Trial chunk upon completion of each financial management task subgoal: Order Ticker, Quantity through Margin, Stock Exchanges through Review, and Complete Order (see Figure 1). Each retrieval reference boosted Do a Trial's base-level activation. The idea is that after completing one subgoal, the task main goal is retrieved and used to retrieve the next subgoal. Therefore Do a Trial's base-level activation tended to be relatively high.

The postcompletion step happened to be needed immediately after a retrieval reference to Do a Trial (after completion of the preceding subgoal). Furthermore, a long time might have elapsed since the postcompletion step's last retrieval, especially when there had been two 15 s interruptions during the trial. The relatively long time elapsed between retrievals of the postcompletion step lead to much decay of its base-level activation. Meanwhile, Do a Trial had received four retrieval references, one at the end of each of the subgoals. Each retrieval reference contributes to a chunk's base-level activation.

This combination of the postcompletion step's decay and Do a Trial's repeated retrieval was crucial for the model's commission of PCE at resumption. Because of these baselevel activation mechanics the postcompletion step would then need a large quantity of spreading activation to have enough total activation to be retrieved reliably at postcompletion step time. Otherwise since Do a Trial had the second-highest retrieval activation because of its high base-level activation, it might be retrieved instead of the post-completion step's representation.

\section*{An Example Model Run}

The model started its run by retrieving a procedure step representation. Because its context at the time would indicate that it was starting the task and the first step is most associated with starting, the first step would usually be the procedure step representation retrieved. After that the model simply looped through its basic behavioral cycle until it either finished a trial of the financial management task or until it was interrupted.

During the interruption, the model cleared its representations of its financial management task context from its working memory constructs-the goal and imaginal buffers-and replaced them with ones representing the interrupting task. At the end of 15 s the financial management task interface replaced the interrupting task's, whereupon the model detected that its visual environment had changed back to the financial management task and so then it initiated its resumption subroutine.

When the model resumed the financial management task it began so by retrieving an episodic chunk. Because which episodic chunk retrieved was a function of base-level activation and transient noise, the most recent episodic chunk was usually the one retrieved.

The episodic chunk held a reference to an imaginal buffer chunk, which the model copied to the imaginal buffer. That imaginal buffer chunk held a record of the subgoal's steps completed at the time the episodic chunk was created. The restored imaginal buffer chunk provided the link necessary to retrieve the next step's representation at resumption.

The imaginal buffer chunk could contain references to as many as four step representations, all previous to the next correct step and all having varying strengths of association to it. This means that the limited activation source from the imaginal buffer could be divided by up to four.

Furthermore, the farther away in the procedure those steps were from the postcompletion step, the weaker their strength of association, and so the less source activation would propagate to the retrieval of the postcompletion step. The eighth step associated less strongly to the postcompletion step than did the ninth, but the eighth step took as much of the imaginal buffer's activation as the ninth.

Expressed in terms of maximum association strength, when it was time to perform the postcompletion step the imaginal buffer chunk spread only \(25 / 48\) ths of available activation to the postcompletion step ( \(\approx 1.8\) with :mas \(=3.5\) ). Roughly half of the activation source available from the imaginal buffer was diverted away from retrieval of the postcompletion step because of the presence of the previous steps' representations.

The model predicted more PCE for interrupted steps than non-interrupted steps because although the goal buffer chunk also held a reference to the just-completed step, the episodic chunk only encoded the imaginal buffer chunk. And because only one other goal slot was occupied, the association from the ninth step to the postcompletion step would get half of goal's available spreading activation, 1.75 units. Thus with the goal buffer chunk present the postcompletion step would get twice as much spreading activation as when the goal buffer chunk was absent due to interruption. This was enough to make the difference between reliable postcompletion step execution and equal chance of PCE when combined with base-level activation.

Furthermore, because Do a Trial got retrieval references four times during each trial-including once immediately before the postcompletion step-it tended to have a much higher base-level activation than did the postcompletion step. So when the model's only source of context representation was the imaginal buffer chunk and the task context was time to perform step the postcompletion step, the postcompletion step and Do a Trial would have similar amounts of total activation. Transient noise added at retrieval time (a standard feature of ACT-R) could tip the balance one way or the other.

\section*{Model Fit}

We used our model to simulate data from 1,000 subjects. This large number of model runs allowed effects to converge on the model's true predictions. The model's means closely matched those of the participants, \(r=.976\), RMSD \(=.0334\). Figure 3 plots the model's means against the participants' means and \(95 \%\) confidence intervals.

\section*{Discussion}

PCE's distinction from anticipation is illustrated by comparison of their rates. If PCE were simply a matter of an anticipation error happening to fall at the last step then PCE and anticipation rates should be identical. However, Figure 3 shows clearly that the two error types are different.

What makes PCE unique is that it is a product of: 1) goal base-level activation decay below that of a competing goal's, 2) working memory structures with limited capacity to spread activation to long-term memory retrieval, 3) the size and structure of working memory representations-a preceding, large subgoal meant there were more items in working memory that would steal some of the available spreading activation away from the postcompletion step's retrieval, and 4) some context representation was not immediately available upon resumption.

\section*{Issues}

Rather than learning the task, the model relied on assumptions about task representation structure. However, those are based on previous efforts with regard to sequence learning and memory (Anderson, Bothell, Lebiere, \& Matessa, 1998a) and are also congruent with wellestablished methods of task analysis, particularly GOMS (Card, Moran, \& Newell, 1983). We adapted some procedural and structural aspects of the Anderson et al.

Figure 3: Mean error rates, human (bars) and model (circles). Error bars display the \(95 \%\) confidence interval of the mean. Panel a depicts interruption trials, controls in b.
model because procedures are a kind of sequence. Mapping spatial groupings of task interface widgets to procedural representation groups of steps led to two important portions of the model's explanation of PCE in the interruption paradigm: groups of procedure steps held in working memory and high availability of the supergoal, Do a Trial.

\section*{Implications}

The model explains PCE partially as a result of working memory constraints, following in the footsteps of Byrne and Bovair (1997). This implies that it should also explain PCE as a function of working memory capacity as their model did. In fact, this model has done just that with very little change (Tamborello and Trafton, submitted). Its anticipation error performance, while imperfect, suggests that the model should be extendable to other types of systematic procedural error, such as perseverations.

The decay process in the model has a cost, which is that suspended goals are forgotten gradually, making them harder to resume. The model carries with it an implied assumption that goals are retrieved at the outset of task execution, and then may decay from working memory before they are actually executed. With respect to PCE, the model implies that the default tendency is to make such errors, not avoid them.

Overall the model is encouraging with regard to our ultimate goal of developing a unifying framework of human error. But it is also encouraging from the standpoint of developing models of human procedural memory and execution, since the same cognitive systems are involved. Eventually it may also prove useful for models of error detection and recovery.

\begin{abstract}
Implicit transfer in sequential learning can occur with some spatiotemporal structures but not with others. Here, we investigated whether the consistent mirror-reversal of visuomotor sequences would lead to implicit transfer. A "set" comprised three sequential button presses and seven consecutive sets comprised a "hyperset." Participants learned hypersets by trial and error with their right hand. Then, they learned another hyperset, in which each set was vertically mirrored, horizontally mirrored, or randomly generated. Even when the participants did not notice the mirrored rule, the mirrored hypersets led to implicit transfer in terms of accuracy for both vertical and horizontal reversals. Furthermore, the vertical reserval also led to implicit transfer of performance speed. Taken together, the present results suggest that people can implicitly apply their learned representations to the mirrored visuomotor sequences.
\end{abstract}

\section*{Introduction}

Implicit learning of behavioral sequences play an important role in our daily life. Our cognitive abilities such as language usage, playing the piano, and driving a car can be improved by implicit acquisition or learning of skills (see reviews for implicit learning; Abrahamse, Jiménez, Verwey, \& Clegg, 2010; Perruchet \& Pacton, 2006). In fields of cognitive science, cognitive psychology, or experimental psychology, several implicit learning paradigms have been proposed (e.g., Serial Reaction Time (SRT) task, Nissen \& Bullemer, 1987; artificial grammar learning (AGL), Reber, 1967; visuomotor button press task, Hikosaka, Rand, Miyachi, \& Miyashita, 1995). Most studies have investigated whether people implicitly learn a sequence. In particular, some have insisted that people can learn both elements and a higher-order structure of a sequence. For example, Stadler and Neely (1997) showed that the structure of a sequence had a larger influence on learning in the SRT task than the length of that sequence, indicating that some structures tend to be easier to learn than others (see also Cohen, Ivry, \& Keele, 1990). Some studies adopting the AGL task suggested that people might implicitly learn fragments or chunks of two, three, or four letters (ServanSchreiber \& Anderson, 1990; Perruchet \& Pacteau, 1990). In the visuomotor button press task, Hikosaka et al. (1995)
observed that participants performed slowly and inaccurately when a higher-order sequence was reversed, but individual elements remained identical. Thus, the previous studies pointed to the possibility that people learned certain levels of higher-order structure of a sequence.

Transfer of motor learning refers that some movement controls are learned in one situation and transferred to another situation (e.g., Schmidt \& Young, 1987). Experiments with key-pressing tasks have demonstrated transfer between sequences that require different arm or finger movements, suggesting that abstract representations underlie sequence production (e.g., Bapi et al., 2006; Kovacs et al., 2009). Namely, this implies that some representations used for motor execution appear to be independent of the effectors producing the action. Cohen et al. (1990), for example, found that transfer of speed occurs when participants learned a tapping task with their three fingers and then, the same tapping task with their index finger (they were not aware that the learning and transfer tasks were identical sequences due to a distraction task).

Previous studies have reported that people implicitly detect reversed or mirrored structures of musical melodies, even when they are unaware of the structure (e.g., Dienes, Kuhn, Guo, \& Jones, 2012). For example, Dienes and Longuet-Higgings (2004) used sequences comprised of twelve musical tones, where the first six tones were randomly generated and the second six tones were altered from the first tones with some specific alternations. During the learning phase, participants were told that the musical melody obeyed some specific rules and in the test phase, they required to answer whether the musical melody followed the rules or not. Results showed that participants who had background experience with atonal music could implicitly detect altered melodies (e.g., reversals and mirrors). Similarly, Kuhn and Dienes (2005) observed that trained participants preferred mirrored melodic structures to non-mirrored structures. Collectively, these results indicate that people could implicitly use the mirror symmetries of learned sequences.

As well as the study of musical melody (e.g., Dienes \& Longuet-Higgings, 2004), in the present study, we were interested in whether implicit transfer of visuomotor sequence learning occurred when learned sequences (i.e., visual configuration and finger movement of the sequence)
became mirror symmetries in transfer. In order to investigate the effects of the mirrored structure on implicit transfer in sequential learning, we employed a sequential button press task (e.g., Hikosaka et al., 1995, 1996, 2002; Watanabe et al., 2006, 2010). Hikosaka et al. (1999) summarized that in the visuomotor learning task paradigm, the early trial-and-error stage was controlled and explicit processes and those in the late learning stage were automatic and implicit. The experimental device consisted of 16 lightemitting diode (LED) buttons mounted in a \(4 \times 4\) matrix while in most studies of the SRT tasks, the device was composed of three or four aligned buttons, which enables us to examine two types of mirror transfer: Vertically mirrored and Horizontally mirrored. In the present study, a fixed visuomotor sequence (which constituted the "hyperset") of seven triads of button presses (hereafter called "sets") was generated for each participant. After participants learned the hyperset by trial-and-error, they were required to perform another hyperset, in which the sets were generated by a specific alternation rule. Here, we prepared three alternation rules, with which a visual configuration of the set was vertically mirrored (hereafter called "vertically mirrored rule"), horizontally mirrored (hereafter called "horizontally mirrored rule"), or randomly generated (hereafter called "random rule").

\section*{Method}

\section*{Participants}

120 right-handed participants ( 68 males, 52 females; mean age \(=21.19\) years, standard deviation \(=2.31\) ) participated in the experiment. All participants had normal or corrected-tonormal visual acuity, normal motor functions, and were naïve to the purpose of this study. All procedures were conducted in accordance with the Declaration of Helsinki.

\section*{Procedure}

We adopted a basic experimental paradigm used in previous studies (e.g., Hikosaka et al., 1995; Watanabe et al., 2010; Figure1). The experimental device consisted of 16 LED buttons mounted in a \(4 \times 4\) matrix and another LED button (called the "home key") at the bottom. Participants used their right index fingers to press the buttons. When participants pressed the home key for 500 ms , three buttons ("set") turned on simultaneously. Participants were required to press the illuminated buttons in the correct order, which they needed to uncover through trial-and-error. If participants were successful, the LEDs turned off, one by one, and a different set was illuminated, for which the participants were again required to discover the correct order. When participants pressed the wrong button, all LEDs were briefly illuminated, and participants then had to restart from the home key. Seven sets were presented in a fixed order, which we called a "hyperset," to complete a trial. A trial was considered an error when participants
pressed the wrong button in all the sets and successful when participants completed a hyperset, and For example, if participants press the wrong button in Set 5, they would need to start over from the home key. The same hyperset was repeated until participants completed it successfully for 20 trials (called a "block"). Participants were asked to perform the task as quickly and accurately as possible.

We prepared four types of hypersets: "Original," "Vertically mirrored," "Horizontally mirrored," and "Random". The Original hyperset was randomly generated for each participant. In the Vertically mirrored hyperset, the spatial configurations of the sets were reversed by the vertical axis from the Original hyperset. In the Horizontally mirrored hyperset, the spatial configurations of the sets were reversed by the horizontal axis from the Original hyperset. In the Random hyperset, the new spatial configurations were randomly generated.

\section*{Original hyperset}

\section*{Vertically mirrored hyperset}

Horizontally mirrored hyperset

Figure 1. Experimental device and schematic flow of the present study. Participants were instructed to learn the correct order by trial-and-error. The LED buttons were square in shape ( \(10 \mathrm{~mm} \times\) 10 mm ) and 8 mm apart. Participants were required to discover a correct order by trial-and-error. A trial was considered successful when participants completed a hyperset, and a trial was considered an error when participants pressed the wrong button in all the sets. For example, if participants press the wrong button in Set 2, they would re-start from the home key. A block is finished when participants successfully completed a hyperset 20 times. The Original hyperset was randomly generated for each participant. For each set, the three buttons were defined in ascending order of [1][2][3]. In the Vertically mirrored and Horizontally mirrored
hypersets, all the sets were spatially mirrored with white dashed line, resulting in the Vertically mirrored and Horizontal mirrored sets, respectively from the Original hyperset. The Random hyperset was randomly generated again for each participant, which is different from the Original hyperset. Note that the number shown on the LED button was not displayed during operation.

All participants first performed a block with the Original hyperset and then a block with the Vertically mirrored, Horizontally mirrored, or Random hypersets, which were randomly assigned. The two blocks were separated by a 5 -min break. No information was given regarding the alternation rule and, in the second block, participants were instructed that a new hyperset was randomly generated. In order to specifically examine the implicit form of transfer, participants were interviewed after the experiment. In the interview, they were asked how they performed and whether they noticed anything peculiar in the second block. If participants spontaneously reported the mirrored rule, they were excluded from our main analyses. Next, the experimenter explained the mirrored rule to the participants and those who recognized the mirrored rule were also excluded from our main data analyses. Methods for distinguishing explicit knowledge and implicit knowledge are still under debate. Several studies have used subjective measures based on confidence ratings (e.g., Ziori \& Dienes, 2006, 2008). Conversely, some studies defined implicit learning that participants were unable to verbalize what they acquired (e.g., Ashby, Alfonso-Reese, Turken, \& Waldron, 1998). In this study, we only focused on whether participants noticed the mirrored rule and, therefore, we defined explicit knowledge that participants were able to recognize the mirrored rule.

\section*{Data Analysis}

As a measure of accuracy, we counted the number of error trials before completing one trial. In order to evaluate speed, we measured the time that had elapsed from the moment the home key was pressed to the moment the third button of the final (7th) set was pressed for each successful trial. Similar parameters have been employed in previous studies and verified (e.g., Watanabe et al., 2006, 2010). We divided the 20 correct trials into five trial sections and calculated mean performance times within each trial section. We defined mean performance times during the fifth section (i.e., 17th to 20th trials) of the first block as a baseline for each individual participant so that we compared the magnitude of transfer among participants who differed on initial performance. We then calculated adjusted performance by subtracting the baseline from performance times during the second block (the Vertically mirrored, Horizontally mirrored, or Random hypersets) and divided by the baseline. This adjusted performance time [ \(\left.\mathrm{P}^{\text {second block }} / \mathrm{P}^{\text {baseline }}\right]\) represents the transfer magnitude of participants' performance times. A value more than 1 indicates that the performance time in the second block is faster than that of
the final trial section in the first block (i.e., baseline). Any difference in adjusted performance times indicates a difference in magnitude of transfer among different hypersets in the second block.

\section*{Results}

Forty participants were assigned for each of the Vertically mirrored, Horizontally mirrored, and Random hypersets. Since nineteen participants in the Vertically mirrored hyperset and seven in the Horizontally mirrored hyperset noticed the mirrored rules, they were excluded from our main analysis. Next, we excluded six participants whose performances in the first block were slower than two standard deviations from each group's average (three participants in Vertically mirrored, two in Horizontally mirrored, and one in Random hypersets). Similarly, we additionally excluded four participants whose performances in the second block were slower than two standard deviations from each group's average (one in Vertically mirrored, one in Horizontally mirrored, and two in Random hypersets). The selection procedure resulted in 17, 30, and 37 unaware participants with acceptable performance, for the Vertically mirrored, Horizontally mirrored, and Random groups, respectively.

We mainly conducted two-way mixed ANOVAs with the five trial sections as a within-subjects factor and the three hypersets as a between-subjects factor, which was called simply "ANOVA" hereafter, and post-hoc tests with the Shaffer's method when performed (called "post-hoc test"). For all hyperset groups, a significant decrease was found in both accuracy and speed measures in the first block, indicating that non-specific learning had occurred (ANOVA; \(F(4,324)>81.45, p<0.0001\); for both measures) and there were no differences among the hyperset groups (ANOVA; \(F(2,81)<0.24, p>0.78\); for both measures; Figure 2a and 2b). No significant interaction between experimental groups and successful trial sections (ANOVA; \(F(8,324)<1.24, p>0.27\); for both measures). These results were accord with those in previous works; the accuracy measure decreased rapidly in the first few completed trials, while the speed measure decreased more gradually (e.g., Watanabe et al., 2006, 2010).

In the second block (transfer block), mean adjusted performance times (i.e., speed) were generally faster (i.e., more transfer was found) in the Vertically mirrored group compared with the Random group (Figure 2c). The ANOVA revealed significant main effects of experimental group \((F(2,81)=3.34, p<0.05\); post-hoc test, Vertically mirrored \(<\) Random, \(p<0.05\) ) and successful trial section \((F(4,324)=75.03, p<0.001\); post-hoc test, 1 st \(>2\) nd \(>3 \mathrm{rd}\) \(=4\) th \(=5\) th section, \(p<0.01\) ). The interaction between experimental group and successful trial section was not significant \((F(8,324)=1.38, p=0.20)\). As for accuracy, the ANOVA revealed significant main effects of experimental group \((F(2,81)=12.38, p<0.0001\); post-hoc test, Vertically mirrored \(=\) Horizontally mirrored \(<\) Random, \(p<\)
0.001; Figure 2d) and successful trial section \((F(4,324)=\) 361.4, \(p<0.0001\); post-hoc test, 1 st \(>\) the other sections, \(p<\) 0.01 ). The interaction between experimental group and successful trial section was also significant \((F(8,324)=\) 14.61, \(p<0.0001\) ) and this interaction shows that in the first trial section, the accuracy was higher in the Vertically mirrored and Horizontally mirrored hypersets than in the Random hyperset \((F(2,81)=15.06, p<0.0001\); post-hoc tests, Vertically mirrored \(=\) Horizontally mirrored \(>\) Random, \(p<0.001\) ) while in the other trial sections, the accuracy was not different among the experimental groups ( \(F(2,81)<2.09, p>0.13\); for the other sections).

Figure 2. Performance in the first and second blocks. Error bars show the standard errors of the mean. All participants performed the Original hyperset in the first block. (a) Average performance time for successful trials in the first block. (b) Average number of errors before the successful completion of each trial in the first block. (c) Average adjusted performance time for successful trials in the second block. The adjusted performance was computed as follows: [ \(\left.\mathrm{P}^{\text {second block }} / \mathrm{P}^{\text {baseline }}\right]\). (d) Average number of errors before the successful completion of each trial in the second block.

A Pearson's chi-squared test revealed a significant difference in the proportion of participants who noticed the alternation rule between the Vertically mirrored and Horizontally mirrored groups ( \(\chi^{2}=6.89, \mathrm{p}<0.01\); Vertically mirrored \(>\) Horizontally mirrored). Therefore, we additionally examined whether the performances of those groups (aware vs. unaware) in the Vertically mirrored hyperset were different. We excluded two participants in the aware group whose performances in the first block were slower than two standard deviations from the group average (i.e., resulting in 17 aware and 17 unaware participants). In
the first block, we confirmed that performance did not differ between the groups \((F(1,32)<2.53, p>0.12\); for speed and accuracy measures; Figure 3 a and 3 b ). In the second block (transfer block), we found that the accuracy was higher when participants were aware of the alternation rule (Figure 3d). For speed, a two-way mixed ANOVA did not reveal significant main effects of awareness \((F(1,32)=2.49, p=\) 0.12 ; Figure 3 c ) while we observed the significant main effects of successful trial section \((F(4,128)=79.63, p<\) 0.0001 ; post-hoc tests, \(\left.1^{\text {st }}>2^{\text {nd }}>3^{\text {rd }}=4^{\text {th }}=5^{\text {th }}, p<0.05\right)\). No significant interaction between group in terms of awareness and successful trial section was not observed \((F(4,128)=2.29, p=0.06)\). For accuracy, a two-way mixed ANOVA revealed significant main effects of awareness \((F(1,32)=15.74, p<0.001\); Unaware \(>\) Aware \()\) and trial section \(\left(F(4,128)=199.73, p<0.0001\right.\); post-hoc test, \(1^{\text {st }}>\) the other sections, \(\mathrm{p}<0.0001\) ), as well as a significant interaction \((F(4,128)=18.18, p<0.0001)\). This interaction shows that in the first trial section, the accuracy was higher in the aware group than in the unaware \((F(1,32)=19.87, p\) \(<0.001\) ) while in the other trial sections, the accuracy was not different among the sorted groups \((F(1,32)<1.19, p>\) 0.28 ; for the other sections). These results confirmed that once participants obtained the alternation rule (i.e., explicit knowledge), they could clearly perform the hyperset with fewer errors (e.g., Watanabe et al., 2006).

Figure 3. Performance of participants who noticed the vertically mirrored rule ("Aware") and who did not ("Unaware") in the second block. Error bars indicate standard errors of the mean. The adjusted performance was computed as follows: [ \(\mathrm{P}^{\text {second block }} /\) \(\left.P^{\text {baseline }}\right]\). (a) Average performance time for successful trials in the first block. (b) Average number of errors before the successful completion of each trial in the first block. (c) Average adjusted performance times in the second block. (d) Average number of
errors before the successful completion of each trial in the second block.

\section*{Discussion}

In the present study, we investigated whether a spatially mirrored sequence in visuomotor sequence support implicit transfer of performance in accuracy and speed. We found that (1) both vertically and horizontally mirrored sequence led to transfer of learning in terms of accuracy even when participants did not notice the mirrored rules; (2) vertically mirrored sequence, in addition, led to transfer in terms of performance speed; (3) the proportion of participants who noticed the vertically mirrored rules were significantly higher than the horizontally mirrored rules; and (4) accuracy in the transfer session was significantly higher for the aware group than the unaware group with the vertically mirrored rule.

Previous studies discussed that people who have an experience of playing the piano implicitly discriminated reversed or mirrored structures of musical melodies (e.g., Dienes et al., 2004, 2012), indicating that people can implicitly understand relationships between original and reversed or mirrored sequences of musical tones. In the literature of intermanual transfer (Grafton, Hazeltine, \& Ivry, 2002), participants conducted the SRT task with the counting tone task (i.e., this distractor task usually makes participants unaware of the hidden repetition of the sequence) with their left hands in the learning block and subsequently they performed the transfer task with their right hands with the original and mirrored ordered sequence (original sequence, both stimulus sequence and order of response locations remained, but the finger movements were different; mirrored sequence, finger movements in transfer block were identical to those in learning block, but the stimulus location was visually mirrored). Seven out of eight participants were not aware of the repetition of the sequence and the results showed that performance of the original and mirror sequence was significantly better than that of the random sequence. In the present study, the Vertically and Horizontally mirrored hypersets produced the better transfer in terms of accuracy than the Random hyperset. Moreover, the Vertically mirrored hyperset led to better transfer in terms of speed than the Random hyperset. The present study is the first empirical study to show that implicit transfer occurs even when the visual configuration and finger movements of a sequence were consistently vertically or horizontally mirrored. The present results indicate that people implicitly apply their learned representation to the mirrored hypersets.

Most procedural and sequential learning in our daily life possess two stages of processing: the controlled exploration of patterns and the process of automatization after a pattern has been discovered (Anderson, 1982). How sequential learning should be done in order to induce implicit transfer likely has two possibilities; less learning (i.e., remain controlled process) or much learning (i.e., reach
automatic process) leads to implicit transfer. These two possibilities probably depend on whether the automatic process of the learning interferes with transfer; once an automatic process is established, the process can be interference when performing a transfer task because different sequence from learning is required and then, the less learning phase might be better to induce implicit transfer. Conversely, as the automatic process does not require much allocation of attention, the process might give allocation of attention when performing transfer, resulting in implicit transfer. Taken together with previous work (Dienes \& Longuet-Higgings, 2004), the results that people could implicitly understand the mirror symmetry might be associated with their automaticity of performance. In the study of music melody, only participants who had played the piano could use the mirrored structure of the music melody, indicating that implicit transfer can occur when cognitive skills (i.e., playing the piano) became automatic process. In the present study, in the first block, the participants completed the hyperset 20 times without errors and in the later learning phase, their performance probably reached at the automatic level (Hikosaka et al., 1999). Thus, these automatic operations likely made an allocation of attention of participants for the transfer task available. For example, Shanks, Rowland and Ranger (2005) showed that performances in the SRT tasks are degraded under doubletask conditions, which indicated that implicit learning depends on availability and allocation of attention and is susceptible to the double-task conditions while the learning process was not automatic. Collectively, once a process of task performance reached automatic, the allocation of attention for the learning task is alleviated, resulting in that the allocation of attention for a transfer task became available, which probably made participants possible to implicitly use the mirrored relationship and transfer their obtained representation to the mirrored sequence.

Next, we discuss the differential results between the Vertically and Horizontally mirrored hypersets. We observed implicit transfer of speed only in the Vertically mirrored hyperset, indicating that the vertically mirrored rule might be easier than the horizontally mirrored rule. However, this differs from the Fitt's law (speed-accuracy trade-off; Fitts, 1954) because distances of finger movements were the same between Vertically and Horizontally mirrored hypersets. Then, the present result might pertain to the residual or subthreshold awareness of the mirrored rules. We observed significantly different proportions of participants who noticed the vertically and horizontally mirrored rules. This indicated that the vertically mirrored rule might be easier to notice than the horizontally mirrored rule; sub-threshold awareness of the vertically mirrored order might prime performance within the consistently vertically mirrored sets. The relationship between awareness and difficulty of the task requires to be investigated, but a task of which most people can notice an alternation rule might be easily transferred.

In Watanabe et al. (2006), after a first hyperset was learned, new hypersets were generated by rotating the sets (i.e., entire stimulus configuration) by \(0^{\circ}, 90^{\circ}, 180^{\circ}\), and \(270^{\circ}\) (clockwise). Participants were not instructed that the new hypersets were based on the first learned hyperset. Through the experiment, half of the participants spontaneously noticed the regularity of the rotation while the other half did not. Watanabe et al. (2006), then, compared the performances of the participants who were aware and unaware of the regularity and found that those who noticed the regularity could perform the new hyperset more accurately than those who did not notice it while the different performance of speed was not observed. We found that performances of participants who noticed the vertically mirrored rule were more accurate than those who did not notice it. This result was basically accord with Watanabe et al. (2006). Once participants obtained explicit knowledge (i.e., were aware of the hidden rule), they performed the test sequence with fewer errors.

In addition, we compared the performance of the participants who were not aware of the regularity of the Vertically mirrored hyperset and those in the Random hyperset, and found implicit transfer of speed. This point differs from the previous study where no effect of explicit knowledge was found for performance speed with the rotated hypersets. Therefore, the vertical reversal might be a special case in terms of spatial transformation of visuomotor sequences.

In conclusion, in the present study, we investigated whether people could implicitly transfer learned sequence with accuracy and speed to a spatially mirrored sequence. We found that even when participants did not notice the mirrored rules, they showed transfer of learning to the vertically or horizontally mirrored sequence. This result indicates that people could implicitly use the relationship between the learning block and transfer block.

\begin{abstract}
The standard approach to Bayesian models of Cognition (also known as rational models) requires researchers to make strong assumptions about people's prior beliefs. For example, it is often assumed that people's subjective knowledge is best represented by "true" environmental data. We show that an integrative Bayesian approach-combining Bayesian cognitive models with Bayesian data analysis-allows us to relax this assumption. We demonstrate how this approach can be used to estimate people's subjective prior beliefs based on their responses in a prediction task.
\end{abstract}

Keywords: Bayesian modeling; rational analysis; cognitive models; Bayesian data analysis; Bayesian inference; knowledge representation; prior knowledge

\section*{Introduction}

In the standard approach to Bayesian models of Cognition (also referred to as rational models), researchers make strong assumptions about people's prior beliefs in order to make predictions about their behavior. These models are used to simulate the expected behavior-such as decisions, judgments or predictions-of someone whose computational-level solution to a cognitive task is well described by the model. Analysis of Bayesian models of cognition usually involves a qualitative comparison between human responses and simulated model predictions. For an overview of Bayesian models of cognition see Oaksford and Chater (1998); but also see Mozer, Pashler, and Homaei (2008); and Jones and Love (2011) for a critique.

As an alternative to the standard approach, we present an integrative Bayesian approach that allows us to relax the assumptions about people's prior beliefs. This approach is motivated by previous efforts to infer subjective mental representations (Lewandowsky, Griffiths, \& Kalish, 2009; Sanborn \& Griffiths, 2008; Sanborn, Griffiths, \& Shiffrin, 2010) and more specifically to combine Bayesian models of cognition and Bayesian data analysis (Huszar, Noppeney \& Lengyel, 2010; Lee \& Sarnecka, 2008). The integrative approach allows us to use people's responses on a cognitive task to infer posterior distributions over the psychological variables in a Bayesian model of cognition. It also allows us to estimate probabilistic representations of people's subjective prior beliefs.

We recently applied this approach to a Bayesian cognitive model of reconstructive memory (Hemmer, Tauber, \& Steyvers, in prep). We estimated individuals' subjective prior beliefs about the distribution of people's heights based on their responses in a memory task. The technical requirements for integrated Bayesian inference were
simplified because the posterior distribution, based on inference in the cognitive model, had a simple Gaussian form. This made it straight forward to define individuals' responses as Gaussian distributed random variables in an integrated Bayesian model.

In this study, we develop a method for applying integrated Bayesian inference that does not require the posterior of the cognitive model to have a simple parametric form. We apply this method to a Bayesian cognitive model for predictions that was developed by Griffiths and Tenenbaum (2006). Their Bayesian model of cognition was a computational-level description of how people combine prior knowledge with new information to make predictions about real-world phenomena. They asked participants to make a series of predictions about duration or extent that were similar to the following examples:

> If you were assessing the prospects of a 60-year-old man, how much longer would you expect him to live?

> If you were an executive evaluating the performance of a movie that had made \(\$ 40\) million at the box office so far, what would you estimate for its total gross?

All of the questions used by Griffiths and Tenenbaum (2006) were based on real-world phenomena such as, life spans, box office grosses for movies, movie runtimes, poem lengths and waiting times. Their assumption was that people make predictions about these phenomena based on prior beliefs that reflect their true extents or durations in the real world.
Although it is possible that people's beliefs about these phenomena are tuned to the environment, this assumption cannot be used to explain how people make similar sorts of predictions about counterfactual phenomena that have no true statistics in the environment. For example, consider the following question:

Suppose it is the year 2075 and medical science has advanced significantly. You meet a man that is 60 years old. To what age will this man live?

There is no "true" answer to this question and therefore no environmental data is available. This creates a problem for a Bayesian model of cognition that requires environmental data in order to make predictions.

\section*{Environmental Statistics as Prior Knowledge}

Researchers can use Bayesian models of cognition to simulate the responses that people would make if their computational-level solution to the prediction problem is well described by the model. This process requires that the model includes representations of the prior knowledge people have about the phenomena being predicted. Researchers can represent prior knowledge in their models by collecting real-world environmental statistics and using them in their models as a stand-in for the subjective prior knowledge of individuals (Griffiths \& Tenenbaum, 2006 Hemmer \& Steyvers, 2009a; Hemmer \& Steyvers, 2009b). Representing prior knowledge in this manner is based on the assumption that our knowledge and representations about real-world phenomena are based on actual exposure to these phenomena in the environment. A researcher's best guess at a participant's knowledge is that it reflects, on average, the actual statistics of that phenomenon in the environment.

\section*{Standard Qualitative Analysis}

In the standard approach to Bayesian cognitive modeling, researchers qualitatively compare model predictions to people's responses. The values of psychological parameters-which represent aspects of cognition that are "in people's heads"-are manually specified or estimated with non-Bayesian methods. For a critique of non-Bayesian analysis of Bayesian models, see Lee (2011). The researcher usually encodes subjective prior knowledge in the model using empirical priors (based on environmental data) or by specifying parametric priors with psychological parameters.

A limitation of this method is that researchers do not apply Bayesian inference techniques to participant response data, in order to make inferences about the prior knowledge and psychological parameters represented in the model. It does not allow for the possibility that participants' prior knowledge could be different from the form assumed by the researcher. Furthermore, a model that requires prior knowledge from real-world data cannot be used to generate predictions if the researcher is unable to encode this data in the model. For example, Griffiths' and Tenenbaum's (2006) model cannot be used to generate predictions for the counterfactual future life spans question; even though it involves the same sort of task as the factual prediction questions.

\section*{Quantitative Analysis: An Integrative Bayesian Approach}

The limitations of the qualitative approach can be addressed by reframing a Bayesian model of cognition as a generative process for human response data. Researchers can then use an integrative Bayesian approach to make inferences about the subjective aspects of the cognitive model.

A Bayesian Model of Cognition for Predictions Griffiths and Tenenbaum (2006) had people make simple predictions

Figure 1. Graphical model (observer perspective)
about the duration or extent of real-world phenomena. For example, when told that a man was currently 60 years old, people had to predict the age to which he would live. We refer to the value that is presented in the question as \(t\) and to the person's prediction as \(t_{t o t a l}\). So if a person predicted that the man would live to be 80 years old, then we would have \(t=60\) and \(t_{\text {total }}=80\).

The Bayesian model of cognition proposed by Griffiths and Tenenbaum used nonparametric environmental priors for \(t_{\text {total }}\). We use a modified version of their model in which \(t_{\text {total }}\) has a parametric prior that is Normal, Erlang or Pareto distributed. We add a switch \(c\) that selects which parametric form is used for the prior.

Figure 1 is a graphical representation of our cognitive model for duration and extent from the perspective of the person making predictions (the observer). Shaded nodes represent variables that contain information that is known to the observer. Unshaded nodes contain information that is unknown to the observer.
The model depicts an observer's subjective model of the conditional dependencies between total duration/extent \(t_{\text {total }}\) of phenomena of different types \(c\)-which are determined by the form of the observer's prior knowledge for the domain. The vector \(\boldsymbol{\theta}\) parameterizes prior distribution types such that \(\theta_{1}, \theta_{2}, \theta_{3}\) parameterize Normal, Erlang and Pareto types, respectively. We specify the prior distribution \(t_{\text {total }}\) as:
\[
t_{\text {total }} \sim \begin{cases}\operatorname{Norm}\left(\theta_{1}\right), & c=1  \tag{1}\\ \operatorname{Erlang}\left(\theta_{2}\right), & c=2 \\ \operatorname{Pareto}\left(\theta_{3}\right), & c=3\end{cases}
\]

The time or duration \(t\) from which the observer must predict \(t_{\text {total }}\) is equally likely for all possible values \(0<t<\) t_total. We implemented this in the model by placing a uniform prior on \(t\) :
\[
\begin{equation*}
t \sim \operatorname{Unif}\left(0, t_{\text {total }}\right) \tag{2}
\end{equation*}
\]

When presented with a prediction question with value \(t\), we assume that observers access the relevant prior knowledge of \(t_{-}\)total by determining the prior type \(c\) and the parameter
values \(\theta_{c}\) and then infer a posterior distribution \(P\left(t_{\text {total }} \mid t, c, \boldsymbol{\theta}\right)\) that is described using Bayes' rule:
\[
\begin{align*}
& P\left(t_{\text {total }} \mid t, c, \boldsymbol{\theta}\right) \propto \\
& \begin{cases}\text { Unif }\left(t \mid 0, t_{\text {total }}\right) f\left(t_{\text {total }} \mid \theta_{c}\right), & t \leq t_{\text {total }} \\
0 & , \\
t>t_{\text {total }}\end{cases} \tag{3}
\end{align*}
\]
where,
\[
f\left(x \mid \theta_{c}\right)= \begin{cases}\operatorname{Norm}\left(x \mid \theta_{1}\right), & c=1  \tag{4}\\ \operatorname{Erlang}\left(x \mid \theta_{2}\right), & c=2 \\ \operatorname{Pareto}\left(x \mid \theta_{3}\right), & c=3\end{cases}
\]

Finally, the observer provides a prediction for the total extent or duration. This response is based on the posterior distribution \(P\left(t_{\text {total }} \mid t, c, \boldsymbol{\theta}\right)\), and could be related to the posterior in a number of ways. The response \(R\) could be a sample from the posterior,
\[
\begin{equation*}
R \sim P\left(t_{\text {total }} \mid t, c, \boldsymbol{\theta}\right) \tag{5}
\end{equation*}
\]
or it could be a function of the posterior such as the median, mean or mode. Griffiths and Tenenbaum (2006) modeled predictions as the median of the posterior. We assume that each response is based on a single sample from the posterior. This assumption provides a technical simplification for modeling how people generate a response from the posterior distribution. We will not explore the theoretical implications of this assumption in depth; however, there is evidence supporting a response model that is based on limited samples from a posterior (Vul, Goodman, Griffiths \& Tenenbaum, 2009).

\section*{Applying Bayesian Data Analysis to the Bayesian Model} of Cognition The goal of the researcher is to apply Bayesian data analysis to the Bayesian model of cognition in order to infer the values of \(\theta\) and \(c\) given \(t\) and observer predictions \(R\) about \(t_{\text {total }}\). This requires an integrative application of Bayesian inference from the perspective of the researcher. Each and every value of \(\theta\) and \(c\) for which the researcher wishes to evaluate the posterior likelihood requires Bayesian inference of the posterior likelihood of the observer's response in the rational model given the values of \(\theta\) and \(c\).

From the perspective of the researcher, the responses provided by an observer are the result of a generative process that encapsulates an application of Bayesian inference to a Bayesian model of cognition (fig. 1) resulting in a posterior distribution (Eq. 3) from which the result is sampled. We call this generative process a Bayesian Inference and Response Process (BIRP) and define it as a probability distribution with likelihood function:

Figure 2. Graphical model (researcher perspective)
\(\operatorname{BIRP}(R \mid t, \theta, c) \propto \begin{cases}\operatorname{Unif}(t \mid 0, R) f\left(R \mid \theta_{c}\right), & t \leq R \\ 0, & t>R\end{cases}\)
Figure 2 shows a graphical model from the perspective of the researcher that incorporates a BIRP. In this model the original stimulus \(t\) and the observer responses \(R\) are data that is known to the researcher. The form of the prior distribution used by the observer is indexed by \(c\), and the parameters for the observer's possible prior distributions are all latent (unobserved) variables for which posterior distributions will be inferred. Observer responses \(R\) are generated as samples from the BIRP:
\[
\begin{equation*}
R \sim B I R P(t, \theta, c) \tag{7}
\end{equation*}
\]

The researcher must place suitable hyper priors on the latent prior type \(c\) and latent parameters for the observer prior distributions \(\mu, \sigma, \beta\) and \(\lambda\). We define the deterministic vector \(\boldsymbol{\theta}=\langle(\mu, \sigma), \beta, \lambda\rangle\) for the purpose of notational compactness.

\section*{Experiment}

We described an integrative Bayesian approach that allows us to make inferences about people's subjective beliefs based on their responses in a prediction task. We ran an experiment in order to collect people's predictions for several of the same questions used by Griffiths and Tenenbaum (2006). We also collected predictions for the counterfactual lifespans question.

\section*{Method}

\section*{Participants}

A total of 25 undergraduates from the University of California, Irvine participated in the study and were compensated with partial course credit.

\section*{Materials}

Prediction questions were presented to participants through a web-based survey. There were 8 different question types

Figure 3. Posterior distributions of people's subjective prior types and parameter values from the researcher's perspective. For each of the eight question types the subplot for the indicator variable \(c\) shows the relative posterior probability for each of the prior types (normal, Erlang, or Pareto). The remaining subplots show the posterior distributions of the parameters for these prior types. Parameters that correspond to prior types with zero posterior probability are shown in gray.
and 5 variations of each question. Each variation corresponded to 1 of 5 possible values of \(t\).The survey instructions and 7 of the questions were identical to those used by Griffiths and Tenenbaum (2006). For the unabbreviated questions and survey instructions, refer to Griffiths and Tenenbaum (2006). Below are abbreviated examples of each of the questions with all 5 of the possible \(t\) values included: (1) Predict the age a man will live to if he is currently (18, 39, 61, 83, 96) years old; (2) Predict what the total box-office intake for a movie that has taken in (\$1, \(\$ 6, \$ 10, \$ 40, \$ 100\) ) so far; (3) Predict the length of a movie that has already been playing for (30, 60, 80, 95, 110) minutes; (4) Predict the total length of a poem from which you were just quoted line (2, 5, 12, 32, 67); (5) Predict the total time a pharaoh will be in power if he had already reigned for (1, 3, 7,11, 23) years in 4000 BC; (6) Predict the total years that a \((1,3,7,15,31)\) year member of the U.S. House serve; (7) Predict how long you will be on hold if you have already been holding on the phone for (1, 3, 7, 11, 23) minutes. There was an eighth question that was not part of the Griffiths and Tenenbaum study: Suppose it is the year 2075 and medical science has advanced significantly. You meet a man that is (18, 39, 61, 83, 96) years old. To what age will this man live?

\section*{Procedure}

Each participant made a prediction about all 5 instances of the 8 different types of phenomena for a total of 40 questions. Each prediction was based on one of the five possible values of \(t\). The questions were presented in a different random order for each participant. Only one question was presented on-screen at a time and participants entered their answer in a text-entry box before moving to the next question.

\section*{Inference and Data Analysis}

Responses from each participant were considered for exclusion on a per question-type basis. If any of a participant's five responses for one of the eight questiontypes were below the value of \(t\) that was presented in the question, then all five of that participant's responses for that question-type were excluded for analysis but their responses for other question-types were still included-as long as they passed the inclusion requirement above. The number of participants that were included in the analysis for each question-type was: 24 for life spans; 23 for box office intake; 23 for movie durations; 25 for poem lengths; 24 for pharaoh reigns; 20 for U.S. representative terms; and 25 for lifespans in the future.

We aggregated participant responses for each question such that each response provided an additional data point for Bayesian analysis. We implemented a customized Markovchain Monte Carlo (MCMC) sampler to perform Bayesian inference using the researcher model. To complete the model, we used the following priors:
\[
\begin{array}{ll}
c \sim \operatorname{Cat}\left(\frac{1}{3} \cdot \frac{1}{3}, \frac{1}{3}\right) & \mu \sim \operatorname{HalfNorm}(\text { prec }=.001) \\
\rho \sim \operatorname{Ga}(1,1000) & \sigma=\operatorname{sqrt}(1 / \rho) \\
\beta \sim \operatorname{Ga}(.1, .05) & \lambda \sim \operatorname{Ga}(.1, .05)
\end{array}
\]

\section*{Results}

Figure 3 shows a complete summary of the posterior distributions for the subjective prior types as well as the posteriors for the psychological variables that parameterized the subjective priors. We used people's predictions to infer the posterior probability that their subjective prior knowledge for each domain was best characterized by a Normal, Erlang or Pareto distribution. Although the inference allowed for uncertainty about the form of the

Figure 4. Estimated subjective priors and model predictions. The first row shows our estimates of people's subjective prior beliefs compared with the environmental distributions collected by Griffiths and Tenenbaum (2006). The bottom two rows overlay people's actual responses (black marks) with the posterior predictive distributions (gray shaded areas) of the Bayesian cognitive models for new (unobserved) responses. The posterior predictive probabilities of responses for the environmental prior model (second row) and the estimated subjective prior model (third row) are proportional to the darkness of the gray areas.
subjective prior-in which case some posterior probability would have been assigned to more than one of the possible forms-in every domain, all of the posterior mass was assigned to a single type of distribution.

The top row of Figure 4 shows the estimated subjective priors that people used to make predictions in comparison to the true environmental distributions that were collected by Griffiths and Tenenbaum (2006). The estimated subjective distributions were generated by sampling a prior type and parameter values from the posterior distributions and then using them to generate a sample.

Our estimates of people's subjective priors for life spans, movie runtimes, movie grosses, poem lengths, U.S. representatives' terms and pharaohs' reigns are remarkably similar in form to the true environmental distributions. The subjective priors for life spans, movie runtimes and pharaohs' reigns are shifted slightly to the right compared to the environmental distributions, suggesting that people's prior knowledge for these domains has the same form as the environmental statistics but may not be tuned perfectly to the environment.

People's subjective prior for waiting times was estimated in the same manner as the other priors even though the environmental data was not available. The estimated subjective prior for waiting times was consistent with an Erlang form. Griffiths \& Tenenbaum (2006) were unable to provide estimates of these posteriors using the standard qualitative analysis, but did use non-Bayesian methods to fit people's responses and found that a prediction function based on a Power-Law (Pareto) prior provided the best fit. It is not immediately clear if our disagreement about the form of the subjective prior for phone waiting times is due to differences in our methodology or to differences in the predictions of our respective participants.

A subjective prior for future life spans was estimated even though it is based on a counterfactual scenario and therefore has no true environmental distribution. This subjective prior appears to have a similar form to the prior for actual life spans, but is shifted to the right with an average life span of 105.

The bottom two rows of Figure 4 overlay people's actual responses (black marks) with posterior predictive
distributions from the Bayesian cognitive model for new (unobserved) responses using the environmental prior (second row) and the estimated subjective prior (third row).

The posterior predicitve distributions are generally similar for both the environmental prior model and the estimated prior model. There are some differences in the predictions of the models which are consistent with differences between the estimated and environmental priors. For example, the estimated prior for life spans did not capture an increased risk of death for infants and therfore the estimated model predicts less deaths at a young age than the environmental model does. This can likely be attributed to the limited range of ages (18 to 96 years) presented to participants. The estimated models for movie grosses and representatives’ terms tend to predict higher values than the environmental model, which is consitent with the tendancy of some participants to overestimate these values.

\section*{Discussion}

We demonstrated that an integrative Bayesian approachcombining Bayesian data analysis with Bayesian models of cognition-allowed us to estimate people's subjective prior knowledge based on their responses in a simple prediction task. This approach allowed us to relax the assumption that representations of people's prior knowledge in a rational model should be veridical with environmental statistics.

Although we did not require environmental data to apply an integrative Bayesian approach, having this data allowed us to compare our estimates of people's subjective beliefs to real-world environmental data. We found that people's beliefs about the phenomena in our study were similar in form to the environmental statistics, but that they showed some deviations. At least one of these deviations-related to infant mortality in the life spans question-likely resulted from the limited range of response data that the model used to estimate subjective priors. Other differences between the estimated and environmental priors seem more likely to be the result of deviations between people's subjective beliefs and the environmental statistics. For example, some people tended to overestimate the total gross of movies and the lengths of representatives' terms and pharaohs' reigns. The integrative Bayesian approach is able to provide explanations and predictions that account for these human responses in a way that traditional rational analysis cannot. Furthermore, in situations where a Bayesian model of cognition requires representations of people's prior beliefs and environmental data is unavailable or non-existent-like it was for telephone waiting times and future life spans in our study-an integrative Bayesian framework can still be used to infer subjective priors and make model predictions.

Taking an integrative Bayesian approach opens the door for researchers to take advantage of all of the methods that have been developed for Bayesian analysis of cognitive process models (Lee, 2008) and apply these methods to Bayesian cognitive models. In addition to the estimation of subjective priors and psychological parameters, this method also allows for individual differences in subjective prior
beliefs (Hemmer, et al., in prep). This is important because if people's subjective priors are not tuned to the environment for a particular domain, then it is reasonable to assume that different people have different subjective priors.

\section*{Acknowledgements}

Thank you to Michael Lee and James Pooley for helpful discussions; and to Tom Griffiths and Josh Tenenbaum for providing us with the environmental data that they collected.

\begin{abstract}
This study aims to develop a Japanese version of the remote associates test required to decompose semantic chunks for use not only in behavioral studies but also in brain researches. Further, this study attempted to reveal the relationship between the process of solving insight problems and brain activities. Results of the behavioral data show that the solution time was significantly longer in the chunked than in the non-chunked condition. The imaging data identified the following brain activities. First, the right and left cingulate gyri, related to conflict monitoring, were more activated during the process of searching for a target in the chunked than in the non-chunked condition. Second, the left posterior cingulate gyrus was more activated when the participants could find a target by overcoming constraints as semantic chunks related to emotional process.
\end{abstract}

Keywords: fMRI; insight; remote associates test; chunk decomposition.

\section*{Introduction}

Reproductive thinking is the application of previously acquired knowledge and efficiently solves typical problems. However, in insight problems, such reproductive thinking forms mental sets, preventing solution and leading problem solvers to an impasse (Dominowski \& Dallob, 1995; Ohlsson, 1992; Smith, 1995). Thus, problem solving is accomplished by overcoming such reproductive thinking. Problem solvers often have an "aha!" experience when solving insight problems (Davidson, 1995; Metcalfe, 1986a,b; Metcalfe \& Wiebe, 1987). Such characteristics of insight process, including an impasse and sudden attainment with the emotional experience, have been studied through psychological experiments. Moreover, in recent years, many studies revealed the mechanisms between characteristic insight processes and brain functions (Dietrich \& Kanso, 2010).

Insight problems generally used for related researches (e.g., nine dots problem, candle problem, triangle of coins) require at least several minutes to solve them. Further, once they are solved, they cannot be reused as problem solving tasks among the same participants. In contrast, when employing brain imaging studies, verbal problems including anagram tasks, riddles, and the remote associates test (RAT) have been used. This is owing to the fact that these studies require not only the use of problems that can be solved within several tens of seconds but also can be used repeatedly for the same participants. However, almost all tasks used in brain imaging
studies are premised on using English speaking participants. Therefore, insight tasks based on a wide variety of languages are required to promote the development of research in this field.

Thus, our research purpose is to develop a Japanese version of the RAT for use in brain research using examples from the standard RAT task widely used in current neuroscience studies. In addition to developing the task, we tried to reveal the relationship between brain activities and the process of insight problem solving, including both processes of an impasse and evoking an emotional experience when solutions are found.

\section*{Japanese RAT Required to Decompose Semantic Chunks}

Insight problem solving characterized by an impasse and the suddenness of solution with emotional experience represents a radical representation change. Problem solvers have to reconstruct their erroneous mental representations constructed at an early stage of insight problem solving, whereas they can take step-by-step analytic approaches in non-insight problems. Such representation change in the insight process has been interpreted based on the theories such as the transition of problem spaces and the chunk decomposition by conducting psychological experiments (Kaplan \& Simon, 1990; Knoblich et al., 1999; Ohlsson, 1992). Familiarity with a class of objects and events leads to the creation of patterns as chunks that capture recurring constellations of features or components. Preserving the mental efforts by using chunked knowledge contributes to efficient problem solving. However, if the available chunk does not work in a way that is helpful vis-à-vis finding a solution, it might work to prevent solving the problem. Moreover, once it is constructed, it is difficult to decimate and an impasse might result (Knoblich et al., 1999; Ohlsson, 1992).

RAT consists of sets of three words drawn from a mutually remote associate cluster. Problem solvers are required to find a fourth word which could serve as a specific kind of associative connective link between these disparate words (Mednick, 1962). One example might be a set of three problem words: "arm," "coal," "peach." The answer to the example is the word "pit." The answer word generate three words or
phrases，＂armpit，＂＂coalpit，＂and＂peach pit，＂being connected with each problem word．However，constraints have not been controlled in the RAT used in cognitive neuroscience research （e．g．，Bowden \＆Jung－Beeman，2003）．Thus，in previous studies using RAT－like problems，the definition of obtaining insight was based on finding a solution，solution time，and／or self－reported sudden，unforeseen flash of illumination．Alter－ natively，this study developed a Japanese RAT with control－ lable constraints based on chunk decomposition．The exis－ tence of chunks，which prevents finding association between problem words，would lead problem solvers to search for a target within incorrect problem spaces and arrive at an im－ passe．They might also get an＂aha！＂experience when an impasse based on chunks is resolved，and subsequently the problems are solved．

\section*{Hypotheses}

As demonstrated in previous neuroscience studies，conflicts attributed to constraints preventing problem solving were as－ sociated with activity in the anterior cingulate cortex（ACC） （Aziz－Zadeh et al．，2009；Kounios \＆Jung－Beeman，2009； Luo et al．，2004；Qiu et al．，2008）．Moreover，in the pro－ cess of insight problem solving，a solution seems to arise suddenly，accompanied by an emotional experience generally known as an＂aha！＂experience（Csikszentmihalyi \＆Sawyer， 1995；Davidson，1995；Metcalfe，1986a，b；Metcalfe \＆Wiebe， 1987）．It is known that such emotional experiences in insight problem solving are associated with activity in the posterior cingulated cortex（PCC）（Qiu et al．，2008）．

In this study，which involves the use of an fMRI while con－ ducting psychological experiments，we propose the following two hypotheses regarding brain activities both when strug－ gling with an insight problem and then solving it．

Hypothesis 1 When problem solvers fail to find a solution， the existence of chunks are associated with activity in the ACC because in preventing solutions conflicts arise．

Hypothesis 2 When problem solvers find a solution，the so－ lutions are associated with activity in the PCC related to emotional experience，in addition to activation in the ACC．

\section*{Task}

Figure 1 illustrates the structure of a Japanese RAT that re－ quires decomposition of semantic chunk．Stimuli of the task are presented on a computer screen containing six kanji char－ acters．The purpose of the task was to find a common kanji character（target）with which each of the three kanji charac－ ters presented on the upper row（problem characters）could form a meaningful word．However，distracters presented be－ low the problem characters prevent the finding of the target because the distracters could form meaningful words with each of the problem characters．Therefore，participants are re－ quired to decompose the semantic chunks between the prob－ lem characters and distracters to find the target through re－ mote association．Moreover，the task can control the exis－ tence of the semantic chunks between problem characters and

Distaceas \(\rightarrow\) 郷 癖 盤

distracters by changing distracters that cannot be connected with the problem words．The kanji characters used in this experiment were known to the participants，who were native Japanese speakers．

\section*{Neuroactivity}

\section*{Methods}

Participants Eighteen healthy，right－handed undergraduate students（aged 19 to 36 years）participated in this experi－ ment．The participants were native Japanese speakers and their handedness was assessed by a modified Oldfield ques－ tionnaire（Oldfield，2004）．The participants provided written informed consent in accordance with the research ethics com－ mittee guidelines of Nagoya University＇s Research Institute of Environmental Medicine．

Design Participants were given a practice session using two examples outside of the MRI scanner．Following the practice session，they engaged in 60 problems while in the scanner． The problems consisted of 30 chunked and 30 non－chunked problems．The chunked and non－chunked problems were counter－balanced between participants（the chunked prob－ lems presented to the half of the participants were treated as non－chunked problem for the other half，and vice versa）．The sequences of problems were also randomized throughout the experimental session．
Figure 2 illustrates the experimental sequence．Each prob－ lem was presented for 30 seconds to the participants．The resting interval between trials was 12 seconds．They were required to press the left button assigned to the index finger of their right hand when finding a target immediately．After pressing the left button，the target，the answer to the problem was presented．Participants were required to press the left button when their answer corresponded to the target，whereas they were required to press the right button assigned to their middle finger when their answers were incorrect．Taking a 10 minute break outside of the scanner，this sequence was re－ peated 60 times．The experiment consisted of two fMRI runs．

Imaging Data Acquisition All scanning whole－brain im－ ages were acquired by using a gradient echo planar image acquisition on a 3T MRI Scanner（Siemens Verio，Siemens Healthcare，Erlangen，Germany）．The functional imaging pa－

Figure 2: Experimental sequence
rameters were \(\mathrm{TR}=2.5 \mathrm{~s}, \mathrm{TE}=30 \mathrm{~ms}, \mathrm{FA}=70^{\circ}, \mathrm{VoF}=20 \mathrm{~cm}\)
20 cm , and 39 slices. To avoid head movement, the participants wore a neck brace and were asked not to talk or move during MRI scanning. High-resolution anatomical images (T1) were also acquired by using gradient echo planar image acquisition. We acquired T 1 images \((\mathrm{TR}=2.5 \mathrm{~s}, \mathrm{TE}=\) \(2.48 \mathrm{~ms}, \mathrm{FA}=8^{\circ}\) ) with 192 sagittal slices, each being 1 mm in thickness. Motion correction was also performed in a standard realign process in SPM8.

Imaging Data Analysis The image data were analyzed using SPM8. Each participants's imaging data was individually preprocessed (realignment, slice time adjustment, coregistration, normalization, smoothing) and the spatially preprocessed data was then estimated to establish a random effects model. Statistical threshold was set at \(p<.001\), uncorrelated with an extended threshold of 10 contiguous voxels.

\section*{Results}

Behavioral Results Results of the solution rates within both 15 and 30 seconds, as shown in Figure 3 (the error bars indicate the standard error). A \(t\)-test showed a significant difference between the two conditions within 15 seconds \((t(17)=2.95, \quad p<.01)\), whereas within 30 seconds no sig-

Figure 3: Solution rate within both 15 and 30 seconds

Figure 4: Solution time within both 15 and 30 seconds
nificant difference was observed \((t(17)=1.90\), n.s. \()\).
Next, we compared the average solution time when the participants could find a target between two conditions (Figure 4). The \(t\)-tests within both 15 and 30 seconds showed significant differences between the two conditions ( 15 sec : \(t(17)=3.67, p<.01 ; 30 \mathrm{sec}: t(17)=3.39, p<.01)\).

These results demonstrate that the search for the targets was prevented more in the chunked than in the non-chunked condition owing to the existence of the semantic chunks.

Imaging Results Next, we compared the brain activations in both the chunked and non-chunked conditions. In the following analyses, we focused on two different trials: participants failed to find a target (failed trials) and participants could find a target (correct trials). In the correct trials, imaging data were analyzed for the entire 30 seconds while the

\end{tabular}
stimuli were presented. In the failed trials, imaging data were analyzed until finding a target.

\section*{Chunked \(>\) Non-chunked (failed trials)}

In the failed trials, this contrast examined the brain areas that were more activated during searching for a target in the chunked condition when compared with those in the nonchunked condition. Several peaks of activation were found, including the right and left cingulate gyri (right BA 24, left BA 24, left BA 32), the left medial frontal gyrus (left BA 32, left BA 11, left BA 6), and the left paracentral lobule (left BA 31) (Table 1). Figure 5 depicts these areas of activation.

\section*{Chunked \(>\) Non-chunked (correct trials)}

In the correct trials, this contrast examined the brain areas that were more activated until a target was found in the chunked condition when compared with those in the non-chunked condition. It was confirmed that the left posterior cingulate (left BA 30) was activated (Table 2). Figure 6 depicts this area of activation.

\section*{Non-chunked \(>\) Chunked (failed trials)}

This contrast revealed no voxels that were significantly more active in the non-chunked than in the chunked condition when the participants could not find targets.

\section*{Non-chunked \(>\) Chunked (correct trials)}

Same as when the participants could not find a target, this contrast revealed no voxels that were significantly more activated in the non-chunked than in the chunked condition when participants found a target.

Figure 5: Brain areas that were more activated during searching for a target in the chunked condition when compared with those in the non-chunked condition in the failed trials

Figure 6: Brain area that was more activated until a target was found in the chunked condition when compared with that in the non-chunked condition in the correct trials

\section*{Discussion}

Results of the behavioral data show that the solution time was significantly longer in the chunked than in the non-chunked condition. Knoblich et al. (1999) constructed an insight task with chunks having different tightness, and displayed that the
problem solving performance while solving problems with a tight chunk declined from those with a loose chunk. Our behavioral results suggest that the semantic chunks, introduced by the Japanese RAT, prevent finding solutions, which is consistent with the related work.

In the following, we will discuss in detail more activated brain areas in the chunked than in the non-chunked condition, both when the participants could find a target and when they could not.
Failed Trials The right and left cingulate gyri (right BA 24 , left BA 24, left BA 32) were more activated during the process of searching for a target in the chunked than in the non-chunked condition. The cingulate gyrus has been widely believed to be related to insight problem solving (Aziz-Zadeh et al., 2009; Kounios \& Jung-Beeman, 2009; Luo et al., 2004; Qiu et al., 2008). For example, Aziz-Zadeh et al. (2009) reported that the ACC is more activated in insight solutions when compared with the search solution while solving anagram tasks. Luo et al. (2004) also showed that relative to the non-"aha" event, the "aha" event was associated with activities in ACC. Botvinick et al. (1999) revealed that the ACC might also be linked with conflict monitoring.

Previous results indicated that the ACC is related to preliminary process to evade impasse in which problem solvers get fixated with incorrect problem spaces as conflict monitoring (Dietrich \& Kanso, 2010). The activation on the cingulate gyrus in our research appears to monitor the process among the competing, an option aroused by semantic chunks and alternatives. This result supposes hypothesis 1 .
Correct trials In addition, when the participants could find a target, the left posterior cingulate gyrus (left BA 30) was more activated until they found a target in the chunked than in the non-chunked condition. Some researches indicated that the retrosplenial cortex, in particular BA 30 and the neighboring posterior cingulate cortex including BA 23 and BA 31 might be associated with the cognitive processing of emotions (Cato et al., 2004; Maddock, 1999; Maddock \& Buonocore, 1997). For example, Cato et al. (2004) showed that activation uniquely associated with word generation to categories with positive or negative versus neutral emotional connotation occurred in the retrosplenial cortex.

One of the essential characteristics of insight problem solving is an impressive and surprising emotional experience upon sudden and discontinuous solution. For example, Csikszentmihalyi \& Sawyer (1995) conducted detailed interviews with creative individuals who have made a creative contribution to the natural sciences, social sciences, arts and humanities, or business/politics, and were generally older than 60 years. The interviewees reported their exciting experiences when receiving insight. Such emotional experience in insight problem solving is known as the "aha!" experience (Davidson, 1995; Metcalfe, 1986a,b; Metcalfe \& Wiebe, 1987). (Qiu et al., 2008) also discussed in their ERP study that the "aha!" feeling might increasingly activate the PCC when Chinese lo-
gogriphs were completed than when they were not solved. In our experiment, the activation of the left posterior cingulate (left BA 30) when the participants found a target suggests that when finding a target, overcoming constraints correlates more with emotional process than without such a constraint.

However, the activation of the cingulate cortex when the participants could not find a target was not confirmed when they could. This result was likely to be caused by the semantic chunks as constraints preventing to solve problems might be decomposed in the early stage of the insight problem solving process when they found a target. Therefore, the activation of the cingulate cortex was not confirmed. These results are partially supported by our hypothesis 2 .

\section*{Conclusion}

This study aims to develop a Japanese version of the RAT required to decompose semantic chunks for use not only in behavioral studies but also in brain researches. Moreover, we tried to reveal the relationship between the brain activity and both process of an impasse and evoking an emotional experience when solutions are found.

Results of the behavioral analysis showed that the Japanese RAT constructed in our research worked well as expected. The imaging data identified the following brain activities. First, the right and left cingulate gyri related to conflict monitoring were increasingly activated during the process of searching for a target in the chunked than in the non-chunked condition. Second, the left posterior cingulate gyrus was more activated when the participants could find a target by overcoming constraints as semantic chunks related to emotional process. These are important initial steps to be taken in the study of the relationship between insight problem solving process and brain activities using the Japanese version of the RAT.

\section*{Acknowledgments}

This study received generous support from the Brain and Mind Research Center, Nagoya University to conduct the experiment using a MR scanner.

\begin{abstract}
The use of a particular attentional paradigm, the paradigm of Sidedness (Ottoboni, Tessari, Cubelli \& Umiltà, 2005) has highlighted as professional volleyball players differ from nonplayers in the ability to encode specific spatial indexes. The presentation of images of hands of potential adversaries incorporates meanings related to sport that make volleyball athletes sensitive to directional spatial characteristics previously unobserved. What appears to be crucial in the generation of such effect is the ability to predict the direction of an action.
\end{abstract}

Keywords: action prediction, action directionality, body, Sidedness, expertise, sport.

\section*{Introduction}

The ability to anticipate events and actions is essential to interact with the environment in a profitable way. For example, anticipating the movement of the opponent is required to prepare the most appropriate response to counter it during many sport actions. Some behavioral studies have revealed significant differences between athletes and nonexperts, in terms of processing capabilities for both visuolperceptual and motor skills. In ball games, for example, experienced athletes are able to anticipate "where" and "when" the ball will be thrown by the ability to extract the essential information expressed by the movements of the opponent before the ball begins its trajectory (Williams \& Grant, 1999; Aglioti, Cesari, Romani \& Urgesi, 2008). It was also shown that expert athletes are better than nonexperts or non-athletes in recognition and storage of complex patterns of actions (Abernethy, 1990; Allard et al., 1980; Starkes \& Allard, 1983; Starkes, 1987). This increased ability seems to be based on reading the observed gesture's kinematics: experienced athletes are able to anticipate perceptual strategies because they have a wider and consolidated visuo-motor repertoire (Savelsbergh et al., 2002; Williams et al., 2002) acting as the basis for their
visual perception, as well as for the resulting motor execution. These skills seem to be supported also by differences in the activation of premotor and parietal cortical areas (Calvo-Merino, Glaser, Grezes, Passingham \& Haggard, 2005; Calvo-Merino, Ehrenberg, Leung \& Haggard, 2010) and processes of mental simulation involving the activation of the motor areas (e.g. the shot at the basket in basketball players; Aglioti, Cesari, Romani \& Urgesi, 2008).

In general, expert athletes do not possess different structural cognitive characteristics from those of non-experts: they are only more skilled in selecting the most effective signal for detecting a change in the position of the opponents among those available (e.g. the trajectory of the ball or an attack action). For example, it has been found that volleyball players orient attention along the horizontal and vertical axes in significantly different manners (Rizzolatti, Riggio, Dascola \& Umiltà, 1987). In the present study we investigated whether professional volleyball players were able to extract relevant information from the vision of individual parts of the body. In particular, we tried to isolate what directional indices athletes were able to process automatically in response to the presentation of hands that imply motion. We wanted to investigate if volleyball players were able to process the intention to act transmitted by the posture of the presented hands, given that it is an essential information for the game (for example to predict the direction of a possible spike action). Such processing capabilities allow athletes to predict the actions of opponents and to anticipate the motor behavior in order to oppose them. The hypothesis is based on results from studies on the perception of photographs of the body or body-parts giving the impression of movement (eg. Kourtzi \& Kanwisher, 2000; Urgesi, Moro, Candidi, \& Aglioti, 2006) . This processing ability would anticipate what the final position is based on information we already have about "already seen and experienced" movements (Freyd, 1983).

Therefore, the posture of opponent's hand might allow volleyball athletes to predict the direction of the ball.

In the present work we used the paradigm of Sidedness, commonly used to define precisely the spatial coding based on the side of the body which the hand or foot is "connected to" (Ottoboni et al., 2005; Tessari et al., 2012a). For example, a left hand presented from the palm view with the fingers oriented upward activates a right spatial code because it is perceived and represented as the right hand of a human body facing the observer. The same hand, but seen from the back (Figure 1A left panel), actives instead a left spatial code because it is represented to the left of a body that turns its back to the observer (Figure 1B right panel).

Figure 1: Figure 1A illustrates the concept of Sidedness, that is, the mode in which each hand is spatially coded in relation to a body as a function of the posture. Figure 1B shows the stimuli used in Experiment 1 and Figure 1C those of Experiment 2.

\section*{Experiment 1}

Using photographs of oriented hands, we aimed at testing if volleyball players were able to process information on a potential attack action by encoding the direction imprinted
to the ball. As anticipated, we suggested that every hand presentation generates different spatial codes: one linked to the Sidedness and one related to the direction of the action. For example, a right palm hand, since it appears to act from left to right (i.e. the ball would be crushed to the right), should direct the attention of the observer to the right, thus the spatial code of Sidedness would be the opposite one, activating a left Sidedness code, in turn. In this way, if players were able to process both codes, we could observe a mutual cancellation. However, our prediction takes into account also the posture of the hand (i.e. palm vs. back). Back hands, that are not salient in the context of the game, are not expected to induce processing of action direction, but only an encoding of Sidedness. On the contrary, the palm hands are assumed to be coded according to both Sidedness and direction, with a consequent annulment of the two opposite spatial codes.

\section*{Method}

Participants Sixteen right-handed volleyball players belonging to elite teams were tested (mean age= 22 years).
Apparatus and procedures The stimuli were photographs of right and left hands in back and palm views with the forearm ( \(23^{\circ} \mathrm{X} 9^{\circ}\) visible angle), rotated of \(30^{\circ}\) along their ulnar axis as in Tessari et al. (2010a; 2012b). See Figure 1b. A red or blue circle was superimposed in the middle of the hand. The experiment was run using a Pentium III, 512 Mb , connected to a 15 " screen. The experiment was controlled by E-Prime 1.1 (SP3) software (Psychology Software Tools Inc.). The stimuli were 120 for both the back and palm conditions and lasted on the screen for 100 ms , each. The next stimulus appeared after participant's response and no longer than 1000 ms after. Participants were required to respond according to the colour of the circle by pressing one of two keyboard keys ("X" and "."), respectively on the left and the right side. Feedbacks about reaction times (RT), errors and omissions were given after each response (it lasts for 1500 ms ). The response conditions were counterbalanced between subjects.
Results Participants whose error threshold was above \(10 \%\) and RTS 2 standard deviations higher or lower than the overall participants' mean for corresponding and noncorresponding pairings in each block were excluded from the analyses. Data were submitted to a \(2 \times 2\) ANOVA for repeated measures with View (Back vs. Palm) and Correspondence (Corresponding pairings vs. Noncorresponding pairings between hand laterality and response hand) as the within-subjects factors. The two factors (View: \(\mathrm{F}(1,16)=60.03, \quad \mathrm{p}<.001, \quad\) and \(\quad\) Correspondence: \(\mathrm{F}(1,16)=42.65, \quad \mathrm{p}<.001) \quad\) and their interaction \((\mathrm{F}(1,16)=33.48, \mathrm{p}<.001)\) were significant. RTs for the palm hands were faster than those for back hands ( \(\mathrm{M}=312 \mathrm{~ms}\), \(\mathrm{SE}=4.22\) vs. \(\mathrm{M}=340 \mathrm{~ms}, \mathrm{SE}=6.07\) ), and corresponding pairings were responded faster than the non-corresponding ones ( \(\mathrm{M}=318 \mathrm{~ms}\), \(\mathrm{SE}=4.61 \mathrm{~ms}\) vs. \(\mathrm{M}=333 \mathrm{~ms}\), \(\mathrm{SE}=6.51\) ). When stimuli were presented from the back view, RTs were faster for corresponding ( \(\mathrm{M}=325, \mathrm{SE}=6.40\) ) than for non-
corresponding pairings ( \(\mathrm{M}=355, \mathrm{SE}=9.01\) ): two-tailed \(\mathrm{t}(15)=-8.34, \mathrm{p}<.001\). For the palm view no difference emerged \((\mathrm{t}(15)=0.04, \mathrm{p}>.05\); non-corresponding pairings \(\mathrm{M}=312\), \(\mathrm{SE}=5.69\), and corresponding pairings \(\mathrm{M}=312\), SE=6.43). See figure 2a.

Figure 2: The graph shows the values of the reaction times in Experiment 1 (upper part) and Experiment 2 (lower part).

\section*{Discussion}

Compared to a previous study on non-athletes, where an Sidedness effect emerged for both back and palm hands (Tessari et al. 2010a; Tessari et al., 2012b), the effect emerged only for the back hands in volleyball players. As hypothesized, the palm hands were more informative and relevant as confirmed by the significant effect of Posture (faster responses to the palm), but also by the absence of effect for the palm hands which seem to have been encoded for both Sidedness and the direction of the potential action. This way, the spatial codes were opposites and Summing themselves resulted in a null effect. To confirm this interpretation we conducted a second experiment where we tried to rule out the Sidedness effect by hiding the forearm in the stimuli.

\section*{Experiment 2}

It is known that a hand or a foot can be referred to an appropriate body of reference only in the presence of physiological link such as the forearm or the ankle, that comply with the biomechanics laws of the human body (Ottoboni et al., 2005; Tessari et al., 2010b). In the absence of such links the Sidedness effect does not emerge. Following this logic, we presented the same hands of Experiment 1 without forearm to clarify whether the null effect obtained with palm hands was given by the sum of two opposite spatial codes (that generated by action direction and the one of Sidedness). In this condition the Sidedness effect should be deleted while the direction effect should remain.
Participants Eight right-handed volleyball players belonging to new elite team were tested (mean age \(=25\) years).
Apparatus and procedures Apparatus and procedure were those of Experiment 1 but hands were presented without the forearm (see Figure 1c).
Results The two factors (View: F (1,7)=0.06, p > .5, and Correspondence: \(\mathrm{F}(1,7)=0.11, \mathrm{p}>.5)\) were not significant but their interaction was ( \(\mathrm{F}(1,7\) ) \(=13.04, \mathrm{p}<0.01\) ). When stimuli were presented from the back view, RTs did not differ for corresponding ( \(\mathrm{M}=309 \mathrm{~ms}\) ) and noncorresponding pairings \((\mathrm{M}=305 \mathrm{~ms}): \mathrm{t}(7)=1.24, \mathrm{p}=.25\). For the palm view corresponding pairings were in trend faster than the non-corresponding ones ( \(\mathrm{M}=304 \mathrm{~ms}\) vs. \(\mathrm{M}=311 \mathrm{~ms}): \mathrm{t}(7)=-1.55, \mathrm{p}=.08\). See Figure 2.

\section*{Discussion}

Using as stimuli photographs of hands without forearm we got a pure effect of compatibility based on the direction of the attack action for the palm hands. For example, a right palm hand that directs attack action to the right induced a faster response with the right hand. Any effect emerged for the back hands without the forearm neither for Sidedness (as in non-athletes; Ottoboni et al., 2005) nor for direction. Therefore it seems that professional volleyball players are able to encode the palm hands as hands potentially performing a directed action while the back hands does not allow (even to experienced athletes) to extract any relevant information for the game.

\section*{Conclusion}

The purpose of this research was to investigate the type of information that the high-level volleyball players extrapolate at the presentation of hands. These athletes were chosen because the volleyball game requires an excellent visual analysis of the spatial information transmitted from the hands of the opponents: they must be able to recognize in the shortest time potential attack actions, so as to implement the best response behavior. We hypothesized that hands slightly rotated were coded as hands in the process of acting and that they would have activated at least two spatial codes: one generated by the Sidedness (the spatial code
referred to a body) and the other conveyed by the direction of a potential spike action. Hands presented by palm and with the forearm allowed a complete activation of the opposite spatial codes (e.g. a right palm hand was coded as on the left of a body following the Sidedness, but the attack action drove attention to the right). However, back hands have only activated a spatial code based on Sidedness. To ensure that what was encoded was the direction of the potential attack action, we decided to rule out the Sidedness effect by presenting the same hands without the forearm. Indeed, the forearm is necessary to link the hand to a reference body and to generate the Sidedness effect (Ottoboni et al., 2005). In this condition, we only found an effect of directionality for the palm hands. Considering the results that emerge from studies of athletes (eg Kourtessis, Michalapoulou and Derrida, 1998; Nicoletti and Borghi, 2007, for a review) it seems that the athletics tasks requiring motor anticipation and quick response are highly dependent on the level of expertise. The extensive motor experience seems to develop a resonance system specific for the actions of a specific sport discipline, which allows to enhance both the predictive and the anticipatory abilities on the basis of a shared representation between the perceived actions and the actions performed in the sensorimotor repertoire (Aglioti et al., 2008). We can therefore assume that also the highly experienced volleyball players are able not only to effectively process bodily indexes but also the direction of a potential expressed action in contrast with non-athletes that are mainly focused on the normal relations between hand and body (Tessari et al. 2010a). It will be interesting to determine whether the described behavior was developed by the athletes during their career or if, alternatively, this capacity is a precondition that led the professional volleyball players to success.

\begin{abstract}
Research in relational learning suggests that simple training instances may lead to better generalization than complex training instances. We examined whether this "simple advantage" extends to category learning in adults with simplified and traditional (more complex) Chinese writing scripts. In Experiment 1, participants learned Chinese characters and their English translations, performed a memorization test, and were asked to generalize their learning to the corresponding characters written in the other script. In Experiment 2, we removed the training phase and modified the tests to examine transfer based purely on perceptual similarities between simplified and traditional characters. We found the simple advantage in both experiments. Training with simplified characters produced better generalization than training with traditional characters, both when generalization relied on recognition memory and on pure perceptual similarities. This finding advances our understanding of how features of a learning opportunity interact with domain-general learning mechanisms to prepare the mind for transfer.
\end{abstract}

Keywords: categorization; generalization; transfer; memory; learning; similarity; features

\section*{Introduction}

We can remember all kinds of details about our experiences in the world but our visual systems have the capacity to ignore all kinds of details as well. Categorization relies on dual processes: attending to similarities while simultaneously ignoring differences. Efficient generalization minimizes the necessary experience with learning instances (e.g., number of learning instances needed or time spent learning) and maximizes appropriate generalization.

Simple instances have been shown to engender rapid learning with selective attention to the right information for the task. Novices briefly trained with simple line drawings of diagnostic features were able to classify chicks with the accuracy of expert chicken sexers (Biederman \& Shiffrar, 1987). Young children who were taught category labels with simple objects were more successful at generalizing to novel category members than when they were shown more complex learning objects (Son, Smith, \& Goldstone, 2008). We refer to this asymmetry of transfer from simple versus complex training instances as the simple advantage.

Most of the research demonstrating the simple advantage have examined learning and transfer of relational concepts in mathematics (Kaminski, Sloutsky, \& Heckler, 2008;

Sloutsky, Kaminski, \& Heckler, 2005; McNeil, Uttal, Jarvin, \& Sternberg, 2009) and science (Goldstone \& Sakamoto, 2003; Goldstone \& Son, 2005). In these relational domains, in order to generalize learning to a new situation, one must pay more attention to structural information rather than superficial details that may differ across instances. Simple learning instances can facilitate such structural extraction by limiting the extraneous details and guiding attention to the right features.

Little is known, however, about whether this simple advantage can also support category generalization, particularly in adults. Although young children are better able to generalize category labels by learning from simplified exemplars (Son, Smith, \& Goldstone, 2008), one might argue that simple learning instances do not benefit adults who are already experts in category learning (relative to infants).

The other side of the argument suggests that the mechanisms underlying infant and adult categorization might not differ significantly (Gureckis \& Love, 2004). For example, research has shown that categorization behavior in infants and adults agree on the basic level (Horton \& Markman, 1980), that infants tend to extract the same prototypes and make the same kind of inferences from category knowledge that adults do (Mervis \& Crisafi, 1980; Baldwin, Markman, \& Melartin, 1993). One exciting possibility is that infants and adults have the same basic categorization generalization "hardware" and only differ in their level of knowledge of the domain. This has been argued for in the analogy literature (e.g., Kotovsky \& Gentner, 1996). To explore this possibility, we train and test English-speaking adults in a novel domain that contains complex and simple corresponding forms: Chinese character scripts.

For a number of political and historical reasons, the traditional Chinese writing system was simplified in 1949. The simplified characters have approximately \(22.5 \%\) fewer strokes than the more complex traditional script (Gao \& Kao, 2002). Several different simplification processes were employed; some based on Chinese history and meaning while others were straightforward perceptual simplifications. As a result, many characters and their components (recurring groups of strokes that make up the characters) took on quite different look (Harbaugh, 2003). Whether these differences between scripts affect the
learnability of characters is the subject of ongoing debate amongst researchers who study Chinese language acquisition (see Chen \& Yuen, 1991; McBride-Chang et al., 2005; Seybolt \& Chiang, 1979). However, there has been little research to examine these differences partially due to complicated issues of aesthetics, history, politics, and tradition. This endeavor, primarily motivated by issues in cognition and learning, may shed light on this debate.

For the purpose of examining the simple advantage in categorization, these rich sets of naturally occurring simple and complex corresponding entities provides an ideally suited domain. As non-Chinese readers lack prior associations with these stimuli, differences in generalization between the scripts may be attributable to differences in the stimuli.

\section*{Purpose of Current Work}

Two studies examined the simple advantage in adults' category generalization with simplified and complex Chinese characters. Does learning with simplified instances lead to greater category generalization than training with complex forms? Secondly, does this simple advantage occur even with minimal prior exposure to simplified forms?

\section*{Experiment 1}

Participants were asked to study flashcards with a Chinese character on one side and an English definition on the other side. After each set, memorization was measured with a match-to-sample task in which students were briefly shown the English definition and had to pick out the matching character out of four answer choices. After the memory test, generalization was measured by the same matching task, except that participants had to match the definitions with characters of the unlearned script. In the Traditional-first condition, participants studied Traditional characters and their English definitions. The Traditional-first memory test involved Traditional characters while the generalization test replaced those choices with corresponding Simplified characters. In the Simple-first condition, participants studied and had a memory test with Simplified characters, but their generalization test had Traditional versions of the learned characters. If simplified learning instances promote generalization, then participants would show better generalization in the Simple-first than in the Traditional-first condition.

\section*{Method}

Participants and Design 14 undergraduates ( 7 females and 7 males) participated for course credit. All reported to having no prior experience with Chinese characters. In this within-subject experiment, half of the participants experienced the Traditional-first condition (learning, memory test, generalization test) before the Simple-first condition while the other half experienced the two conditions in the reverse order.

Materials and Procedures Although there are historical or semantic reasons behind some types of simplification, the subset of characters chosen for this study are perceptually simplified forms of their traditional counterparts. In each pair of characters, up to two components (stroke groups called radicals) of the Traditional characters were omitted to produce their simplified version. Thus, Simplified characters had fewer strokes as well as fewer components. The Simplified characters used had 3-13 strokes per character (average 7.23 strokes), and their Traditional version had \(8-22\) strokes per character (average 14.06 strokes). There were 4 sets of 12 unique character pairs but each participant only studied two of these sets in either the Simplified or Traditional script. The number of omitted strokes, the number of omitted components, the location of the omitted components within each character, and the usage frequency were balanced across the character sets.
In the training phase, each participant received a randomly assigned set of 12 flashcards of either Traditional or Simplified characters according to their assigned condition. Each character was printed in black 36 pt SimSun (宋体) font and the English words were printed in black with 24 pt Calibri font. Participants were told to study the Chinese-English pairs, and that they would be tested on them later. They were not given a time limit for studying and most finished within 15 minutes.

Once participants handed in the flashcards, they were administered the memory and generalization tests on a computer using E-Prime 2.0 (Psychology Software Tools, Inc., Sharpsburg, PA, USA). For both tests, there were 12 trials, one for each of the 12 characters in the training set. A trial began with a fixation cross lasting for 0.5 seconds, followed by an English word for 2 seconds, then 4 Chinese characters. The distractor characters were randomly chosen from the set of trained characters. The inter-trial interval was 1 second. The order of the trials was random across participants. No feedback was provided after each trial, but average accuracy and response time were given at the end of each task. Figure 1 shows a sample trial and procedure.

Figure 1: (a) Exact match test procedure and (b) Generalization test procedure of the Simple-first condition in Experiment 1.

In the memory test, participants chose from Chinese characters identical to those in their training set. The generalization task was set up identically to the
memorization task, except that the answer choices in this task were characters written in the unlearned script. Before the generalization trials, these instructions appeared, "There are two types of scripts in the Chinese written language, Traditional and Simplified. You have just studied characters written in one of these two scripts, and now we would like to see how well you can recognize the same characters written in the other script."

Participants were given a 5-minute break before they were given another set of 12 flashcards with characters written in the other script. The entire procedure was repeated for the second set of characters.

\section*{Results and Discussion}

Proportion correct and average response time data for correct responses are presented in Figures 2 and 3 (see left panels).

Preliminary analyses There were no significant differences among the four sets of characters ( \(p s>.10\) ) and no effect of condition order ( \(p s>.10\) ), so accuracies and response times for each condition were collapsed across those variables.

Memorization and Transfer Results We conducted two 2 x 2 (condition x test type) repeated-measures analysis of variance (ANOVA) for accuracy and reaction time.

Accuracy. There was a main effect of test. Performance on memory test \((M=.99, S D=.03)\) was better than generalization \((M=.86, S D=.10), F(1,12)=26.89, p<\) \(0.001, \eta^{2}=.69\). There was a main effect of condition, \(F(1,12)=8.98, p<.05, \eta^{2}=.43\), and a significant interaction, \(F(1,12)=9.04, p<.05, \eta^{2}=.43\). Post-hoc \(t\)-tests confirmed that although the two conditions exhibited similar memory performance, the Simple-first condition generalized more accurately than the Traditional-first condition. Participants in both Traditional-first ( \(M=.99, S D=.03\) ) and Simple-first ( \(M=.98, S D=.04\) ) conditions successfully learned the word pairs and recognized them equally well, \(t(12)=1.00, p=.34\). Generalization accuracy was significantly higher in the Simple-first condition ( \(M=.91\), \(S D=.06\) ) than in the Traditional-first condition ( \(M=.80\), \(S D=.14), t(12)=3.045, p<.025\), with Bonferroni correction. As predicted, participants who initially learned Simplified characters generalized their learning to the transfer script better than those who learned Traditional characters.

Response Times for Correct Trials (given in seconds per trial). Participants were faster on the memorization trials ( \(M\) \(=2.71, S D=.92)\) than generalization \((M=5.54, S D=2.15)\), \(F(1,12)=46.25, p=.00, \eta^{2}=.79\). Those in the Simple-first condition \((M=3.87, S D=1.40)\) were generally faster than those in Traditional-first condition ( \(M=4.38, S D=1.67\) ), \(F(1,12)=5.24, p<.05, \eta^{2}=.30\). Thus, when participants were trained with Simplified script, they tended to make

Figure 2: Accuracy data from the memorization and generalization tests in Experiment 1 (left panel) and from the exact match and generalization tests in Experiment 2 (right panel). (Error bars: \(\pm 1\) SE)

Figure 3: Response time data of accurate responses from the memorization and generalization tests in Experiment 1 (left panel) and from the exact match and generalization tests in Experiment 2 (right panel). ((Error bars: \(\pm 1\) SE)
more correct matches on both tests and did so faster than those who were trained with Traditional script. There was no significant interaction between condition and test type, \(F(1,12)=1.69, p=.22\).

In summary, when trained with Simplified characters, participants were both faster and more accurate than when trained with Traditional characters. More importantly, even though Simplified and Traditional characters were remembered equally well, Simplified training exemplars led to better generalization than Traditional ones. However, the simple advantage may be dependent on the amount of exposure to the learning instance. In Experiment 2, we ask whether training with Simplified characters is more efficient than training with Traditional characters even without extended training experience.

\section*{Experiment 2}

To extend the findings of Experiment 1, we removed the training phase and modified the memorization and generalization tests to examine matches based purely on perceptual similarity. If simplicity promotes transfer by containing only the relevant perceptual features, then the simple advantage should persist even when generalization relies only on perceptual similarities between simplified and traditional characters.

\section*{Method}

Participants and Design 23 undergraduates ( 10 males, 13 females) who reported having no knowledge of Chinese characters participated for course credit. Experiment 2 was also a within-subject design so order was counterbalanced across participants. Twelve were randomly assigned to participate in the Traditional-first condition before the Simple-first condition, and the other 11 participated in the Simple-first condition before the Traditional-first condition.

Materials and Procedures The stimuli and procedures were nearly identical to Experiment 1. The key difference in Experiment 2 was the lack of a training phase thus participants never connected any of the characters to English meanings. Each trial began with a fixation cross, followed by a Chinese character for 2 seconds, and 4 answer choices. In exact match trials, participants matched characters to identical characters. On the generalization task, participants were shown a character in one script and had to choose the match among characters written in the other script. A sample trial and procedure are shown in Figure 4.
(a) Exact Match Test

(b) Generalization Test

Figure 4: (a) Exact match test procedure and (b)
Generalization test procedure of the Traditional-first condition in Experiment 2.

\section*{Results}

Preliminary analyses Like Experiment 1, there was no effect of character set nor condition order \((p s>.10)\) so the data were collapsed across those variables.

Exact match and generalization test results Average proportion correct and average response time results are presented in Figures 2 and 3 (right panels). Again, we
conducted two \(2 \times 2\) (condition x test type) repeatedmeasures analysis of variance (ANOVA) for accuracy and reaction time.

Accuracy. Results were consistent with findings from Experiment 1. There was a main effect of test such that participants made significantly more correct responses on the exact matching task \((M=.97, S D=.05)\) than on the generalization task \((M=.68, S D=.14), F(1,22)=129.72, p\) \(<.001, \eta^{2}=.86\). There was also a main effect of condition, \(F(1,22)=33.42, \mathrm{p}<.001, \eta^{2}=.60\), and a significant interaction, \(F(1,22)=12.33, p<.01, \eta^{2}=.36\). Post-hoc analyses confirmed that this difference was driven by the differential effect of the sample script on generalization. Follow-up pairwise \(t\)-tests showed no significant difference between the Simplified or Traditional exact match-tosample task, \(t(22)=1.32, p=.20\). However, the Simple-first condition produced significantly better generalization performance \((M=.79, S D=.14)\) than the Traditional-first condition \((M=.57, S D=.18), t(22)=4.83, p<.001\), with Bonferroni correction. Again, as in Experiment 1, training with Simplified characters promoted greater generalization to Traditional characters than vice versa.

Response Times for Correct Trials (given in seconds per trial). There was a main effect of test type, \(F(1,22)=59.46\), \(p<.001, \eta^{2}=.73\), such that participants were faster in the Simple-first condition than in the Traditional-first condition. There was a significant interaction, \(F(1,22)=5.70, p<.05\), \(\eta^{2}=.21\), that suggested that although the Simple-first condition was faster than the Traditional-first condition in the exact-matching task, RTs in the generalization task were similar. Bonferroni-corrected pairwise \(t\)-tests confirmed a significant difference in RTs for the exact matching task for accurate responses between the Simple-first and Traditionalfirst condition, \(t(22)=3.91, p<.01\), and showed no significant difference conditions on generalization, \(t(22)=\) \(1.05, p=.21\).

While there was no difference in accuracy on the exact matching trials, Traditional characters required more time per correct response than Simplified characters (1.55 seconds vs. 1.32 seconds). This result is interesting in light of classic experiments and theories of similarity.

Similar to Podgorny and Garner's (1979) classic work that demonstrated participants judge the similarity of two Ss on a screen faster than two Ws, we also find that some Chinese characters are self-identified faster than others. Tversky's feature-based contrast model of similarity (1977) suggests that complex objects that share a greater number of overlapping features are more self-similar than simple objects. Traditional characters contain more strokes so one might assume that they should be more self-similar and should result in shorter RTs in our exact match task. However, it is important to keep in mind that the distractors in the field were also complex. These complex characters may be more similar to each other thus forcing participants to spend more time to distinguish the target among them.

\section*{General Discussion and Conclusion}

We examined the simple advantage for generalization between simple and complex Chinese scripts. In Experiment 1, participants studied the characters and their English translations before attempting to generalize their learning to the same characters of the unlearned script. In Experiment 2, participants had only brief controlled exposure to the characters before undergoing the generalization test. In both experiments, there was a generalization advantage when the initially shown exemplar was simple.

Contrasting the results of these studies, generalization performance in Experiment 1 was more accurate yet slower than Experiment 2. This pattern is reasonable given the differences in the tasks across experiments. Those in Experiment 1 had to recall the characters from memory when given their English definitions whereas those in Experiment 2 saw exemplar characters immediately before making their choice. Taking more time to recall the trained characters may have helped participants in Experiment 1 generalize more accurately. A longer reaction time is probably less effective when generalization was more purely perceptual.

In the following sub-sections, we will discuss the theoretical and educational implications of these findings.

\section*{Theoretical Implications}

These findings are consistent with results of past research on generalization by shape with young children (e.g., Son et al., 2008): simple instances promote better category generalization. Why are these instances advantageous for transfer? Simple training instances may allow for efficient encoding of the right initial features and/or retrieval of useful representations. Learning from complex characters may be detrimental just by having additional non-diagnostic features that are not present in novel transfer cases. Furthermore, complex instances may generally require greater attentional resources to learn and use.

Adults seem to face similar difficulties in categorization learning as children - that potentially useful and distracting features may not be psychologically separable at the time of learning (Schyns \& Rodet, 1997). Being exposed to a simplified version first may have enabled our adult learners to recognize the complex character as containing the simple character along with other new features. Initial learning with a complex stimulus does not provide a decomposed perceptual vocabulary and thus the learner might miss the shared components between the complex and simple stimuli.

Additionally, this work raises more issues regarding the relationship between similarity, recognition memory, and category generalization. If recognition memory or category generalization is taken as a measure of similarity, this set of results provides further evidence for the asymmetry of similarity. There is an accuracy and/or RT asymmetry between the initially viewed exemplar and the potential matches such that performance is aided by an initially simple exemplar. Furthermore, this work raises the
possibility that similarity judgments based on immediately seen features may operate differently than when based on features retrieved from exemplars in memory.

\section*{Practical Implications}

If the end goal of education is generalization, the simple advantage appears to have broad implications. Even though generalization would likely occur with enough time and resources devoted to training with many complex, detailed instances (e.g., Kellman, Massey \& Son, 2010), the present research suggests that simple training instances may be able to foster generalization more efficiently. Although previous research has directly examined the simple advantage with math and science domains, this research suggests that simple learning instances might also be useful in learning categories in general.

More directly, these results bear on the cognitive role of scripts in Chinese reading. Broadly speaking, there are no measurable differences in reading or spelling between the two scripts (Chan \& Wang, 2003). A few studies suggest that learning to read with simplified characters is more related to visual skills than learning to read traditional characters (Chen \& Yuen, 1991; McBride-Chang et al., 2005). Young children learning to read in mainland China (using simplified script) were more likely to base similarity judgments of characters based on visual characteristics than children from Hong Kong (primarily taught with traditional script) (Chen \& Yuen, 1991). Although further research is necessary to determine whether learning a few characters in a lab setting is similar to learning hundreds of characters to gain literacy, our findings suggest that there might be a benefit of starting with simplified characters. Particularly if the goal is to read both scripts, learning the simplified script may be more helpful for learning the traditional script than the reverse.

Simplified characters contain fewer but more diagnostic components (radicals) so it may be advantageous to treat these recurring radicals as basic orthographic units. Perhaps an emphasis on explicitly learning these units early on may foster better generalization to full blown characters. Research on Chinese literacy (e.g., Tsai \& Nunes, 2003) shows that expert readers are generally quite sensitive to these components. Whether such pedagogical practice supports future learning of new Chinese characters is a question for future research.

However, the relevance of these findings for Chinese literacy is limited in two significant ways. First, the characters used in these studies were only simplified via the component omission process. Future research should incorporate character sets created through other simplification methods such as replacing a complex component (e.g., four dashes) with a simpler one (e.g., a line) to draw broader conclusions about the simple advantage for Chinese reading. Second, reading is more than merely identifying or recognizing characters. Traditional characters include cues to pronunciation and meaning that have been removed in simplified characters.

These cues may be equally or even more important to full fledged reading than ease of recognition.

\section*{Conclusions}

The simple advantage seems to be stable across a variety of tasks and domains, from categorization and object recognition to more complex forms of formal learning. This suggests that this effect stems from domain-general learning mechanisms that bridge or incorporate both perceptual and conceptual learning. In some sense, all learning situations are ill-constrained because a novice does not know which information is relevant or irrelevant. Simplicity supports learning by getting at the heart of this problem: the few features that are presented are all relevant.

\begin{abstract}
How is semantic memory structured and searched? Recalling items from semantic categories is a classic assay of semantic memory, and recall dynamics tend to exhibit semantic and temporal clustering, as if memory items are organized and retrieved in clusters. Recent analyses show this clustering to be approximately scale-free in terms of distributions of interretrieval intervals (IRIs). This finding is replicated and extended in the present study by asking participants to type as many animals as they can recall from semantic memory. To begin to explain these results, the organization of semantic memory is modeled as a network based on Wikipedia entries for nearly 6,000 animals. The Wikipedia animal network is found to be scale-free in terms of its degree distribution, and aspects of the network are found to correlate with aspects of recall. Semantic similarity based on Wikipedia entries is found to compare favorably with a measure based on latent semantic analysis. It is concluded that semantic memory processes can be usefully theorized as searches over scalefree networks.
\end{abstract}

Keywords: semantic memory, scale-free networks, Lévy foraging; category recall; latent semantic analysis; Wikipedia

\section*{Introduction}

Category recall is a classic approach to investigating semantic memory. Participants produce as many items from a semantic category as possible in a specified period of time (Bousfield \& Sedgewick, 1944). Items tend to be recalled in clusters. For the category of "animals", for instance, part of a typical sequence might be "lion, tiger, cougar, leopard... kitten, cat, tabby". This sequence contains two groups of semantically similar items, big wild cats followed by house cats. Such clusters can be of varying kinds and sizes, and they tend to correspond with short IRIs, relative to longer pauses when switching from one cluster to the next (Grunewald, Lockhead \& Gregory, 1980).

Clustering seems to be a general feature of semantic memory. Work in this area has a long history, with early experiments showing that, when participants memorize words presented in random order, they tend to recall those words in clusters based on semantic categories (Bousfield \& Sedgewick, 1953). Therefore clustering must be related to memory encoding, retrieval, or both. In clinical work, semantic category recall is used as a diagnostic for mental disorders. Schizophrenic patients, people with semantic dementia and people with Alzheimer's all show specific deficits in category generation tasks (see Murphy, Rich \& Troyer, 2006).

Previous work has sought to account for clustering in category recall with patch foraging models (see Hills, Jones \& Todd, 2012). Patch foraging theorizes semantic memory as a set of patches of similar items. Memory search consists of series of quick retrievals of items from within a patch, interleaved by longer times for switching to the next patch when a sufficient number of items in the current patch have been found. Framed this way, optimal foraging can be expressed in terms of the time to leave a patch. It is optimal to switch when the instantaneous rate of recall per unit time drops below the long-term expected rate of recall (Charnov, 1976). Category switch times, and times in other human search tasks, have been found to be consistent with patch foraging (Cain, Vul \& Mitroff, 2012).

Patch foraging models lead one to expect short and long IRIs corresponding to successive recalls within patches versus between patches, respectively. However, recent work on category generation tasks has examined distributions of IRIs and found them to have no particular mean or means (Rhodes \& Turvey, 2007). When the category recall task was conducted for sufficiently long periods of time (e.g. ten to twenty minutes for recalling animals), IRIs were found to be power law distributed. In particular, the frequency of IRIs were inversely related to their size, P(IRI) \(\sim 1 /\) IRI \(^{\alpha}\). Such power law distributions have no characteristic scale in theory, which means that their means and variances diverge as more samples are drawn. The implication is that the organization of semantic memory is scale-free rather than just patchy.

Power law IRI distributions fall outside the purview of patch foraging models, but they have been studied extensively in animal foraging models (Viswanathan et al., 1996). Unlike patch models, animal foraging models explicitly consider the space in which items are to be found, such as trees and bushes in a meadow where birds are foraging for nuts and berries. Interestingly, the same power law distribution found in category recall is also found in IRIs during foraging for a wide range of species (Sims, Southall \& Humphries, 2003). Theorists have related these findings to so-called Lévy walks (Mandelbrot, 1982), which are random walks with path lengths drawn from a power law distribution. While it is unlikely that foraging paths are literally random Lévy walks, they may capture an important property of foraging. The reason is that Lévy walks sometimes may be efficient search strategies when their exponent \(\alpha\) is near 2 (Viswanathan et al., 2000). Consistent
with this idea, IRIs in animal foraging and category recall have both been found to resemble Lévy walks with \(\alpha \sim 2\) (Rhodes \& Turvey, 2007; Sims, Southall \& Humphries, 2003).

What do these findings tell us about the process of searching semantic memory in category recall? They suggest that simple Lévy walks might characterize much about memory search, but they also might tell us about the structure of semantic memory. Items in memory are often theorized in terms of networks, in which case one is led to ask whether these networks are structured in such a way that searching them results in power law IRIs. As it turns out, recent work on semantic networks provides evidence that their degree distributions also follow an inverse power law, termed scale-free networks (Steyvers \& Tenebaum, 2005).

A network consists of interconnected nodes, and the degree of a node is its number of connections. Scale-free networks are those whose distributions of node degrees follow an inverse power law. Many natural and manmade networks are scale-free, such as power grids, brain networks and the World Wide Web (Strogatz, 2001). Steyvers and Tenenbaum (2005) analyzed three different types of data as reflections of semantic networks: word associations, WordNet entries (Miller, 1995) and Roget's Thesaurus. In all three cases, data were used to link items in a network based on similarity or associative relations, and in all cases networks were scale-free.

This evidence for scale-free networks suggests that items fall into clusters with no characteristic size, analogous to the power law IRI distributions. This analogy suggests that scale-free semantic networks might account for power law IRI distributions, as well as the semantic clustering of items in category recall tasks. In the present study, we collected data in a category recall task, and tested whether recall sequences and IRIs can be explained by a scale-free model of semantic memory.

We draw and expand upon previous studies as follows. Category recall data were collected via typed instead of spoken responses, as in previous studies. This difference allowed us to test whether previous findings replicate when response dynamics are on the order of seconds (typing) instead of milliseconds (speech). Typing also allowed us to test whether the same power law distribution occurs in IRIs, as well within responses (typing durations). If so, we would have evidence that recall processes unfold continuously throughout the task, rather than in alternating stages of recall and response execution (Kawamoto, Kello \& Jones, 1998; Spivey \& Dale, 2006).

We then built a semantic network of animals using over 6000 pages from Wikipedia. We followed an information theoretic method used previously to show that the entirety of Wikipedia can be formalized as a scale-free network (Massuci et al., 2012). We test whether this method replicates when analyzing only one subset domain of Wikipedia, and we test whether the resulting measures of animal similarity and network structure can be used to explain category recall data. We also compare Wikipedia
measures of semantic similarity with those generated from latent semantic analysis (LSA) of linguistic corpora (Landauer \& Dumais, 1997). LSA has become a standard co-occurrence method, whereas Wikipedia is a new encyclopedic method. Thus LSA provided a baseline for evaluating our new method. We end by discussing the implications of our results for Lévy and patch foraging models, semantic memory, and search processes in general.

\section*{Experiment}

\section*{Methods}

Participants and Procedure. Nineteen undergraduates at University of California, Merced participated for course credit. Participants were instructed to recall as many members from the category of "animals" as they could in twenty minutes, after first completing three minutes of practice with naming colors. Responses were typed and recorded using a Flash interface that stored the timing of each key press. Key press times were used to calculate the interval from the end of one response to the start of the next, termed inter-response interval (IRI), and the time from start to end of the response, termed typing duration (TD).

\section*{Results}

The average number of animals produced by each participant was 117 (SD = 38.6). Distributions of IRIs and typing durations were plotted in logarithmic coordinates to gauge whether they resembled power law distributions. As shown in Figure 1, the negative linear relation is indicative of a power law, and multi-model inference tests (Akaike, 1974) confirmed that 4 subjects were best fit by a power law, and the other 15 were best fit by a lognormal (which is akin to a constrained or truncated power law in this case). The deviations from linear at left end of these distributions were due to minima that constrained and thereby distorted the power law relationship. Distortion aside, the slope of these distributions in logarithmic coordinates was near -2 , which replicates the category recall findings of Rhodes and Turvey (2007). Thus memory retrieval dynamics followed the same pattern for slower typed responses, relative to faster spoken responses.

Typing durations also followed the same power law relation, suggesting that memory retrieval is ongoing during response execution. To test whether this result may have been due to variations in response length, typing durations were normalized by the number of letters in each response. As shown in Figure 1, normalized distributions had the same overall shape as the others. Thus response length did not factor into the results.

In addition to IRIs, the category recall task also yields series of recalled animals. Visual inspection of these series (not shown herein) indicated that, as expected, semantically related animals tended to be recalled in close proximity compared with less related animals. Next we describe the Wikipedia semantic network model and test whether it can
account for the relative positioning and clustering of items in recall sequences.

Figure 1. Response histograms in logarithmic coordinates.

\section*{Semantic Memory Modeling}

The network method developed by Masucci et al. (2011) is based on transforming each given Wiki page into a probability distribution over lemmas, and then using JensenShannon divergence (JSD) to measure the distance between two probability distributions. Animal Wiki pages were found using the Dbpedia ontology (Auer, Bizer \& Kobilarov, 2007) which contains a list of all articles in Wikipedia associated with a given tag. A list of 129,027 animal articles in Wikipedia was compiled and all stub articles, redirect pages and articles with less than 500 words of main text were removed. This left us with 5,701 animal pages. Formatting, references, and function words were removed from these pages, and remaining words were lemmatized to collapse across different inflectional forms.

The resulting frequency counts over lemmas on each page were normalized to create probability distributions, and each distribution served as a semantic representation of the corresponding animal. These representations can be used to determine which animals are and are not linked in a semantic network, provided there is a good measure of similarity between probability distributions. Note that two distributions for two given pages may overlap only partially in their corresponding sets of lemmas. This means that our similarity measure must encompass and normalize over varying degrees of overlap.

A well-known measure of similarity between two probability distributions is the Kullback-Liebler (KL) divergence, defined as
\[
\mathrm{KL}\left[\rho_{1}, \rho_{2}\right]=\int_{\Delta} \rho_{1}(x) \ln \frac{\rho_{1}(x)}{\rho_{2}(x)} \mathrm{d} x
\]

This divergence is asymmetric and non-normalized, whereas JSD is a symmetric extension of KL divergence, normalized between zero and one:
\[
\operatorname{JSD}\left[\rho_{1}, \rho_{2}\right]=\frac{1}{2}\left(\operatorname{KL}\left[\rho_{1}, \frac{\rho_{1}+\rho_{2}}{2}\right]+\operatorname{KL}\left[\rho_{2}, \frac{\rho_{1}+\rho_{2}}{2}\right]\right)
\]

JSD can be thought of as providing a measure of how often the same lemmas are used with the same frequency between two Wikipedia pages.

Semantic Network. JSDs were calculated for all pairs of probability distributions, and an undirected semantic network was created by connecting any two animals with a JSD similarity below a given threshold. The threshold was chosen to be just high enough to merge \(90 \%\) of the animals into a single, interconnected network (every node could be reached from every other node by traversing the network, and unconnected nodes were removed from analysis).

Figure 2. Degree distribution of the Wikipedia semantic network in logarithmic coordinates.

The structure of the resulting network was sparse, smallworld and approximately scale-free. Average minimum path length was 3.65 , average clustering coefficient was 0.529 , the diameter of the network was 14 and the degree distribution followed a power law distribution (Figure 2). This finding replicates Masucci et al. (2011) for a subset of Wikipedia, and it provides convergent evidence with Steyvers \& Tenenbaum (2005) that semantic memory can be expressed as a scale-free network.

\section*{Accounting for Category Recall Results}

Semantic networks are often compared with offline human behaviors that can be expressed as structures. Wikipedia provides crystallized, idealized representations of animals, but it stands to reason that online measures of human behavior would be sensitive to these representations. We examine three such measures from our category recall data: 1) Animal response similarity as a function of distance in recall sequences, 2) First-order transitions in recall sequences, and 3) IRIs as a function of shortest path length in the scale-free semantic network.

To provide a benchmark for these three measures, we also computed semantic similarity using LSA. As a cooccurrence method, LSA has strengths and weaknesses compared with our Wikipedia-based method. Its main strength is that LSA can provide a representation for every word in a set of documents, whereas the Wikipedia method can only provide representations for existing entries.

However, each Wikipedia entry unambiguously corresponds to a particular semantic item. By contrast, LSA merges all the different meanings and usages of each given word, like "fish", into a single semantic representation. Also, LSA vectors cannot be combined to form compound word representations that correspond to animals like "flying fish" and "zebra finch".

Responses were corrected for spelling mistakes, and multi-word responses like "black bear" were reduced to their superordinate category, i.e. "bear" in this case. LSA vectors were calculated using a term by term comparison from the "general reading to first year college" corpus. Of the 299 unique animal names produced in the category recall experiment, we were able to compute LSA vectors for 196 of them, and Wiki probability distributions for 293 of them.

\section*{Average JSD Values Between Relative Positions}

Average LSA Values Between Relative Positions

Figure 3. Mean JSD and LSA measures as a function of relative positions, with standard error bars.

Recall Proximity. The first measure we examine is related to evidence marshaled for patch foraging models. Hills et al. (2012) used a co-occurrence method called BEAGLE (Jones \& Mewhort, 2007) to show that items
produced within a patch are more semantically related as a function of proximity in a sequence. Given the evidence for patches of all sizes, and hierarchical nesting of patches as evidenced by power laws, we tested whether the analysis could be extended to all items in category recall sequences, without setting patch boundaries.

JSD and LSA measures were computed between pairs of animal responses in category recall sequences, as a function of the relative position of items, from 1 (adjacent) to 10 (nine intervening items). JSD and LSA measures of semantic similarity were averaged for each relative position, and then normalized by the mean and standard deviation for all pairwise JSD and LSA similarities, across all relative positions. Results are shown in Figure 3.

The JSD and LSA measures produced comparable results showing that semantic similarity decreased as a function of positional distance in sequences. This result confirms visual inspection of sequences, as well as previous research (Bousfield \& Sedgewick, 1953) showing that similar items tend to be recalled in nearby positions. Both measures also compared favorably with the Hills et al. (2012) results, which showed a distinct effect of similarity only for immediately adjacent items in recall sequences. Quantitative differences between LSA and Wikipedia methods were also observed: Compared with Wikipedia, LSA registered relatively higher similarities for immediately adjacent items, but similarity fell off more quickly with increasing distance.

Transitional Probabilities. LSA and JSD measures used in the recall proximity analysis can serve as a basis for predicting performance in category recall. We used LSA and JSD measures to compute first-order transition probabilities as a simple means of predicting each recall item in a sequence, based only on the previous item. This analysis extends the previous one because each transitional probability is computed relative to all possible recall items, which is more akin to a model of category recall that simulates dynamics of semantic memory, e.g. by traversing a scale-free semantic network.

For each recalled item, all animals that could be recalled next were arranged according to the JSD or LSA similarity between them, creating a ranking of possible transitions. Transitions to every ranking were normalized by the total number of JSD or LSA transitions. Probabilities were standardized by setting them relative to random chance. In particular, each probability was divided by random chance for each analysis ( \(1 / 293\) and \(1 / 196\), respectively) to show proportion above or below chance.

As shown in Figure 4, for both JSD and LSA measures, participants were most likely to transition from each animal name to the name estimated to be most semantically similar. JSD transitions to the highest ranked word made up around \(7 \%\) of total transitions, and for LSA it was around 3\%. This effect falls off after the first \(30-50\) most similar items, and is most pronounced for the JSD measure. The JSD measure appears to be better at predicting transitional probabilities compared with the LSA method.

Figure 4. Standardized probability of first-order transitions between items by similarity ranking for JSD and LSA measures.

Accounting for IRIs. The previous two analyses focused on the sequencing of recalled items, but the times between recalls are arguably more at issue in theories of semantic memory. Both patch and Lévy foraging theories aim to explain IRI effects-patch transition times for the former, and IRI distributions for the latter. We tried using JSD and LSA similarities alone, as in the previous two analyses, to account for IRIs. However, they did not correlate reliably with IRIs under any transformation of the data we tried.

Despite the lack of a direct link between semantic similarities and IRIs, a semantic network built from similarities still may account for IRIs by virtue of network structure and dynamics that capture interactions among items in memory. We used the scale-free semantic network reported earlier, based on Wikipedia JSDs, to account for IRIs observed in our category recall experiment. We did not build a network based on LSA values because the lack of semantic representations for word phrases like "tiger shark" prohibited us from creating a sufficiently rich network.

Simulating network dynamics is beyond the present scope, but we accounted for IRIs using a standard measure of network structure that is likely to have a strong influence on network dynamics. Minimum path length is the minimum number of links needed to traverse from one node to another. Minimum path length provides a measure of how
disparate two nodes are in the context of an interconnected network, and will directly impact any walker or spreading activation mechanism used to formulate network dynamics.

Figure 5. Mean logged IRI between words with different minimum path length separation in the semantic network.

Minimum path lengths were computed between all adjacently recalled items in all sequences from the category recall experiment. Minima ranged from 1 to 6, but we only examined pairs from 1 to 4 because there were too few at 5 and 6 to afford analysis (1 each). IRIs were logarithmically transformed due to their heavy tails, and mean log IRIs were computed for each minimum path length, as shown in Figure 5. There was a significant effect of path length on log IRIs, \(\beta=.403, t(1067)=7.44, p<.001\), and they accounted for a significant proportion of variance \(R^{2}=.049, F(1\), 1067) \(=55.36, p<.001\). IRIs were shorter for immediately connected items compared to the baseline mean IRI, and IRIs were progressively greater than baseline as path length increased from 2 to 4 . This result provides evidence that a scale-free semantic network may account for IRIs in category recall experiments, even when semantic similarities alone are not enough to account for the data.

\section*{Discussion}

In the present study, we showed that category recall performance can be modeled using scale-free semantic networks. The category recall data were collected as series of typed responses, and IRI distributions had the same shape as in previous experiments using spoken responses. This replication suggests that the present analyses should generalize to other semantic memory paradigms. Typed responses also indicated that memory dynamics unfold during response execution as well as the pauses between responses, which will be important to account for in future models and simulations.

Previous studies have provided behavioral evidence that semantic memory is organized as a scale-free network (Steyvers \& Tenenbaum, 2005), and we showed that a semantic network of animals built from Wikipedia pages is indeed scale-free. We used a measure of Wikipedia page similarity to account for basic aspects of recall sequences, and we showed that this measure of similarity compared
favorably with a more standard LSA measure. We also showed that a basic aspect of scale-free network structure explained some of the variance in category recall IRIs.

The next step in this line of work is to implement network dynamics to test whether scale-free network structure can account for the scale-free, power law distribution of IRIs observed in category recall tasks. This test will bear on Lévy foraging theories that would explain power law IRIs in terms of random or correlated walkers. A parallel step will be to test whether network dynamics can account for evidence suggesting that foragers spend optimal amounts of time foraging within patches, and switch to new patches when current rates of recall fall below the long-run average. While our model does not have clear delineations between patches, because items fall into nested clusters with no characteristic scale, it may still account for patch evidence. Recent modeling work showed that random walks on semantic networks might account for this evidence without reference to patches (Abbott, Austerweil \& Griffiths, 2012).

Finally, it will be informative to apply the Wikipedia method of network creation to other phenomena of semantic memory, in other semantic domains. In doing so, it will be important to compare this method with a range of cooccurrence methods, as well as other encyclopedic methods.

\begin{abstract}
Bayesian inference has been shown to be an efficient mechanism for describing models of learning; however, concerns over a lack of constraint in Bayesian models (e.g., Jones \& Love, 2011) has limited their influence as being a description of the 'real' processes of human cognition. In this paper, we review some of these concerns and argue that cognitive architectures can address these concerns by constraining the hypothesis space of Bayesian models and providing a biologically-plausible mechanism for setting priors and performing inference. This is done in the context of the ACT-R functional cognitive architecture (Anderson \& Lebiere, 1998), whose sub-symbolic information processing is essentially Bayesian. To that end, our focus in this paper is on an updated associative learning mechanism for ACT-R that implements the constraints of Hebbian-inspired learning in a Bayesian-compatible framework.
\end{abstract}

\section*{Introduction}

Bayesian approaches to reasoning and learning have been successful in such fields as decision-making (Tenenbaum, Griffiths, \& Kemp, 2006), language learning (Xu \& Tenenbaum, 2007), and perception (Yuille \& Kersten, 2006). Most specifically, Bayesian inference has been exceptional in discovering some of the structure of language and word learning with substantially less training than traditional connectionist networks.

Despite their successes, Bayesian models have come under attack for being unconstrained, unfalsifiable, and overly reliant on optimality as an assumption for reasoning (see Jones \& Love, 2011; Bowers \& Davis, 2012 for an exhaustive review; and Griffiths et al., 2012 for a counterargument). While these criticisms are not without merit (nor are the Bayesians' rebuttals fully convincing), the issue of constraints remains a critical argument. It is also not a new argument. Over 25 years ago the constraint argument was leveled against the field of connectionism (Fodor \& Pylyshyn, 1988). Then it was argued that, via several learning rules and organizing principles, any behavior could theoretically be captured by connectionist networks.

The degree that progress has slowed for the explanatory power of connectionist networks is beyond the scope of this paper; however, constraints on neural network development using a common learning rule in a stable cognitivelyplausible architecture have been advanced (O'Reilly, 1998; O’Reilly, Hazy, \& Herd, 2012). By corollary, to address similar concerns, the Bayesian movement needs to develop constraints which balance the computational transparency of
their models with algorithmic and implementation (i.e., neural) level cognitive plausibility.

Interestingly, ACT-R 6.0 (Anderson et al., 2004) is a cognitive architecture which already uses Bayesian-inspired inference to drive sub-symbolic learning (i.e., to generate and update the activation strength of chunks in declarative memory). The architecture is both constrained by learning rules (e.g., activation equations; base-level learning) and neuro-cognitively justified by many studies (Anderson \& Lebiere, 1998; Anderson et al., 2004; Anderson, 2007). While there have been difficulties in adapting some aspects of the Bayesian approach (e.g., in implementations of associative learning), ACT-R serves as an example whereby Bayesian inference can be constrained by a neurallylocalized and behaviorally-justified cognitive architecture. In this sense, ACT-R can act as a bridge between all three layers of Marr's tri-level hypothesis.

For the remainder of this paper, we present an overview of the debate over the applicability of Bayes inference to cognition and argue that ACT-R represents the kind of constraint that addresses criticisms against Bayesian models. We will further describe an updated associative learning mechanism for ACT-R that links Bayesian-compatible inference with a Hebbian-inspired learning rule.

\section*{Bayesian Inference}

The essential feature of Bayesian inference is that it reasons over uncertain hypotheses \((H)\) in probability space (i.e., from \(0-100 \%\) certainty). The Bayes rule is defined as:
\[
P(H \mid D)=\frac{P(D \mid H) \cdot P(H)}{P(D)}
\]
where the posterior probability of an outcome \(P(H \mid D)\) is derived from the likelihood \(P(D \mid H)\) of the hypothesis explaining the data, combined with the prior probability of the hypothesis \(P(H)\), and normalized by the probability of the data \(\mathrm{P}(D)\). Thus, updating one's belief is based on one's prior belief influenced by the likelihood that some new evidence supports this belief. At its core, Bayesian inference is an excellent derivation of the scientific method.

A difference between Bayesian models and connectionist implementations is that Bayes models of human cognition tend to use richer, more structured, and symbolic knowledge than connectionist models, which tend to use more distributed representations operating over less structured input. This level of inference places Bayesian models at the computational level of Marr's tri-level hypothesis, whereas cognitive architectures and connectionist networks operate
more at the algorithmic level (Marr, 1982). By remaining at a higher level of description, it is argued that Bayesian descriptions of cognitive behaviors are better understood as a framework for explaining cognition as opposed to an explanation of how cognitive operations and representations should behave in a given task (Tenenbaum et al., 2011).

This higher level of description leads to many of the criticisms leveled against Bayesian models. We wish to address three related criticisms of Bayesian models: (1) they are unconstrained; (2) they are unfalsifiable; and (3) there is little neuro-scientific evidence to support Bayesian theory. It is easy to see how (2) and (3) follow from (1) since without constraint, it is theoretically possible to redefine the priors and hypothesis space of the model to curve fit to any data. Part of the issue with (3) is that Bayesian description tends to operate at the computational level, yet be described in stronger, more algorithmic terms (e.g., probabilistic population codes; Ma et al. 2006).

These criticisms have led to Bayesian theory being criticized as a 'just-so' story (i.e., that the Bayesian framework commits the ad hoc fallacy; Bowers \& Davis, 2012). However, rebuttals by Griffiths et al. (2012), rather than addressing these criticisms in a constructive manner, countered with essentially a 'you-too' argument. Griffiths et al. (2012) argued that curve-fitting models to data is not an exclusive sin of Bayesian models, however, the transparency with which Bayesian models do so make them easy targets. In fact, as Griffiths et al. counter, criticisms (1) and (2) may be leveled against any model or architecture with sufficient parametric degrees of freedom (which they implicitly argue is a feature of most or all existing models). This argument against architectures had previously been espoused by Roberts and Pashler (2000) over a decade ago.

In a recent Science article by Tenenbaum et al., (2011) Bayesian inference is defined as being synonymous with probabilistic inference. This leads to criticism (2). The difficulty with making 'Bayesian' and 'probabilistic' synonymous terms is that any algorithm that approximates probabilistic reasoning can be argued to be approximating Bayesian inference and thus be essentially Bayesian. Conversely, any Bayesian algorithm that does not successfully reproduce human data can lead to the argument that the issue isn't with the Bayesian algorithm per se, but in the transformation of data into a probability space (e.g., by not having the correct priors or correct hypotheses) or in the lack of human-like limitations of the algorithms to carry out the computations. It is for this reason that some have argued that probabilities are "epistemologically inadequate" (McCarthy \& Hayes, 1969).

Instead of offering more criticisms, we wish to offer solutions. The issue with constraints is that, even if Bayesian models do not have too many parameters, there is effectively unlimited freedom in setting priors and the hypothesis space (which greatly influences the performance on the model). What is needed is a way to constrain the generation of the initial probability space and set of algorithms to carry out inference for a set of models. For
instance, Kruschke (2008) reviewed two Bayesian models of learning backward blocking in classical conditioning, the first using a Kalman filter (Dayan, Kakade, \& Montague, 2000) and the other using a noisy-logic gate (Danks, Griffiths, \& Tenenbaum, 2003). Both models gave substantively different predictions, with the Kalman filter model unable to reproduce human behavior.

Furthermore, there are several tasks whose results do not readily fit within a naïve Bayesian explanatory framework. For instance, simple Bayesian models do not capture violations of the sure-thing principle. Given a random variable \(x\) that has only two possible outcomes A or B, naïve Bayesian inference requires \(p(x)\) to fall between \(p(x \mid A)\) and \(p(x \mid B)\). A violation occurs when \(p(x)>p(x \mid A)\) and \(p(x)\) \(>p(x \mid B)\) or vice versa. Shafir and Tversky (1992) showed this violation of the sure-thing principle in a prisoner's dilemma task. Finding these unintuitive results that naïve Bayes models do not easily address, and finding constrained parameter learning rules (such as the noisy-logic gate) provides much needed constraints and falsifiability to the Bayesian framework. Rather than being seen as antiBayesian results, these models should be seen as shaping the boundaries of Bayesian explanatory power.

Finally, while there is contested neuro-scientific evidence as to neural assemblies firing probabilistically, this does not necessarily imply a Bayesian implementation-level explanation, but instead implies the softer claim of a Bayesian-compatible behavioral explanation of neural phenomena, especially when the Bayesian inferences are justified within a neurally-plausible cognitive architecture.

In considering many of the criticisms of Bayesian theory, it is important to note that more research needs to be done to find constraints. As we previously argued, connectionist networks were not sufficiently constrained until sufficient model testing was performed and architectures developed using a common learning rule and constrained set of parameters. For the Bayesian framework, we argue that all of criticisms (1) - (3) can be addressed by situating Bayesian inference within a cognitive architecture, and furthermore that ACT-R 6 is already such an architecture.

\section*{The ACT-R Architecture}

ACT-R is a computational implementation of a unified theory of cognition. It accounts for information processing in the mind via task-invariant mechanisms constrained by the biological limitations of the brain. ACT-R 6 includes long-term declarative memory and perceptual-motor modules connected through limited-capacity buffers. Each module exposes a buffer, which contains a single chunk, to the rest of the system. A chunk is a member of a specific chunk type, and consists of a set of type-defined slots containing specific values.

The flow of information is controlled by a procedural module implemented using a production system, which operates on the contents of the buffers and uses a mix of parallel and serial processing. Modules may process information in parallel with one another. So, for instance, the visual and motor modules may both operate at the same
time. However, there are two serial bottlenecks in process. First, only one production may execute during a cycle. Second, each module is limited to placing a single chunk in a buffer.

Each production consists of if-then condition-action pairs. Conditions are typically criteria for buffer matches, while the actions are typically changes to the contents of buffers that might trigger operations in the associated modules. The production with the highest utility is selected to fire from among the eligible productions. In general, multiple production rules can apply at any point. Production utilities, learned using a reinforcement learning scheme, are used to select the rule that fires.

When a retrieval request is made to declarative memory (DM), the most active (highest \(A_{i}\) ) matching chunk is returned:
\[
A_{i}=B_{i}+S_{i}+P_{i}+\varepsilon_{i}
\]
where activation \(A_{i}\) is computed as the sum of base-level activation ( \(B_{i}\) ), spreading activation ( \(S_{i}\) ), partial matching \(\left(P_{i}\right)\) and stochastic noise \(\left(\varepsilon_{i}\right)\). Spreading activation is a mechanism that propagates activation from the contents of buffers to declarative memory proportionally to the strength of association between buffer contents and memory chunks. Partial matching is a mechanism that allows for chunks in memory that do not perfectly match a retrieval request to be recalled if their activation overcomes a similarity-based mismatch penalty.

\section*{ACT-R as a Constrained Bayesian Architecture}

ACT-R's sub-symbolic activation formula approximates Bayesian inference by framing activation as log-likelihoods, with base-level activation \(\left(B_{i}\right)\) as the prior, the sum of spreading activation and partial matching as the likelihood adjustment factor(s), and the final chunk activation \(\left(A_{i}\right)\) as the posterior. The retrieved chunk has an activation that satisfies the maximum likelihood equation.

ACT-R provides the much needed constraint to the Bayesian framework through the activation equation and production system. The calculation of base-levels (i.e., priors) occurs within both a neurally- and behaviorallyconsistent equation:
\[
B_{i}=\ln \left(\sum_{j=1}^{n} t_{j}^{-d}\right)
\]
where \(n\) is the number of presentations for chunk \(i, t_{j}\) is the time since the \(j^{\text {th }}\) presentation, and \(d\) is a decay rate (community default value is .5). This formula provides for behaviorally-relevant memory effects like recency and frequency, while providing a constrained mechanism for obtaining priors (i.e., driven by experience). Thus, we can address the constraint criticism (1) through this well justified mechanism (see Anderson et al., 2004).

In addition, the limitations on matching in the production system provide constraints to the hypothesis space and kinds of inferences which can be made. For instance there are constraints on the kinds of matching that can be accomplished (e.g., no disjunction, matching only to specific chunk types within buffers) and, while userspecified productions can be task-constrained, the
production system can generate novel productions (through proceduralization) using production compilation. In addition, the choice of which production to fire (conflict resolution) also constrains which chunks (i.e., hypotheses) will be recalled (limiting the hypothesis space), and are also subject to learning via production utilities.

In production compilation, a new production is formed by unifying and collapsing the conditions of the production, and possibly automatizing a given memory retrieval. This new production has a unique utility and can be considered an extension of the hypothesis space; perhaps with enough learning compiled productions are more analogous to overhypotheses (Kemp, Perfors, and Tenenbaum, 2007).

In summary, the conflict resolution and production utilities algorithms both constrain the hypothesis space and provide an algorithm for learning how the space will evolve given experience, constrained within the bounds of a neurally-consistent functional cognitive architecture. This bridges Bayesian inference from a computational-level framework within an algorithmic-level architecture. However, this argument for constraint is not without criticisms (some of which will be addressed in the Discussion). As an example of increasing constraints and grounding mechanisms, we will now present an updated associative learning mechanism in ACT-R.

\section*{Associative Learning}

Associative learning - the phenomenon by which two or more stimuli are associated together - is ubiquitous in cognition, describable as both a micro (Hebbian learning between neurons) and macro (classical and operant conditioning) feature of behavior. Associative learning is a flexible and stimulus-driven mechanism which instantiates many major phenomena such as classical conditioning, context sensitivity, non-symbolic spread of knowledge, and pattern recognition (including sequence learning and prediction error). At the neural level, associative learning is the process by which cells that fire together, wire together.

In its simplest form, Hebbian learning can be described as: \(\Delta W_{i j}=x_{i} x_{j}\), where \(W_{i j}\) is the synaptic strength of the connection between neurons \(i\) and \(j\), and \(x_{i}\) and \(x_{j}\) are the inputs to \(i\) and \(j\) (Hebb, 1949). When both \(i\) and \(j\) are active together, \(\mathrm{W}_{i j}\) is strengthened. While the traditional Hebbian rule was unstable due to a lack of mechanisms to control for weakening of connections (i.e., long-term depression; LTD) or to set a maximum state of activation (i.e., to implement a softmax equation; Sutton \& Barto, 1998), several variants have addressed these issues to provide a stable learning rule.

At a macro level, associative learning is a mechanism where, when a stimulus is paired with a behavior, future presentation of the stimulus primes this behavior. Models of classical conditions are a common macro-level application of associative learning. At this level, associative learning allows animals and humans to predict outcomes based on prior experience with learning mediated by the degree of match between the predicted outcome and the actual result (Rescorla \& Wagner, 1974; Pearce \& Hall, 1980).

While macro-level models are normally processed at a more symbolic level, micro-level sub-symbolic processing can capture statistical regularities from the environment without recourse to explicitly coding context information. There is evidence that humans do not explicitly encode positional information when sequentially recalling a list of items, yet ACT-R's model of list memory required explicit position information to drive recall (Anderson et al., 1998).

Despite being a pervasive factor of human intelligence, associative learning is no longer directly implemented in ACT-R. One reason for this absence is due to difficulties in scaling models in its Bayesian implementation of associative strengths, which treated both the activation strength and associative strength of knowledge elements (e.g., chunks) as likelihoods of successful recall.

\section*{Bayesian Associative Learning Rule}

Associative learning was deprecated in ACT-R 5 due to a lack of scalability in spreading activation as the number of chunks in a model increased and as new productions fired (i.e., new contexts generated). Instead, a simpler spreading activation algorithm was used. The reason for this was that the Bayesian formula used to calculate strength of association \(\left(S_{j i}\right)\) led to some unintended consequences which would render larger and longer-running models unstable.

In ACT-R 4/5, the strength of association \(\left(S_{j i}\right)\) represented the \(\log\) likelihood ratio that chunk \(N_{i}\) was relevant given context \(\mathrm{C}_{j}\) :
\[
S_{j i}=\ln \left(\frac{P\left(N_{i} \mid C_{j}\right)}{P\left(\bar{N}_{l} \mid C_{j}\right)}\right)=\frac{P\left(N_{i}\right)}{P\left(\bar{N}_{l}\right)} \prod_{j} \frac{P\left(C_{j} \mid N_{i}\right)}{P\left(C_{j} \mid \bar{N}_{l}\right)}
\]

When \(C_{j}\) is usually not in the context when \(N_{i}\) is needed, \(P\left(N_{i} \mid C_{j}\right)\) will be much smaller than \(P\left(\bar{N}_{l} \mid C_{j}\right)\) and the \(S_{j i}\) will be very negative because the log-likelihood ratio will approach 0 . In a long-running model, these chunks may have been recalled many times without being in context together, leading to strongly inhibitory \(S_{j i}\).

Once a connection was made, the initial prior \(S_{j i}\) was set by the following equation:
\[
S_{j i}=\ln (m / n)
\]
where \(m\) is the total number of chunks in memory and \(n\) is the number of chunks which contain the source chunk \(j\). This ratio is an estimation of the likelihood of retrieving chunk \(i\) when \(j\) is a source of activation. As a convenience unconnected chunks were set at \(50 \%\) likelihood. \({ }^{1}\)

As can be seen from the previous two equations, given sufficient experience or sufficient numbers of chunks in the model, these context-ratio equations specify that \(S_{j i}\) values will become increasingly and unboundedly negative as more chunks are present in the model and more unique contexts experienced. This is a direct result of \(S_{j i}\) reflecting the statistics of retrieval of chunk \(j\) given that source \(i\) is in the context, and is a version of the Naïve Bayes Assumption.

The issue is with the ratio-driven global term \(\left(C_{j}\right)\) which alters \(S_{j i}\) values for a chunk whenever a new chunk is added

\footnotetext{
\({ }^{1}\) Before \(C_{j}\) appears in a slot of \(N_{i}\), the total probability of retrieving a chunk unconnected to \(C_{j}\) is 0 (which means \(S_{j i}=-\infty\) ).
}
and/or production fires, and is magnified by the loglikelihood calculation which penalizes the inevitable low context ratio in long-running models.

\section*{Spreading Activation in ACT-R 6}

Due to the abovementioned issues with scalability, associative learning was deprecated in ACT-R and a simpler spreading activation function was implemented that does not activation, but instead spreads a fixed amount of activation:
\[
S_{j i}=\operatorname{smax}-\ln \left(\text { fan }_{j i}\right)
\]
where smax is a parameterized set spread of association (replacing the \(m\) term from the previous equation), and fan \(_{j i}\) is the number of chunks associative with chunk \(j\) (the \(n\) term). \(F a n_{j i}\) is traditionally the number of times chunk \(j\) is a slot value in all chunks in DM and represents interference.

With a default smax usually between 1.5 and 2 (Lebiere, 1999), this means that a chunk can appear as a value in 6-8 chunks before becoming inhibitory. In the context of a modeling a single session psychology experiment this may be reasonable, but if ACT-R models long-term knowledge effects, then \(S_{j i}\) will become inhibitory for most chunks. \({ }^{2}\)

As previously discussed, associative learning is a ubiquitous mechanism in both human and animal cognition, which serves as a kind of statistical accumulator which is applicable at both the micro (neural) and macro (cognitive) behavioral level. It seems that to abstract this essential learning mechanism, we are losing out on the exact kind of human-model comparisons that might provide evidence for these much-needed constraints. Perhaps, it is in part for this reason that ACT-R (and other cognitive architectures) have had their explanatory power limited due to a lack of newer, more complex models being built from extant successful models (ACT-R Workshop, 2012).

To both reconcile the difficulties in previous implementation of associative learning and show how we can constrain Bayesian-compatible inference in a cognitive architecture, we will now present a Hebbian-inspired associative learning rule influenced by spike-timing dependent plasticity (STDP; Caporale \& Dan, 2008).

\section*{Hebbian-Inspired Associative Learning Rule}

The major issues with the Bayesian associative learning rule were the reliance on ratio-driven log-likelihoods and the fact that context \(\left(C_{j}\right)\) was a global term which altered \(S_{j i}\) whenever a new chunk was created and whenever a production fired. This is due to the fact that low loglikelihoods become strongly inhibitory, and the generation of context-based ratios necessitates low-likelihoods in a long-running model. In short, this Bayesian account based on the Naïve Bayes Assumption does not adequately capture some of the features of associative learning such as locallydriven strengthening of associations and bounded decay.

An alternative framework is to eliminate the ratio function and remove the global nature of context, while also moving to a frequency-based algorithm instead of a probabilitybased algorithm. The former removes the aforementioned

\footnotetext{
\({ }^{2}\) After presenting this at the 2012 ACT-R Workshop, a flag was written in ACT-R to set a floor of 0 in the \(S_{j i}\) computation.
}
issues with scalability, while the latter eliminates \(S_{j i}=\) \(\lim _{x \rightarrow 0}(\ln x)=-\infty\), where \(x\) is the likelihood. That said, a benefit of using log-likelihood in probability space is that there is no need to squash activation strength (e.g., use a softmax rule to keep \(S_{j i}\) values from overwhelming \(B_{i}\) in the activation equation) because likelihoods cannot go above \(100 \%\) while frequency-based Hebbian activations can theoretically grow unbounded. Thus, the switch to frequencies is about reshaping the range of \(S_{j i}\) values and making \(S_{j i}\) independent of changing global context.

Basing associative learning on frequencies also adds a more Hebbian flavor to the algorithm. Learning, rather than being a global property of the system (as in the Bayesian mechanism) is instead a local property based on cooccurrence and sequential presentation. As previously discussed, our Hebbian-inspired mechanism is influenced by STDP. Unlike traditional Hebbian implementations which simply give a bump to association so long as the presynaptic and post-synaptic neurons both fire within a given temporal window, in STPD if the pre-synaptic neuron fires before the post-synaptic then the association is strengthened (long-term potentiation; LTP). Conversely, if the postsynaptic neuron fires before the pre-synaptic then the association is inhibited (long-term depression; LTD).

This theory of neural plasticity was adapted to our modeling approach by assuming that the sources of activation from chunks in buffers act similarly to presynaptic firings, and the set of chunks in the buffers at the time the new chunk is retrieved is similar to post-synaptic firings. The associative learning rule fires when a request is made to retrieve a chunk from declarative memory. First, a positive phase occurs (LTD; or Hebbian) where the current contents of the buffers spread activation and a new chunk is retrieved. The association between this new chunk and the sources of activation are strengthened according to standard Hebbian learning rules. However, once this new chunk is placed in the retrieval buffer, a negative phase occurs (LTP; or anti-Hebbian) where the retrieved chunk will negatively associate with itself and with its context. In formal terms:
\[
\begin{aligned}
\Delta S_{j i} & \alpha \cdot F\left(N_{i} \mid C_{j}^{p r e}\right) \\
\Delta S_{j i} & =-\alpha \cdot F\left(N_{i} \mid C_{j}^{\text {post }}\right)
\end{aligned}
\]
where \(\alpha\) is a Hebbian learning term, \(F\left(N_{i} \mid C_{j}^{\text {pre }}\right)\) is the context of source chunks \(C_{j}^{\text {pre }}\) at the time of the retrieval request for chunk \(N_{i}\), and \(F\left(N_{i} \mid C_{j}^{\text {post }}\right)\) is the context of chunks \(C_{j}^{\text {post }}\) after chunk \(N_{i}\) has been retrieved. Note that only changes in context will have a net \(\Delta S_{i i}\) due to the balanced positive and negative learning phase. Furthermore, these associations are not symmetric (i.e., \(S_{j i} \sim=S_{i j}\) ).

This balanced Hebbian/anti-Hebbian mechanism is geared towards developing a local, scalable learning rule while maximizing neural plausibility by incorporating a negative inhibitory learning phase. We argue that this inhibitory phase, while seemingly unintuitive \({ }^{3}\), is actually a relevant

\footnotetext{
\({ }^{3}\) Some have found the notion of a chunk being self-inhibitory very unintuitive, because it conflicts with the idea that a chunk should be maximally similar to itself and self-activating.
}
and necessary mechanism to account for refractory periods in neural firings.

An advantage of this Hebbian-inspired implementation is that it avoids the inhibitory associations of low loglikelihoods, but the learning rule requires a form of softmax equation (either driven by expectation or more simple decay/inhibition) to keep \(S_{j i}\) values from overwhelming base-level \(B_{i}\) (i.e., from the likelihood overwhelming the prior, in Bayesian terms). At the micro/neural level, softmax approximates a maximum likelihood, while at a macro/ behavioral level, softmax simulates learning as expectation violation. In Bayesian terms, the more active (c.f., likely) the existing association between chunks \(A \rightarrow B\), then the less marginal increase in \(S_{j i}\) when chunk \(A\) is a source in the retrieval of chunk \(B\).

There are several beneficial effects from this kind of implementation. The first is that the mechanism is more balanced and geared towards specializing associative activations rather than just increasing all activations. Thus, the mechanism is more stable as it grows (i.e., it will not tend towards all associations becoming either strongly excitatory or inhibitory; \(S_{j i}\) doesn't vary with number of chunks in memory). Second, since the retrieved chunk selfinhibits, this reduces the chance that it will be the most active chunk in the following retrieval request (due to recency effects), which can cause models to get into selffeedback loops. In short, this inhibition leads to a natural refractory period for retrieving a chunk. Third, by selfinhibiting and spreading activation to the next context, it provides a forward momentum for the serial recall of chunks. Combined with recency and frequency of base level, this provides a mechanism for automatic serial recall of lists without the need for coding of explicit positional information (something required in prior models of list memory; Anderson et al., 1998) and marking of previously retrieved chunks through finst-like mechanisms. The uniqueness of the subsequent context drives order effects.

There are still, however, several design decisions and more empirical justification required in order to strengthen the constraint argument. Currently, the softmax learning term is based on ACT-R's base-level learning equation. However, several candidate equations need to be compared against human performance data to determine the best possible match. Furthermore, existing models of list memory and sequence learning need to be re-envisioned in terms of the new associative learning mechanism.

In summary, this balanced Hebbian/anti-Hebbian learning mechanism avoids the issues of scalability (e.g., runaway activations) that have been associated with prior implementations of associate learning in ACT-R. In addition, this mechanism is constrained by neural plausibility constraints, can still be discussed in Bayesiancompatible terms, and fits within the Bayesian description of ACT-R's sub-symbolic activation.

\section*{Discussion}

This paper has described how a functional cognitive architecture can constrain Bayesian inference by tying
neurally-consistent mechanisms into Bayesian-compatible sub-symbolic activations. This combination of grounded implementation- and algorithmic-level functions into cognitive-level Bayesian inference defuses many criticisms of Bayesian inference, and provides a launch-point for future research into constraining the Bayesian framework across all three levels of Marr's hypothesis. An example of this research was provided by examining a novel implementation for associative learning in ACT-R. In addition to the sub-symbolic layer being driven by Bayesian mathematics, it is also compatible with neural localization and the flow of information within the brain.

It has been argued that ACT-R's numerous parameters don't really provide the kind of constraint necessary to avoid the criticisms discussed in this paper (Tenenbaum et al., 2011). However, the use of community and researchjustified default values, the practice of removing parameters by developing more automatized mechanisms (such as the associative learning replacing spreading activation), and the development of common modeling paradigms mitigates these criticisms by limiting degrees of freedom in the architecture and thus constraining the kinds of models that can be developed and encouraging their integration. In summary, the evolution of the architecture is not a process of invalidation, but instead moving towards more constrained and more specific explanations.

As we have argued, the associative learning mechanism is an attempt to increase constraint within the architecture and promote a broader explanatory power to numerous cognitive phenomena. This mechanism is geared towards specializing associative strength to capture both symbolic and nonsymbolic associative learning. A major contribution of this mechanism is its balance between Hebbian (LTP) and antiHebbian (LTD) learning at each retrieval request, which provides numerous benefits over traditional Hebbian and Bayesian implementations.

\begin{abstract}
The relationship between the notion of information in information theory, and the notion of information processing in cognitive science, has long been controversial. But as the present paper shows, part of the disagreement arises from conflating different formulations of measurement. Clarifying distinctions reveals it is the contextfree nature of Shannon's information average that is particular problematic from the cognitive point of view. Context-sensitive evaluation is then shown to be a way of addressing the problems that arise.
\end{abstract}

\section*{Introduction}

One of the longest standing puzzles of cognitive science is what to think about information theory. Set out in its standard formulation more than 60 years ago, this framework (Shannon and Weaver, 1949) is acknowledged to be a remarkably general and precise area of mathematics. So it is of great interest to discover whether the notion of information developed in information theory has anything to do with the notion of information processing at the heart of cognitive science.
In the original publication, Shannon notes that 'the semantic aspects of communication are irrelevant to the engineering aspects' (Shannon and Weaver, 1949, p. 31). On the assumption that information processing in cognitive science deals with semantic aspects in particular, a fundamental disconnect seems implied. But this is muddled somewhat by the qualification (in Weaver's contribution to the joint publication) that Shannon's assertion 'does not mean that the engineering aspects are necessarily irrelevant to the semantic aspects' (Shannon and Weaver, 1949, p. 8). Adding to the ambiguity, researchers such as Meyer (1957/1967), Miller (1953), Garner (1962), Mackay (1956) and Attneave (1959) note a range of ways in which issues of a semantic nature can be addressed in information-theoretic terms. Quinlan (1993) and others demonstrate algorithms that operate specifically on this basis. Recent decades have also seen increasing use of information-theoretic quantification in cognitive neuroscience (e.g. Tononi et al., 1996; Lungarella et al., 2005; Friston, 2010).

The range of positions adopted on this issue deepens the mystery. Haber (1983) argues that informationtheoretic measures cannot address psychological questions due to being 'entirely independent of the recipient' (Haber, 1983, p. 71). Temperley (2007), on the
other hand, takes the view that the difficulty with them is they are calculated purely from the perspective of the recipient. Luce takes the view that information theory cannot address questions about structural representation of content because the 'elements of choice in information theory are absolutely neutral and lack any internal structure' (Luce, 2003, p. 185). On the other hand, a community of researchers examines ways in which information-theoretic quantification can explain emergence of structural representation in sensory processing (e.g. Attneave, 1959; Barlow, 1961; Uttley, 1979; Srinivisan et al., 1982; Atick, 1992).

For Haber, it is beyond dispute that 'the demise of information theory in psychology' has already occurred (Haber, 1983, p. 71). But intermediate positions are also common. Barwise notes that while 'traditional information theory is not a semantic theory at all' it 'puts important constraints on cognitive theories' (Barwise, 1983, p. 65). Churchland and Churchland (1983) are more positive still, seeing information theory as having a significant 'role to play in an account of cognition' (Churchland and Churchland, 1983, p. 67), and arguing the connection can be made through something called 'calibrational content' specifically, where this is defined to be informationally quantifiable 'measurement or detection concerning the status of the objective world' (Churchland and Churchland, 1983, p. 67). Others are doubtful of there being any connection at all. Dretske, for example, argues that information theory does not even 'deal with information as it is ordinarily understood' (Dretske, 1983, p. 56). \({ }^{1}\)

The present paper argues that one of the reasons the situation has become so confused is that the debate has conflated different formulations of measurement. \({ }^{2}\) The notion of measurement at the heart of the framework is the logarithmic principle, originally proposed by Hartley

\footnotetext{
\({ }^{1}\) Curiously, this view is part of an informational epistemology. However, Dretske's hard-line is consistent with the fact that his account has little in common with information theory (Sayre, 1983). In Kyburg's view 'Dretske seeks to clothe a relatively traditional approach to epistemology in new information-theoretic clothes' (Kyburg and Jr, 1983, p. 72).
\({ }^{2}\) I ignore areas of the framework (concerned with noisy and/or non-discrete systems) that have not figured in the debate.
}
(1928). There is also the probabilistic formulation of the logarithmic principle: \(-\log p\). Finally, there is the averaging formula
\[
-\sum_{x} p(x) \log p(x)
\]

This is called the entropy. These formulations build on each other. The averaging formula uses the probabilistic formulation, which is itself based on the logarithmic principle. \({ }^{3}\) But the three formulations have different implications for the question of connectivity with cognitive science.

The position often taken is that there is one form of information-theoretic quantification, and it is the averaging formula. Information measurement is taken to involve calculations of entropy specifically (e.g. Dretske, 1983; Sayre, 1983; Luce, 2003). This may be a consequence of the extent to which the results of (Shannon and Weaver, 1949) are derived by means of this formulation. But these results involve objectives of telecommunications specifically. Regarding the objectives of cognitive science, the logarithmic principle and the probabilistic formulation are equally of interest.

The present paper reviews the steps that lead from the logarithmic principle to Shannon's averaging formula. Account is taken of the semantic implications of different stages of the argument. Some aspects of the connectivity debate are clarified along the way, and consideration is given to the problems that arise from the use of context-free forms of measurement. Derivation of context-sensitive quantities is shown to be a viable alternative, and some examples are set out that show how this approach connects to the representational concerns of cognitive science.

\section*{Context-sensitive information}

Mathematical quantification of information begins with the logarithmic principle. Proposed originally by Hartley (1928), this has a number of foundations, as reviewed by Shannon (Shannon and Weaver, 1949, pp. 31-33). Where an outcome is within a known set, the informational value must relate to the number of outcomes in the set. A simple way of measuring the informational value of something that reveals a particular outcome is thus in terms of the number of possible outcomes that might have been revealed. This is a potential way to measure the informational value of a 'message' to a 'receiver' then, to use Shannon's own terminology. But as Hartley points out, it is much better to use a logarithmic function of the number of outcomes. This yields a measurement in which the quantity of information is also the number of digits needed to identify the outcome,

\footnotetext{
\({ }^{3}\) In practice, Shannon derives the entropy formula as the only acceptable way of measuring the 'choice' permitted by a distribution.
}
provided the same base is used for logarithm and digits. The usual approach uses base 2 . The quantify of information can then be stated in terms of 'bits' (short for BInary digiTS). The measure quantifies both the amount of information obtained, and the number of binary digits needed to encode the outcome.

On the logarithmic principle, then, the informational value of anything that reveals one of \(n\) outcomes is just \(\log n\). To obtain a value measured in bits, we take the logarithm to base 2. (Use of this base is assumed henceforth.) The process can be illustrated using any set of mutually exclusive outcomes. Let's say a new regulation requires Wi-Fi hotspots to be classified according to level of service, with the possible classifications being W1, W2, W3 and W4. Given there are four possible outcomes, the informational value of anything that gives the classification of a hotspot is then \(\log 4=2\) bits. This is also the number of base 2 (binary) digits required to identify a classification.

An advantageous property of the logarithmic principle is that it generalizes straightforwardly to the case where outcomes have different probabilities. Instead of defining the information obtained from a one-in- \(n\) outcome as \(\log n\) bits, it can be defined more generally as \(-\log p\) bits, where \(p\) is the probability of the outcome. This accommodates the simple case of equiprobable outcomes, since \(-\log \frac{1}{n}=\log n\). But it also accommodates there being a mixture of probabilities.
Let's say Wi-Fi hotspots are classified as W1 with probability \(\frac{1}{2}\), as W2 with probability \(\frac{1}{4}\), and as W3 and W4 with probability \(\frac{1}{8}\). The discovery that a hotspot has a W4 classification is more informative in the sense of being contrary to expectation, than observing it has a W1 classification. This is reflected in the information value obtained. The value of a W1 classification is just \(-\log \frac{1}{2}=1\) bit, whereas the informational value of a W4 classification is \(-\log \frac{1}{8}=3\) bits.

The probabilistic formulation of the logarithmic principle also provides the means of calculating averages. Given \(p(x)\) is the probability of outcome \(x\), the average informational value of an outcome is the weighted average
\[
\begin{equation*}
-\sum_{x} p(x) \log p(x) \tag{1}
\end{equation*}
\]

This is the entropy formula, centrepiece of Shannon's development of the logarithmic approach. It can be used whenever there is a probability distribution over outcomes. The distribution for Wi-Fi hotspots yields an average information value of 1.75 bits, for example.

The average information has a number of appealing properties. It can be seen as measuring the uncertainty that exists with respect to the outcomes, in the sense of quantifying the 'choice' allowed by the distribution (Shannon and Weaver, 1949, p 48-53). As a weighted
average, it can also be seen as defining the information that an outcome is expected to have. Given \(-\log p\) is an encoding cost, we can also look at the formula as the average cost of encoding an outcome. (Shannon proves the average cost can be no less: Shannon and Weaver, 1949, p. 62-64).

It is important to notice, however, that this approach makes no distinction between subjective and objective perspectives. In order for probability \(p(x)\) to be what fixes the amount of information an agent obtains from outcome \(x\), this must be the probability the agent attributes to \(x\). On this basis, \(p(x)\) is subjective. But where it is used in the averaging formula, \(p(x)\) becomes the objective probability of \(x\). In fact, Shannon's framework makes no distinction between subjective and objective probabilities. In the telecommunications context that is the framework's main focus, this makes sense. A telecommunications device adopting a personal perspective would be worthless. In other contexts, however, subjective factors may be of more relevance. It is of interest, then, to consider ways in which context-sensitive information values can also be calculated.

Consider the case where there is a set of two outcomes, both of which have information values calculated in an objective way (i.e., by the logarithmic principle). A context-sensitive value can then be calculated for any distribution attributed, and any outcome arising. This is just the expected value of the distribution in regard to the outcome. On the principle that probability attributed to the given outcome must increase the distribution's value, while probability attributed to any other outcome must decrease it, the expected information is a weighted average in which outcome values are either positive or negative:
\[
I\left(P_{S}\right)=\sum_{x \in S} P_{x} \begin{cases}I(x) & \text { if } x \text { is given }  \tag{2}\\ -I(x) & \text { otherwise }\end{cases}
\]

Here, \(S\) is the set of outcomes, \(P_{S}\) denotes the distribution attributed, and \(I(x)\) is the informational value of outcome \(x\). (Calculated by the logarithmic principle, \(I(x)=\log |S|)\).) This formula is valid whenever there are just two outcomes. Where there are more than two, the number of outcomes not given is greater than 1, and thus greater than the number given. It is then necessary to ensure commensurability between additions and subtractions by normalizing the latter with respect to \(|S|-1\), the number of non-given outcomes. The general form of the context-sensitive evaluation is thus
\[
I\left(P_{S}\right)=\sum_{x \in S} P_{x} \begin{cases}I(x) & \text { if } x \text { is given }  \tag{3}\\ -\frac{I(x)}{|S|-1} & \text { otherwise }\end{cases}
\]

This is the expected information value of distribution \(P_{S}\) to the attributing agent, where a particular element
of \(S\) is given, and all outcomes have known information values. It can also be seen as measuring the degree to which the distribution predicts the outcome in question.

Context-free evaluation of information (e.g., Eq. 1) is valid in most situations. Hence the generality of Shannon's framework. But where subjectivity is a possibility, context-sensitive evaluation (by Eq. 3) is entailed. The effects of evaluating information inappropriately can be illustrated using the hotspots example again. Let's say a particular agent expects every hotspot to be a W1. The agent attributes a probability of 1 to the W1 classification, and a probability of 0 to W2, W3 and W4. In objective reality, however, not all hotspots are W1: at least one is classified as W2. There is a subjective context, then, requiring amounts of information to be calculated in a context-sensitive way.

Should we choose to evaluation information in a context-free way regardless, the results are likely to be meaningless. The attributed distribution places all probability on one outcome. Its entropy is zero. On the strength of this, the average informational value of each outcome is deemed to be zero bits. This is appropriate in the case of a W1 classification, since the agent deems this to be the outcome in all cases. Unfortunately, it is also the value in the case of a W2 classification, which is a case the agent deems to be impossible.

This nonsensical result is a consequence of applying context-free evaluation to a situation in which there is a subjective context. On the context-free interpretation, there cannot be a W2 classification: its assumed probability is zero. Given the subjective perspective that is in force, context-sensitive evaluation using Eq. 3 is required. This produces a result that makes more sense. The context-sensitive value is found to be 1 bit for a W1 classification, and \(-\frac{2}{3}\) bits for any other classification. Notice the potential for negative context-sensitive values, in contrast with context-free (entropy) values, which are always non-negative.
The general difficulty that arises for cognitive science will then be evident. Situations of interest for this discipline involve subjectivity by definition. The tendency to equate information-theoretic evaluation with contextfree measurement is thus an obstacle. But there is another aspect to the problem. Both context-free and context-sensitive forms of evaluation are calculated with regard to a set of mutually-exclusive outcomes. The evaluations obtained depend solely on probabilities attributed, and the number of outcomes in the set. The difficulty is that each outcome has the potential to signify something completely different. Information values reflect the original outcomes, rather than any interpretations that may be forthcoming, however. Where an additional semantics is imposed on outcomes, both contextfree and context-sensitive values may be meaningless in relation to the interpretations that apply.

Evaluations that are context-sensitive in the sense of being calculated by Eq. 3 may thus fail to be contextsensitive with regard to an imposed semantics. There are thus two ways in which information-theoretic evaluations can be inadequate from the cognitive point of view. The semantic disconnect that commentators such as Luce (2003), Haber (1983) and Dretske (1983) see as inherent in information theory originates in these two ways.

\section*{Illustrations}

A useful context for illustrating context-sensitive evaluation is that of weather forecasting. Imagine we live in a world where the weather has just two outcomes: rain and sun. Let's say the forecast issued by the local met office for a particular day is showery, and that this signifies \(60 \%\) chance of rain, and \(40 \%\) chance of sun. Assume the outcome is rain. Eq. 3 can then be used to obtain a context-sensitive value for the attributed distribution given this particular outcome. With the forecast being showery, rain is predicted with probability 0.6 . The outcome is in fact rain, and the information value of each outcome is assumed to be \(\log 2=1\) bit. The context-sensitive value of the distribution is thus \((0.6 \times 1)-(0.4 \times 1)=0.2\) bits. If the outcome is sun, on the other hand, the value is \((0.4 \times 1)-(0.6 \times 1)=-0.2\) bits.

Figure 1: Context-sensitive evaluations.

The diagram of Figure 1 illustrates the two cases considered. In this and ensuing schematics, outcomes are represented by small circles, labeled with the outcome's name and informational value. Circles are filled where the outcome is given. Circles enclosed within the same bar are within the same choice of outcomes: the bar represents the choice. Where one outcome signifies a distribution over others - e.g., showery specifying rain with probability 0.6 - the relationships are indicated using connecting lines. Annotations placed over these lines show the probabilities that are attributed.

The figure shows evaluations of the showery distribution for the two outcomes rain and sun. Notice how the values reflect the degree to which the distribution predicts the outcome given. The evaluation is negative where the implied distribution mispredicts the outcome, and positive otherwise. At the same time, its relatively indiscriminate nature ensures both values are small compared with those of the outcomes themselves.

Figure 2: Derived evaluation of outcomes.

In the illustrated scenario, distributions are signified by entities (i.e., forecasts) that are themselves outcomes. By definition, these inherit the informational values of the distributions they designate. Any higher-level distribution must then be evaluated in terms of the derived values of predicted outcomes. To illustrate, let's say that in a certain season the forecast is always either showery or bright, with the latter meaning \(20 \%\) chance of rain and \(80 \%\) chance of sun. Context-sensitive values for these forecasts are then derived as in Figure 2. Potentially there can then be a second level of structure. A forecast of unsettled might mean \(70 \%\) chance of showery and \(30 \%\) chance of bright. The context-sensitive value of this forecast would then be calculated in terms of the derived values of showery and bright, rather than values obtained by the logarithmic principle.

\section*{Analysis of representation}

Context-sensitive evaluations can be calculated wherever we have both a distribution and a given outcome. Where one outcome signifies such a distribution itself, the value obtained also belongs to the signifying outcome, as noted above. Context-sensitive evaluations can thus be a way of evaluating probabilistic representation. Such evaluations can be made at multiple levels. Where one outcome signifies a distribution over several others, one of which does the same thing, there are two levels of representation. The latter is embedded within the former. Context-sensitive measurement of information is a way of evaluating outcomes at multiple levels of representation.

An assembly of signifying outcomes is a kind of representation structure, then. Such structures can take any form we like. For example, we might configure a representation structure in a way that expresses a category hierarchy. Let's say we have three categories as follows: a fruit category, in which the members are apple and plum; a bread category in which the members are pita and bun, and a food category in which the members are fruit and bread. To express this category hierarchy as a representation structure, categories must be treated as linked outcomes. Since category members are equiprobable instances of their category, member outcomes are always

Figure 3: Representation structure in the form of a category hierarchy.
equiprobable attributions of the corresponding category outcome. The representation structure expressing the category hierarchy is thus the one of Figure 3. (Notice this diagram tabulates the probabilities involved, rather than displaying them on an individual basis.)

Regardless of what a representation structure expresses, it retains its capacity for informational evaluation. This can be a way of explaining the functionalities that are forthcoming. Where a representation structure is arranged as a category hierarchy, for instance, there is the possibility of explaining classifications mathematically. Classifying an outcome in a particular way can be seen to identify the category outcome with the highest context-sensitive evaluation.

Consider the values that are obtained in the representation structure of Figure 3, where apple is given. These are shown in Figure 4. The context-sensitive value of the correct classification (fruit) is 0.67 bits, whereas the value of the incorrect classification (bread) is -0.67 bits. The classification can be explained as identifying the most informative category outcome.

Representation structures can be arranged in a broad range of ways and can thus express any model constructed in terms of representational relationships. Their probabilistic foundation means they can represent conventional Bayesian models, for example. Being able to incorporate multiple levels of representation, they can express hierarchical Bayesian models. Another possibility is schematic models, involving representational relationships of a conjunctive nature.

Consider a schematic model in which a particular entity is considered to be a combination of other enti-

Figure 4: Context-sensitive evaluation as classification.
ties. Viewed as a representation structure, this is a case in which one outcome designates multiple distributions, each of which concentrates probability on a single outcome. Such cases can be analyzed using context-sensitive evaluation in the usual way. But in so doing it is necessary to take the possibility of multiple designations into account. This must be done in accordance with the principle that information can be summed only if is independent. Where distributions are not independent, the evaluation obtained is the maximum (i.e., greatest independent value) rather than the sum of values arising.

Figure 5: Representation structure with disjunctive and conjunctive elements.

Figure 5 extends the bread/fruit scenario to illustrate what happens where representation structure includes conjunctive designations of this type. The bread/fruit structure from the previous diagram is seen here in the lower-left corner. At the same level of representation,
there is a cake/crumble choice. At the top level of representation, the outcome fruitcake is specified in a way that requires both fruit and cake. The effect is to reproduce the conjunctive character of a schema. As previously, the evaluations arising can explain classifications. If apple and cake are both given, the context-sensitive value of fruitcake is 1.67 bits. In the case of fudgecake, the value is 0 bits. Classifying a composite of apple and cake as fruitcake is then explained in terms of this category being most informative for the given context.

\section*{Conclusion}

The traditional objection to use of information theory in cognitive science has been the assumption that it does not deal with semantic aspects of information. On close examination, this is found to be an over-simplification. Where information values are calculated by means of the entropy formula, they are context-free in the sense of ignoring any element of subjectivity. They may also be context-free in the trivial sense of ignoring a superimposed semantic interpretation. The latter problem can be resolved simply by outlawing such applications. The former can be resolved by pursuing evaluation in a way that takes subjective context into account. On this basis, information-theoretic evaluation can be of relevance to cognitive science. Specifically, it can be a way of mathematically explaining category representation.

\begin{abstract}
We investigated whether emotions are activated during comprehension of emotion words. In the first part of the study, an experiment was conducted in which participants read sentence pairs each describing an emotional state and then engaged in a judgment task. Sentences were paired to either match or mismatch in emotion (happy, sad, or angry). We predicted that the sentences that mismatch in emotion produced longer reaction times than those where the emotion was the same, and that shifts between negative emotions had less of an impact. In the second part of the study, we calculated the frequency of first-order co-occurrences of nouns and adjectives related to happy, sad, and angry emotional states. This analysis demonstrated emotion words are more often accompanied by similar emotion words. Match and mismatch of emotion explained RTs as did statistical linguistic frequencies of the words. The combination of these two studies contributes to a growing body of research that supports the importance of both symbolic and perceptual processing of emotion.
\end{abstract}

Keywords: emotion; embodied cognition; symbolic cognition; statistical linguistic frequencies.

\section*{Introduction}

Theories of embodied cognition claim that cognition is fundamentally based in perceptual experiences. That is, concepts only become meaningful through comprehenders mentally reenacting prior physical and perceptual experiences with the concept in the real world (Barsalou, 1999; Barsalou, Simmons, Barbey, \& Wilson, 2003; Glenberg \& Kaschak, 2002; Pecher \& Zwaan, 2005; Havas, Glenberg, \& Rinck, 2007; Semin \& Smith, 2008). For instance, Glenberg and Kaschak (2002) proposed the action-
sentence compatibility effect whereby language processing is facilitated when a congruent response motion is used to respond to sentences describing motion away from or towards the body. That is, sentences describing motion away from the body (e.g., close a drawer) were processed faster when response motions were also moving away from the body, and vice versa. These results and findings similar to these demonstrate that linguistic processing is facilitated through perceptual-motor information (see Leventhal, 1982 for an overview).

Similar to action related sentences, sentences with emotional content have also provided support for an embodied cognition account. Mouilso, Glenberg, Havas, and Lindeman (2007) found that reading 'angry' sentences resulted in faster movements away from the body and reading 'sad' sentences resulted in faster movements toward the body. In other words, when people read angry content, they processed the sentence faster with an aggressive action toward it, whereas 'sad' sentences evoke a withdrawal action, suggesting that emotional language can affect bodily responses.

Embodied responses have also been linked to cognition through the facial feedback hypothesis (Strack, Martin, \& Stepper, 1988; Zajonc, Murphy, \& Inglehart, 1989). The facial feedback hypothesis demonstrates that facial expressions might influence emotional assessments. For example, when participants were instructed to smile, cartoons were perceived as more humorous than when subjects were not smiling (Strack et al., 1988), showing that bodily states can affect both judgments and cognition.

Most literature supporting an embodied cognition account, however, demonstrates evidence without physical manipulation. For example, Pecher, Zeelenberg, \& Barsalou
(2003) found that subjects read sentences describing features within the same modality faster than sentences describing features of differing modalities. When participants read a sentence like apples can be tart followed by the sentence apples can be sweet (describing the same gustatory modality) response times were faster for the second sentence when the second sentence did not describe a shift in modality, such as is the case when a visual modality was presented in strawberries can be red or radios can be loud. The modality of the target words impacted how those words were perceived. Processing costs incurred from the mismatched sentences resulted from a perceptual modality shift, suggesting that perceptual embodied features indeed impact language processing times.

Recently, the modality switching costs have been explained by language statistics (Louwerse \& Connell, 2011). By computing the word frequencies of the cooccurrences of modality words from a large corpus of English, Louwerse and Connell were able to identify modality shifts similar to Pecher et al. (2003). This analysis was not only applicable to the adjectives (e.g., tart - sweet being more frequent than tart - red or sweet - red), but also to concept words (e.g., apples - strawberries being more frequent than apples - radio or strawberries - radio). Louwerse and Connell (2011) showed that these frequencies explained the response times that were attributed to an embodied cognition account. That is, faster response times were best explained by language statistics, slower response times were best explained by perceptual simulations. Louwerse and Connell's explanation was that the linguistic system offers a 'quick and dirty' shallow heuristic that can provide good enough performance in cognitive tasks without recourse to deeper conceptual processing in a perceptual simulation system. On the other hand, ultimately concepts are grounded and can be perceptually simulated. The explanation by Louwerse and Connell can be captured in the Symbol Interdependency Hypothesis, which proposed that conceptual processing can be explained by both symbol and embodied mechanisms (Louwerse, 2007; 2008; 2011). When we encounter a word, we garner a rough meaning from its linguistic (symbolic) neighbors using language statistics, but to fully ground the word, we perceptually simulate its physical and somatosensory features. Thus, words can rely on other words to establish a fuzzy sense of meaning without necessarily always being grounded themselves. In other words, perceptual information is encoded in language, such that mental representations are both perceptual and linguistic. Human beings can rely on such a linguistic short-cut when processing language in real time. However, if a deeper meaning or understanding is needed, grounding the world in perceptual experiences provides rich sensorimotor information about meaning. Importantly, language has encoded sensorimotor information, such that language users can utilize these cues in cognitive processes.

In short, the Symbol Interdependency Hypothesis proposes the following: 1) language encodes perceptual
information; 2) language users rely both on language statistics and perceptual simulation in cognitive processes; 3) the relative dominance of language statistics and perceptual simulation factors is modified by stimulus type and task.

Although modality shifts have been shown to support the Symbol Interdependency Hypothesis (Louwerse \& Connell, 2011), the question can be raised whether the finding for modality shifts can be extended to other semantic domains that have shown embodiment effects, such as emotions. In the current study we investigated whether (a) verifying properties from different emotions for concepts produces switching costs, similar to the modality shifts; (b) whether language has encoded the emotions of words, similar to the modality of words; (c) whether emotion shifts can be explained by a language statistics account.

To explore these questions we applied Pecher et al.'s (2003) modality shift paradigm to emotions. Emotional sentences shifted from happy to sad, sad to happy, happy to angry, angry to happy, sad to angry, and angry to sad. According to an embodied cognition account, switches between emotions should take longer to process than nonswitches (happy-happy, sad-sad, angry-angry). Alternatively, according to a language statistics account, cooccurrence frequencies of word pairs should be able to equally account for subject RTs. We thereby made two hypotheses: (1) as with modality shifts, emotion shifts would take longer to process than non-shift sentence pairs, which would be in support of an embodied cognition account and (2) the same pattern of emotion shift cost would emerge from language such that emotion words that matched in valence would co-occur more frequently than the words that did not match in valence, which would be in support of a linguistic account.

\section*{Experiment 1: Emotion Shift}

\section*{Method}

Participants Thirty-three undergraduate students enrolled in an introductory psychology course participated for course credit.

Materials Sixty emotion sentences were created, following the method described in Pecher et al. (2003) with each sentence in the format \(X\) can be \(Y\). There were 3 experimental types of emotions depicted in the sentences: angry, happy, and sad. For example, birthdays can be happy (happy emotion), and insults can be devastating (sad emotion).

The reason we selected angry, happy, and sad emotions was motivated by work from Isenhower et al. (2003) who found that people tend towards more positive states of emotion. That is, switching from positively valenced to negatively valenced emotions yields a greater disruption and requires additional cognitive processing. Further motivation came from a more recent study by Stein and Sterzer (2012). In this study, Stein and Sterzer demonstrated that people identify happy faces more quickly than angry faces. We
therefore selected happy, sad, and angry words, and thus had one positively valenced emotion (happy) and two negatively valenced emotions (sad and anger).

Procedure Participants were seated at a computer in a standard computer lab. The instructions for the experiment were presented on the screen and read aloud by the experimenter. Five practice items preceded the experimental phase to ensure participants understood the task. Participants saw sentences one at a time in the center of the screen and then were asked to respond to the question Is the characteristic true of the items it described? Participants pressed designated yes or no keys on the keyboard. RT and accuracy were recorded.

\section*{Results}

Incorrect responses were not included in the analyses. RT outliers were defined as 2.5 SD above the mean per subject per condition and were removed from the analysis. This removal affected less than \(3.6 \%\) of the data.

A mixed-effect analysis was conducted on RTs with emotion shift as the fixed factor and participants and items as random factors (Baayen, Davidson, \& Bates, 2008). The model was fitted using the restricted maximum likelihood estimation (REML) for the continuous variable (RT). F-test denominator degrees of freedom were estimated using the Kenward-Roger's degrees of freedom adjustment to reduce the chances of Type I error (Littell, Stroup, \& Freund, 2002). Participants and items were treated as random factors in the analysis.

For the factor emotion shift no differences were found in RT, \(F(1,114)=.431, p=.513\). This is somewhat surprising given that an emotion shift was predicted to increase RTs akin to the modality shifts. However, when individual emotion pairs were separated by transition (e.g., happy-sad, happy-angry), RT differences were obtained with an emotion shift from happy sentences to sad sentences, \(F(1,421)=30.41, p<.001\), with slower RTs for the shift than no-shift (i.e., a happy sentence followed by a happy sentence). Also, when shifting from happy sentences to angry sentences a significant difference was found between the two conditions, \(F(1,380)=20.82, p<.001\), there were slower RTs for the emotion shift sentences than no-shift. When the sad to angry sentences were compared, again a difference approaching significance was found between emotion shift and no-shift conditions, \(F(1,455)=5.88, p<\) .056, where the shift between sentences yielded longer RTs than no-shift. In contrast, the comparison of sad to happy sentences yielded no significant differences between emotion shift and no-shift sentences, \(F(1,395)=.02, p<\) .89. When switching from angry to happy sentences, a significant effect was found, \(F(1,485)=20.69, p<.001\), again with faster RTs for the emotion shift sentences than no-shift. Finally, a significant effect was found when switching from angry to sad sentences, \(F(1,430)=5.05, p<\) .03 , however with faster RTs for the emotion shift sentences than the no-shift sentences.

In summary, a shift from happy to sad, happy to angry, sad to angry, and angry to happy yielded significant results, while the shift from sad to happy was not significant. Figure 1 shows the means and standard deviations for each emotion shift pair.

Even though no overall effect for emotion shift was found, patterns for specific emotion transitions did show shift effects, with specific emotion to emotion shifts resulting in longer RTs than non-shifts. More specifically, the shifts from happy to the two negative emotions, shows a significant increase in RT. The emotion shift from angry to happy was also significant, but showed a decrease in RT from angry followed by angry. This is in line with Stein and Sterzer (2012), who found that people are quicker to identify happy faces, rather than angry faces. We interpret this decrease in RT in terms of the nature of the shift. Angry followed by angry produces the longest RT, while happy followed by happy produces the shortest RT. As there is a tendency to prefer to shift toward a more positive state (Isenhower, Frank, Kay, \& Carello, 2010), the reaction times for the non-shifts reflected this. Moreover, the shift from angry to happy decreases from its origin (angry followed by angry), because of the natural tendency to shift to the more positive state. This is supported by the significant differences when emotion shifts took place between angry and happy, angry and sad, and sad and angry.

However, we still are unable to determine whether an embodiment effect exists for emotion switching, as there was no overall effect for shifts as there were for Pecher et al. (2003), but only specific emotion to emotion effects.

Figure 1. Emotion shifts, means, and standard deviations. ** \(p<.01, * p<.05, n . s\). not significant. The means and standard deviations located at the emotion words indicate no emotion shift (e.g., a happy sentence followed by a happy sentence).

To determine whether or not overall shifts for emotions occurred, we ran a second experiment whereby the
embodiment effect would be enhanced by an embodied facial feedback paradigm.

\section*{Experiment 2: Facial Feedback Hypothesis}

In order to determine if emotion switching indeed supports an embodied cognition account, we examined the effects of the facial feedback hypothesis (Strack, et al., 1988; Zajonc, et al., 1989) by assessing the effects different conditions (frowning or smiling) had on RTs when judging emotion shift sentences. We hypothesized that neither frowning nor smiling would produce a significant effect between the negative emotions (sadness and anger), due to the trend towards positive (Isenhower et al., 2010). In addition, we hypothesized that the specific emotion to emotion shifts found in Experiment 1 would show similar patterns.

\section*{Method}

Participants Twenty-six undergraduate students enrolled in an introductory psychology course participated for course credit.

Materials The same materials were used as in Experiment 1.

Procedure The procedure was the same as that used in Experiment 1, with one important addition. Participants were also randomly assigned to one of two facial feedback conditions (Strack et al., 1988). In the one condition, the participants held a pen in their lips \((n=15)\) to simulate frowning; in the other, the participants held a pen in their teeth ( \(n=11\) ) to simulate smiling.

\section*{Results}

As in Experiment 1, emotion shifts did not yield a significant difference in RT, \(F(1,117.27)=.16, p=.70\). Furthermore, there seemed to be no main effect of the facial feedback conditions, \(F(2,78.24)=.73, p=.49\). Next, we investigated the emotion transitions per facial feedback condition (smiling vs. frowning).

Frowning Facial Feedback When participants held the pen in their lips to simulate frowning, the shift from happy to sad was significant as it was in the previous experiment without the facial feedback task, \(F(1,236)=6.69, p=.01\), with higher RTs for the shift sentences than no-shift. The shift from happy to angry was also significant as found in the previous experiment, \(F(1,202)=8.36, p<.004\), with higher RTs for the shift sentences than no-shift. Also the shift from angry to happy was significant as previously found in Experiment 1, \(F(1,248)\) 4.31, \(p<.04\), with lower RT for the shift sentences than no-shift. Again, this is in line with Isenhower et al. (2010) and Stein and Sterzer (2012), in that the preference is to shift from a negative state to a positive state. This is especially true given the fact that participants were frowning due to the facial feedback task. The shifts from sad to angry and angry to sad were found to be non-significant, unlike the findings in Experiment 1. These results lend support to the facial feedback hypothesis, in that frowning (pen held in lips) is associated with both
sadness and anger; it would stand to reason why there were no significant differences between these two conditions as they are both negative emotions and the motor system necessary for their simulation was already active, facilitating the effect. Figure 2 shows the means and standard deviations for each emotion shift pair, the shift direction, and the no shift means and standard deviations.

Figure 2. Emotion shifts, means, and standard deviations for frowning facial feedback condition. \({ }^{* *} p<.01\), * \(p<\) .05, n.s. not significant.

Smiling Facial Feedback When participants held the pen in their teeth to simulate smiling, the shift from happy to sad was significant, \(F(1,168)=8.98, p<.003\), with higher RT for the shift sentences than no-shift . The shift from happy to angry was significant, \(F(1,164)=15.48, p<.0001\), with higher RTs for the shift sentences than no-shift. The shift from sad to happy approached significance, \(F(1,134)=3.81\), \(p<.053\), with lower RT for the shift sentences than no-shift. Finally, the shift from angry to happy was also significant, \(F(1,179)=17.84, \mathrm{p}<.001\), with lower RT for the shift sentences than no-shift. Again, the decrease in RT for angry to happy is in accord with Stein and Sterzer (2012). The shifts from sad to angry and angry to sad were not found to be significant. Figure 3 shows the means and standard deviations for each emotion shift pair, the shift direction, and the no shift means and standard deviations. The main difference between the smiling condition and the previous frowning condition is the significant difference found in the sad to happy shift, which was not found in Experiment 1, or the frowning facial feedback condition. This difference supports the findings by Isenhower et al. (2010), in that since people have a tendency to tend towards a positive state, which they have in part done by smiling.

Figure 3. Emotion shifts, means, and standard deviations for smiling facial feedback condition. \({ }^{* *} p<.01, * p<.05\), n.s. not significant

\section*{Corpus Linguistic Study}

So far, the results seem to suggest that emotional states can be based in embodied cognition, as some emotion to emotion shifts seem to indicate that emotion switching usually incurs some sort of processing cost. However, this is not the whole picture, as it does not take into consideration the linguistic nature of the words. We therefore investigated whether emotion shifts are encoded in language (Louwerse, 2008; Louwerse \& Connell, 2011). To do this we calculated the frequency of first-order co-occurrences of all the possible combinations of the nouns and adjectives in the present study by utilizing the Web 1T 5-gram corpus (Brants \& Franz, 2006). This corpus consists of 1 trillion word tokens (13,588,391 word types) from 95,119,665,584 sentences. The volume of the corpus allows for an extensive analysis of patterns in the English language. The frequency of co-occurrences of the word pairs was computed for bigrams, trigrams, 4 -grams and 5 -grams. For instance, the frequency of the phrase birthdays can be happy \{happy, birthday \(\}\) was determined by considering these words next to one another \{happy birthday\}, with one word in between \{happy w1 birthday\}, with two \{happy w1 w2 birthday\}, three intervening words \{happy w1 w2 w3 birthday\}, and so on.

A mixed effects analysis was conducted on the frequency of co-occurrences of the emotion adjectives and the noun referents. The independent variable was whether the emotion words were the same or different emotion, and the log frequency of the word pair was the dependent variable.

For all possible combinations of both nouns and adjectives, the log frequency of the co-occurrences were found to be significant, \(F(1,7078)=212.76, p<.001\), with word pairs where there was no emotion shift ( \(M=2.08, S E\) \(=.04)\) being more frequent than word pairs where an
emotion shift was present ( \(M=1.11, S E=.054\) ). This pattern was also found for just the nouns \(F(1,3479)=\) 148.11, \(p<.001\), with word pairs where there was no emotion shift ( \(M=4.29, S E=.08\) ) being more frequent than word pairs where an emotion shift was present ( \(M=2.60\), \(S E=.11\) ). Again, this pattern was found for adjectives, \(F(1\), 3598) \(=\) 279.17, \(p<.001\), with word pairs where there was no emotion shift ( \(M=2.53, S E=.05\) ) being more frequent than word pairs where an emotion shift was present ( \(M=\) \(1.00, S E=.07\) ).

In addition, we also compared the log frequencies of each of the word pairs to the experimental RT over the collapsed match and mismatch conditions (extracted from Experiments 1 and 2). Language statistics significantly predicted RTs, \(F(1,113.564)=34.53, p<.001\). However, language statistics did not predict emotional transitions. Statistical linguistic frequencies explained RTs of general emotion shifts, but not RTs of specific emotion transitions.

\section*{General Discussion}

Previous studies have found that two sentences that elicit a modality shift produce cognitive switching costs, compared to sentences that describe the same modality (Pecher et al., 2003). This finding has been reported as evidence for an embodied cognition account, because the increased RTs are an indication that comprehenders perceptually simulate the sentences. Others have shown that modality is encoded in language. Based on language statistics, concepts and their features can be categorized in visual, auditory, olfactory and gustatory modalities (Louwerse \& Connell, 2011). Moreover, when the RTs for modality shifts were investigated with both language statistics and perceptual simulation as independent variables, fast RTs were best explained by language statistics and slower RTs were best explained by perceptual simulation. Louwerse and Connell (2011) concluded that language statistics serves as a coarse-grained system that serves as a shallow heuristic. Perceptual simulation, on the other hand, serves deeper conceptual processing. The idea that language encodes perceptual information and that these linguistic cues can be used by language users in shallow comprehension tasks is predicted by the Symbol Interdependency Hypothesis and supported by various studies (Louwerse, 2008; Louwerse \& Hutchinson, 2012; Louwerse \& Jeuniaux, 2008; 2010).

The current study investigated whether emotion shifts mimicked the patterns found for previous studies investigating modality shifts. Even though across three experiments no general effect was found for shifts, specific transitions between emotions did yield differences in RTs. Moreover, evidence was found that language encodes emotion shifts, and language statistics explained RTs for these general shifts.

The findings of the current study are supported by the Symbol Interdependency Hypothesis as well as by findings reported in other studies. Language statistics explained coarse-grained emotion shifts. However, language statistics
did not explain fine-grained shifts. On the other hand, assuming that a perceptual simulation system is responsible for the other RT differences that were obtained in the two experiments, the perceptual system did not explain the coarse-grained differences in general emotion shifts, but did explain the fine-grained shifts between specific emotions.

These results provide further evidence for the theory that conceptual processing is both linguistic and embodied, whereby less precise linguistic processes account for general patterns in processing, whereas perceptual simulation provides the fine-tuning.

\title{
Geographical Estimates are Explained by Perceptual Simulation and Language Statistics
}

\begin{abstract}
Several studies have demonstrated that language encodes geographical information. That is, the relative longitude and latitude of city locations can be extracted from language. Whether people actually rely on these linguistic features is less clear. Recent studies have suggested that language statistics plays a role in geographical estimates, but these studies rely on map drawings, a fundamentally perceptual task. The current study investigated the extent to which people rely on map representations and statistical linguistic frequencies by using a linguistic task. Participants saw U.S. city pairs in their iconic positions (a more northern city is presented above a more southern city, or a more western city is presented to the left of a more eastern city), and in their reverse-iconic positions (a more southern city is presented above a more northern city, or a more eastern city is presented to the left of a more western city). For iconic city pairs both in the east - west (Seattle - Boston) and north - south (Memphis - Miami) configurations, RTs were determined by the iconicity. No effect was obtained for statistical linguistic frequencies. However, when city pairs were presented in a reverse-iconic configuration, for both horizontal (Boston Seattle) and vertical (Miami - Memphis) orientations, both perceptual and linguistic factors explained RTs. These findings support the idea that cognition relies on a shallow heuristic, a linguistic system, and a fine-grained and more precise perceptual simulation system.
\end{abstract}

Keywords: embodied cognition; symbolic cognition; geography; spatial cognition

\section*{Introduction}

Is San Francisco close to New York? Is Boston close to Miami? Judging the distance between cities can be approached in more than one way. This judgment can be deep and precise, as with perceptual simulation, or quick and shallow, as with symbolic representation. For instance, humans can make geographical estimates on the basis of their perceptual experiences from locomotion and stationary
viewing, from static pictorial representations, such as diagrams, paintings and photos, provided on a map, and they can acquire information via dynamic pictorial representations, including animations, and videos (Freundschuh \& Mercer, 1995).
The importance of a perceptual simulation system has been strongly advocated by accounts of embodied cognition (Barsalou, 1999; Barsalou, 2008; Glenberg \& Kaschak, 2002; Pecher \& Zwaan, 2005; Semin \& Smith, 2008). According to Barsalou, Solomon, and Wu (1999), perceptual states are transferred into memory and function symbolically, rather than an arbitrary representation such as language. As an example, overwhelming evidence in favor of an embodied cognition account has accumulated, showing that processing within modalities is faster than having to map across modalities, and suggesting that modality switching comes at a price (e.g., Marques, 2006; Pecher, Zeelenberg, \& Barsalou, 2003; Spence, Nicholls, \& Driver, 2001). Furthermore, language comprehension seems to be influenced by action representations primed in experimental tasks (e.g., Glenberg \& Kaschak, 2002; Kaschak et al., 2005; Klatzky, Pellegrino, McCloskey, \& Doherty, 1989; Zwaan, Stanfield, \& Yaxley, 2002), and visual representations get activated during language comprehension (see also Boroditsky, 2000; Fincher-Kiefer, 2001; Matlock, Ramscar, \& Boroditsky, 2005).

One particular study nicely illustrates the embodied cognition account. Zwaan and Yaxley (2003) presented iconic word pairs either as they occur in the real world, such as attic over basement, or the reverse-iconic orientation, such as basement over attic. They found significant differences between the iconic and reverse-iconic configurations of these word pairs. They concluded that the explanation for the iconicity effect was that words activate their perceptual representations (attics presented above basements are processed faster than basements above attics, because of their iconic relationship in the real world).

Louwerse (2008) questioned whether the Zwaan and Yaxley (2003) finding should be solely attributed to perceptual simulation. Statistical linguistic frequencies, the co-occurrence of words in a given frame, showed that items that are normally high in space preceded items that are normally low in space more frequently than vice versa, suggesting that language encodes spatial information (e.g., we say up and down, top and bottom, knees and toes, rather than down and up, bottom and top and toes and knees). Moreover, statistical linguistic frequencies explained RTs better than the perceptual factor. These findings demonstrate that there is a complementary linguistic explanation to a perceptual simulation explanation.

Louwerse and Jeuniaux (2010) showed that the extent to which cognitive processes can be explained by perceptual simulation or language statistics (frequency of word cooccurrence) depends on a variety of factors, including the nature of the stimulus (e.g., words versus pictures) and the cognitive task (e.g., shallow or deep cognitive task). In Louwerse and Jeuniaux (2010), participants saw either pictures or words in their natural orientation (e.g., ceiling above floor), or in their reverse orientation (e.g., floor above ceiling). Statistical linguistic frequencies were better able to explain RTs than perceptual ratings when the word pairs were used, with the reverse result when picture pairs were used. Similarly, when participants were asked to make a real-world judgment task, the effect for perceptual ratings on RTs was larger than that for statistical linguistic frequencies, with the opposite result for a semantic judgment task. Importantly, effects for both language statistics and perceptual simulation were found for both stimulus types and both cognitive tasks, however, their relative dominance was modified by task and stimulus.
These findings have been captured through the Symbol Interdependency Hypothesis, which proposed that conceptual processing can be explained by both symbol and embodied mechanisms (Louwerse, 2007; 2008; 2011). When we encounter a word, a rough meaning is elicited by using the linguistic, that is symbolic, neighbors. This is accomplished by using language statistics, where words that often appear together are related in important ways that can facilitate initial cognitive processing. In order to fully ground the word, we can mentally simulate the features of the word in order to process the word in a deeper way. Human beings can use the fuzzy sense of words by a linguistic (symbolic) short-cut when processing language as it occurs. In addition, language is encoded with sensorimotor and spatial information. The Symbol Interdependency Hypothesis is composed of three components. First, language encodes perceptual information. Second, during cognitive processes users of language rely on language statistics and perceptual simulation. Finally, the dominance of either language statistics or perceptual simulation is dependent on the type of task and stimulus.

Do these three claims also hold for spatial cognition within geographical representation? Using newspapers such as the New York Times and the Wall Street Journal

Louwerse and Zwaan (2009) were able to estimate the longitude and latitude of the largest cities in the US computationally, based on the idea that "cities that are located together are debated together." That is, by computing the \(n \times n\) frequencies of the co-occurrence of city names in the newspapers, a two-dimensional multidimensional scaling analysis yielded correlations with the longitude and latitude of the cities. The Louwerse and Zwaan (2009) findings are not limited to the English language. Louwerse, Hutchinson, and Cai (2012) found similar results using Arabic for predicting cities in the Middle East, and Chinese for predicting cities in China. It is interesting to note the presence of this effect was found for three languages each with different writing directions (English- left to right, Arabic- right to left, and Chinese, at least historically- top to bottom). This shows, at the least, that it is possible to map out cities in different locations, within different writing systems, by using the frequency of co-occurrences of city names within a large corpus.
Language encodes geographical information. The question is whether this also means that humans use these encodings. Louwerse and Zwaan (2009) stated that between \(16 \%\) and \(35 \%\) of the latitude and longitude variance in human location estimates can be attributed to linguistic coding. These percentages were found by using a bidimensional regression analysis correlating human and computational longitude and latitude estimates (by a large newspaper corpus). However, it is unclear whether \(84 \%\) and \(65 \%\) and of the latitude and longitude variance in human location estimates can be attributed to spatial information. Moreover, given that language encodes spatial information, it is difficult to disentangle linguistic and perceptual processes. It could be argued that proximity can explain estimation bias when determining distance between two locations (Tobler, 1970). However, Friedman, Kirkman, \& Brown (2002) tested this hypothesis by comparing latitude estimates by participants in Canada and Texas. Their findings did not support the proximity hypothesis, whereas participants in Texas exhibited greater bias in their estimates of Mexican locations than the participants from Canada. The explanations proposed by Friedman et al. included cognitively based beliefs, geopolitically based beliefs, and socio-culturally based beliefs. It was also argued by Brown (2002) that seeding effects can affect real-world judgments, such as proximity and size estimation of two cities. However, many of the experiments contained in Brown (2002) were designed for numerical estimates such as population, or how many square kilometers is for a given country. While they were robust and interesting effects, they do not necessarily apply here, because the tasks in the present study utilize the distance between two cities, not estimations of numbers about those locations.
Louwerse and Benesh (2012) investigated to what extent geographical estimates could come from language statistics and from perceptual simulations by comparing readers who had read Tolkien's Lord of the Rings trilogy and The Hobbit with participants who studied a map and had never seen the
text. As in Louwerse and Zwaan (2009), computational estimates of co-occurrence of the location of the cities in Middle Earth were determined. Participants were asked to draw the location of the cities on a piece of paper. Again, computational estimates of co-occurrence for cities mentioned in the text correlated with the longitude and latitude of cities in Middle Earth. Interestingly, estimates from those who studied a map correlated with the actual geographical location in Middle Earth more than the estimates from those who had read the text did. On the other hand, estimates from those who had read the text correlated more with the computational estimates of co-occurrence than the estimates from those who studied a map did. These results support the claims made by the Symbol Interdependency Hypothesis: 1) Language (Lord of the Rings) encodes geographical (Middle Earth) information; 2) Those who read Lord of the Rings and those who studied the map relied both on language statistics and perceptual simulation in their estimates; 3) the relative dominance of language statistics and perceptual simulation factors is modified by whether participants read the text or studied the map.

Importantly, human estimates in Louwerse and Zwaan (2009) and Louwerse and Benesh (2012) were derived from an experimental setting in which participants were asked to draw the location of cities on a piece of paper, which is a perceptual task. Given that the cognitive task determines the effect of language statistics and perceptual simulations (Louwerse \& Jeuniaux, 2010), the estimates how much of human geographical estimates come from language statistics and come from perceptual simulations is likely to be biased.
We therefore conducted an experiment in which participants were not asked to draw a map (a perceptual task) but to estimate geographical distances from words (a task that better justifies linguistic processing).

\section*{Experiment}

In a between subjects design, participants viewed United States city pairs in either a horizontal or vertical orientation. These city pairs randomly appeared in either their natural orientation (i.e., a more northern city was presented above a second city, or a more western city was presented to the left of a second city), or the opposite of their natural orientation. In this iconic orientation, we predicted that participants would rely on perceptual information. Conversely, when the location of the city pairs was reversed (i.e., reverse-iconic), we predicted that participants would rely on language statistics.

\section*{Methods}

Participants Ninety-three undergraduate native English speakers at the University of Memphis (67 females) participated for extra credit in a Psychology course. Fortyfive participants were randomly assigned to the vertical presentation condition and forty-eight participants were randomly assigned to the horizontal presentation condition.

Materials The experiment consisted of the largest 50 cities in the United States using the U.S. Census data from 2000 and were presented in 2,450 name pairs.

Procedure In two presentation conditions (horizontal or vertical), we presented subjects with city pairs in their iconic configuration and their reverse iconic configuration. Participants were randomly assigned to view either the vertical or horizontal configuration. To reduce order effects, participants were counterbalanced across four groups per condition.

The city pairs were presented on a \(1280 \times 1024\) computer screen. Participants were asked whether the named United States cities were closely located. The vagueness of the question intentionally left open the question of closeness for the participant to decide. A more specific question would have added a number of constraints that would influence the judgment in unintended ways. The center of the screen was positioned at eye level. Each trial began with the presentation of a fixation cross for 3000 ms . The participants would select their choice (yes or no) by designated buttons on a keyboard then a fixation cross would appear on the screen for the next trial.

\section*{Results}

Outliers were defined as response times (RTs) that were 2.5 SD above the mean per subject per condition and were removed from the analysis. This affected less than \(5 \%\) of the data.

The perceptual factor was operationalized as the differences in latitude or longitude of the cities. Language statistics was operationalized as the log frequency of \(a-b\) (e.g., for North - South: New York - Miami; for East West: Los Angeles - Boston), or \(b-a\) (e.g., for North South: Miami - New York; for West - East: Boston - Los Angeles) order of word pairs using the large Web 1T 5-gram corpus (Brants \& Franz, 2006). This corpus consists of 1 trillion word tokens (13,588,391 word types) from \(95,119,665,584\) sentences. Using the log frequency of the co-occurrence of word pairs enables linear regressions to be performed comparing frequencies with other types of data, because raw frequencies of those co-occurrences are extremely skewed (Gries, 2010).

A mixed-effect regression analysis was conducted on RTs with linguistic frequency and the perceptual factor as fixed factors and participants and items as random factors (Baayen, Davidson, \& Bates, 2008). The model was fitted using the restricted maximum likelihood estimation (REML) for the continuous variable (RT). F-test denominator degrees of freedom were estimated using the Kenward-Roger's degrees of freedom adjustment to reduce the chances of Type I error (Littell, Stroup, \& Freund, 2002). Participants and items were treated as random factors in the analysis.

Note that the strength of a model association is represented as a weighted ratio of the \(F\) statistic. \(R^{2}\) and \(F\) used in ordinary regression analysis are closely related, since where \(k\) is the number of model parameters and \(N\) is
the number of cases, such that \(F\) has \((k, N-k-1) \mathrm{df}\). See also Pedhazur (1997, p. 105) and Louwerse and Jeuniaux (2010). See Figure 1.
\[
F=\frac{\frac{R^{2}}{k}}{\frac{1-R^{2}}{N-k-1}}
\]

Figure 1. Weighted ratio of the \(F\) statistic.

Vertical Configuration The perceptual factor explained RTs in the iconic pairs, \(F(1,964.821)=17.7, p<.001\), with larger distances yielding lower RTs. The linguistic factor, however, did not explain RTs for the iconic word pairs, \(F(1,960.549)=0.45, p=.50\).

For the reverse iconic configuration the perceptual factor also explained RTs, \(F(1,984.502)=8.382, p=.004\), except that the effect was considerably smaller. Importantly, for these reverse-iconic word pairs a significant effect on RTs was obtained for the linguistic factor, \(F(1,970.543)=6.18, p\) \(=.013\), with higher frequencies yielding lower RTs. Figure 2 gives an estimate of effect sizes, which are calculated by differences between groups as opposed to within the two original groups.

Horizontal Configuration For the horizontal configuration, a similar pattern emerged as for the vertical configuration. That is, the perceptual factor explained RTs for city pairs in their iconic order, \(F(1,962.735)=9.645, p<.002\), but no significance found for language statistics when the position of the city pair was in the iconic order, \(F(1,995.626)=\) \(1.254, p=.263\).

For the reverse-iconic order the perceptual factor again explained RT, \(F(1,987.520)=9.565, p=.002\). Importantly, an effect for language statistics was obtained when city pairs were presented in their reverse-iconic order, \(F(1,1012.479)\) \(=4.068, p=.044\) (Figure 3).

\section*{Discussion}

The goal of the present study was to determine to what extent humans rely on language statistics and on perceptual simulation in spatial cognition. Previous work has found that language encodes geographical information, so much so that by computing the rates of co-occurrence of city names in the text, multidimensional scaling techniques allow for estimating the relative longitude and latitude of cities. Experiments have shown that humans rely on perceptual simulation, for instance, a perceptually grounded memory of the text. However, there is also evidence humans rely on language statistics, similar to those obtained from computational estimates. Because the existing literature used human estimates from map drawings, the current paper investigated to what extent linguistic and perceptual factors would affect cognitive processes in a more linguistic task.

Figure 2. Absolute \(t\)-values of the linguistic frequency and latitude differences in reverse-iconic and iconic orientation in the vertically positioned city names.

Figure 3. Absolute \(t\)-values of the linguistic frequency and longitude differences in reverse-iconic and iconic orientation in the horizontally positioned city names.

When city pairs were presented to participants in their iconic order, their distance best explained RTs. The larger the distance, the larger the RTs. No effect was obtained for language statistics in the iconic order. For the reverse-iconic order, the perceptual factor again explained RTs, but language statistics did so as well. This suggests that when the task or the stimulus invites for perceptual simulation, humans rely on perceptual simulation. When perceptual simulation is harder, other heuristics, such as language statistics are used. This finding lies fully in line with the results obtained by Louwerse and Jeuniaux (2010) showing that linguistic and perceptual factors dominate in conceptual processing when they are relevant.

Further research should investigate the weaker effects for the horizontal condition compared to those for the vertical condition. Barsalou (2008) argues that locating objects on a left/right axis is more difficult possibly due to the symmetry of the body and less salient cues to differentiate those objects. Perhaps this weaker effect is due to embodiment factors. However, this difference might also be explained by linguistic factors. When reporting two spatially related words in English, such as up-down or left-right, the top or the left most word is most often reported first. There is the possibility that there are less instances of the left-right phenomenon found in language. Future study of the nature of this phenomenon could illuminate why this weaker effect has been found. In the past, it has been shown that the linguistic system is used more often when quick decisions are made, and the perceptual system is used when slower decisions are made (Louwerse \& Connell, 2011). However, more specific investigation is recommended in the future as to the exact mechanisms of these speed differences and to what degree they affect decisions.

These findings reported in this paper are also in line with the Symbol Interdependency Hypothesis, which claims that cognitive processes rely both on language statistics and perceptual simulation. Because language encodes spatial information, including geographical information, language users can utilize these cues in their comprehension process. Geographical judgments then rely on both a shallow heuristic, called the linguistic system, and a fine-grained and more precise perceptual simulation system.

\title{
Empirical investigation on spatial templates for a diagonal spatial term
}

\begin{abstract}
The meaning of spatial relations have been intensively studied in cognitive science research. A spatial template is one of the typical representations of spatial relations, which maps a position of a located object to its acceptability for the corresponding spatial term. Spatial templates have been investigated for several orthogonal spatial relations. However, diagonal spatial relations have attracted less attention. The present study aims at empirically determining the spatial template for a Japanese diagonal spatial term, "migiue (upper right)". The data was collected with various geometrical conditions changing the size of objects and the aspect ratio of the background. The analysis of the data revealed that the reference axis for "migiue (upper right)" was the direction of \(45^{\circ}\), and the acceptability of the diagonal relation could be affected by the acceptable regions of the adjacent orthogonal relations.
\end{abstract}

Keywords: spatial language; diagonal spatial term; spatial template;

\section*{Introduction}

There have been numerous studies on language and spatial relations in cognitive science (Talmy, 1983; Herskovits, 1985; Tversky \& Lee, 1998; Levinson, 2003; Coventry \& Garrod, 2004). Understanding a spatial relation involves reference objects (RO), located objects (LO), selection of an appropriate reference frame with respect to the context (CarlsonRadvansky, 1997; Carlson-Radvansky \& Jiang, 1998), and the meaning of the spatial relation. As a representation of the meaning of spatial relations, Logan and Sadler (1996) proposed a spatial template that maps an LO position to the acceptability for the corresponding spatial term. They determined the spatial templates for six projective spatial terms ( "above", "below", "left of", "right of", "over" and "under") and four topological spatial terms ("next to", "away from", "near to", and "far from") through experiments. The LO positions were discretised by a \(7 \times 7\) grid and each cell was assigned to an acceptability scale from 1 (bad) to 9 (good).

Surprisingly, diagonal spatial relations have attracted less attention than orthogonal spatial relations. One reason might be the fact that spatial terms expressing diagonal spatial relations tend to be lengthy in English, e.g. "the LO is in front of and to the right of the RO". In contrast, as Gapp (1995) noted, such combinations of spatial terms were very common in German and could be expressed in a simple form. This is also the case in Japanese, the target language of the present study. For instance, "migi (right)" and "ue (above)" can be directly combined to make a term "migiue (upper right)" for representing the upper right direction.

Another reason could be related to the so-called oblique effect, which claims humans show greater sensitivity to ratings with the orthogonal orientations, i.e. vertical and horizontal, than to other diagonal orientations (Appelle, 1972; Furmanski \& Engel, 2000; Meng \& Qian, 2005). The orthogonal spatial relations are more important for humans, thus these relations might have been intensively studied.

For investigating the acceptability of spatial relations, several researchers have used a radial grid layout (Huttenlocher, Hedges, \& Duncan, 1991; Gapp, 1995; Hayward \& Tarr, 1995; Crawford, Regier, \& Huttenlocher, 2000; Huttenlocher, Hedges, Corrigan, \& Crawford, 2004) instead of a square grid layout as Logan and Sadler (1996) did. They were interested in how angular deviation affected the acceptability of spatial terms. The spatial terms they were mainly concerned with were, however, still limited to orthogonal spatial terms \({ }^{1}\). They did not explicitly concern themselves with the acceptability of diagonal spatial terms such as "migiue (upper right)".

Against this background, the present study discusses the acceptability of a Japanese diagonal spatial term. More concretely, we aim at determining a spatial template for a Japanese term "migiue (upper right)" \({ }^{2}\) with taking into account three geometrical factors: the size of RO and LO, and the aspect ratio of the background. The background aspect ratio has rarely been taken into account in past studies.

\section*{Experiment 1}

\section*{Method}

Participants Thirty four undergraduates and graduates (30 males and 4 females) from Tokyo Institute of Technology participated in the experiment. Each participant received 1,000 JPY for his/her participation. All participants were native Japanese speakers.

Material and design We have four quadrants to consider for diagonal spatial terms: "upper right", "upper left", "lower right" and "lower left". Assuming symmetric acceptability

\footnotetext{
\({ }^{1}\) Gapp (1995) investigated diagonal spatial terms as a combination of two orthogonal spatial terms. He did not, however, take into account the dominance of orthogonal relations over diagonal relations.
\({ }^{2}\) Although we denote this target term as "upper right" in the rest of the paper, the actual term used in the experiments was the original Japanese term "migiue".
}

Figure 1: Example of stimulus
among these four quadrants, we investigated spatial templates for the upper right quadrant only. To obtain spatial templates for "upper right", we basically followed the goodness rating experiment described in (Logan \& Sadler, 1996). Figure 1 shows the interface of a trial that was presented to the participants. Against the coloured background, a square (the reference object: RO) is placed in the center, and the circle (the located object: LO) is placed someplace within the upper right quadrant of the background. A sentence describing the spatial relation between the RO and LO is presented below the figure; "En ha seihôkei no migiue ni aru. (the circle is to the upper right of the square.)" in this example. The participants were instructed to rate the relevance of the sentence describing the spatial relation between two objects on the scale of 1 (bad) to 7 (good) by clicking one of seven buttons.
\begin{tabular}{c|c|c|c|c|c|c|c|c|c|c|} 
& \multicolumn{2}{c}{1} & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 \\

\hline
\end{tabular}

Figure 2: Grid configuration for reference objects (Experiment 1)

The grid for the upper right quadrant with the origin at the RO position was configured as shown in Figure 2. The size of a cell was \(50 \times 50\) pixels. The LO was placed one of these cells with its centroid at the center of the cell. The RO was placed with its centroid at the left bottom corner of the cell A1. The grid lines were invisible to the participants. We considered three geometrical factors: the RO size (R), the LO size \((\mathrm{L})\) and the aspect ratio of the background (A).

We had two variations for the object size: large ( \(50 \times 50\) pixels) and small ( \(25 \times 25\) pixels), and three variations for the background aspect ratio: 5:5, 5:7 and 5:9. Depending on the background aspect ratio, the cells from the first column to the fifth column (5:5), the cells from the first column to the seventh column (5:7) and the cells from the first column to the ninth column (5:9) were used for the LO position respectively. The total size of the background was \(500 \times 500\) pixels for the \(5: 5\) case, \(500 \times 700\) for the \(5: 7\) case, and \(500 \times 900\) pixels for the \(5: 9\) cases. The number of LO positions varied depending on the background aspect ratio: 24 for the 5:5 case, 34 for the \(5: 7\) case and 44 for the 5:9 case \(^{3}\). The total number of trials for the acceptability rating became 408 ((\#RO size \() \times(\#\) LO size \() \times(\#\) LO position for the three aspect ratios) \(=2 \times 2 \times(24+34+44))\). In addition to these trials, 136 fillers were added in which the LO was placed in other quadrants with the sentences being changed accordingly. The total number of the trials for a participant was \(544(408+136)\).

Procedure The 544 trials were presented to each participant one by one on a 24 inch computer display of an iMac. The sequence of the trials were pseudo randomly generated with the occasional insertion of fillers for each participant. At one third and two thirds of the trial sequence, the participants were allowed to take a short break as long as he/she wanted. The participants finished their task within 20 to 40 minutes.

Figure 3: Spatial template for "migiue (upper right)"
(Experiment 1, \(\mathrm{R}=\) large, L=large)

Results Figure 3 shows spatial templates for "upper right" with a large RO and LO. Each cell denotes the average rating across all participants. The mean standard error of the averages in Figure 3 is 0.217 . This value is comparable to the result from (Logan \& Sadler, 1996), which is 0.271 . From

\footnotetext{
\({ }^{3}\) Note that the RO is fixed at the A1 position.
}
these templates, we can see that the direction of a \(45^{\circ}\) angle is the most relevant as a reference axis for "upper right" (red coloured cells) regardless of the background aspect ratio. In addition to these three templates, we had nine more templates for a combination of three geometrical factors: the RO size, the LO size and the background aspect ratio. We omit the other templates due to space constraints. The tendency of the other templates is similar to Figure 3.

Table 1: Result of four-way (A, R, L, P) ANOVA (Experiment 1)

\end{tabular}

Analysis We conducted a four-way ANOVA with average ratings as the dependent variable, and the background aspect ratio (A: 5:5, 5:7 and 5:9), the RO size (R: large and small), the LO size (L: large and small), and the LO position ( \(\mathrm{P}: 24\) positions) as the independent variables. Since the cells in the four right-most columns in Figure 2 were not included in the 5:5 aspect ratio configuration, we adopted only 24 cells in the column 1 to 5 for the analysis. Table 1 shows the result of the multivariate ANOVA indicating significant main effects of the LO position (P) and the RO size (R).

Figure 4: Interaction between object sizes
To investigate the effect of the aspect ratio (A) and the RO size (R) at each LO position (P), we conducted multiple comparisons for the interactions, P-A and P-R. The result of the multiple comparisons (Bonferroni's method) is shown in Table 2. Table 2 reveals that the effect by the RO size \((\mathrm{R})\) is

Table 2: Result of multiple comparisons

Figure 5: Overlaid spatial template of three aspect ratios (Experiment 1, R=large and \(\mathrm{L}=\) large)

Discussion Although there is no significant main effect of the background aspect ratio (A) in Table 1, several positions show a significant main effect of the aspect ratio in Table 2, i.e. B3, B4, D3, E3, E4 and E5. Among these positions, the ratings for the positions above the reference axis of "upper right", i.e. the \(45^{\circ}\) line, (D3, E3, and E4) were the highest with the aspect ratio 5:5. In contrast, the ratings for the positions below the reference axis (B3 and B4) were the highest
with the aspect ratio 5:9. This tendency was observed at other cells. Figure 5 shows an overlaid spatial template for "upper right" with different background aspect ratios (5:5, 5:7 and 5:9, i.e. three templates in Figure 3). The upper, middle and lower figures in a cell denote the acceptability ratings for the background aspect ratio 5:5, 5.7 and 5.9 respectively. The red coloured cells denote the reference axis for "upper right" and the dotted line denotes the diagonal line of the background with aspect ratios 5:7 and 5:9. This figure suggests that although the reference axis for "upper right" remains at the \(45^{\circ}\) direction regardless of the background aspect ratio, the acceptability for the positions below the reference axis is affected by the boundary of the background, i.e. the diagonal line of the background.

Figure 6: Effect by the RO size (Experiment 1)
Considering the earlier research results (Gapp, 1995; Regier \& Carlson, 2001; Kobayashi, Terai \& Tokunaga, 2008), given a fixed size of the background, a larger RO is expected to give a higher average rating, since the good region would enlarge according to the RO size. Figure 4, however, indicates the opposite result; the smaller RO gives the higher average rating. This would be explained by the effect of other spatial relations, "above" and "right" in this case. A larger RO enlarges the good region for "above" and "right" as well as that for "upper right". Considering the oblique effect, the orthogonal ("above" and "right") relations would be dominant over the diagonal ("upper right") relation, thus the enlargement of the good region for the diagonal relation would be suppressed by those of the adjacent orthogonal relations. The main effect of the RO size at positions A2 and C1 in Table 2 also supports this hypothesis. Figure 6 illustrates this explanation. When the RO is large (the left figure), the centroid of the LO is at the edge of the good region for "right" (the gray area), while when the RO is small (the right figure), the LO centroid is out of the good region. Thus, the acceptability of "rightness" in the right figure could be lower than that in the left figure, and the good region for "right" interferes less with that of "upper right". This hypothesis would explain the reason why the small RO gave a higher rating.

The interaction between the RO and LO sizes can be also explained in terms of the interference by the good region of the adjacent orthogonal spatial relations. As Figure 4 shows, when the RO is small, the average rating for the small LO is significantly higher than that for the large LO ( \(p<.05\) ), and

Figure 7: Interaction between the RO and LO sizes
when the LO is small, the average rating for the small RO is significantly higher than that for the large \(\mathrm{RO}(p<.01)\). Figure 7 illustrates the explanation for this observation. Two LOs are depicted as white circles in the same cell for comparison. The centroid of the LOs moves relative to the good region for "right" according to the combination of object sizes. When the RO is small (the right figure), the centroid of the LOs is out of the good region for "right", and the overlapping area between the LO and the good region drastically decreases as the LO becomes small (the inner circle). Actually, there is no overlap in this case. When the RO is large (the left figure), the centroid of the LOs is at the edge of the good region, and the difference of overlapping areas is less than that of the small RO case. The ratios of the overlap against the LO are the same; both overlapping areas are half of the object sizes. Thus, the good region for "right" has less effect on the good region for "upper right". That leads to the higher average rating for the small RO and LO. Table 2 shows a significant difference by the RO size (R) at the lowest horizontal cell (A2), which falls into the good region for "to the right of the RO". The difference is also significant at the leftmost vertical cell (C1), which falls into the good region for "above the RO". These significant interactions support the above explanation. In summary, we have drawn a hypothesis that since orthogonal relations are dominant over diagonal relations, the good region of the former would interfere with that of the latter. We conducted a follow up experiment in order to verify this hypothesis, which is described in the next section.

Figure 8: Grid configuration for reference objects
(Experiment 2)

\section*{Experiment 2}

\section*{Method}

Participants Thirty three graduates and undergraduates (28 males and 8 females) from Tokyo Institute of Technology participated in the follow up experiment. There was no overlap in participants between the two experiments. Each participant received \(1,000 \mathrm{JPY}\) for his/her participation. All participants were native Japanese speakers.

Material and design The experimental setup is the same as Experiment 1 except for the grid configuration. In Experiment 2, the position of the RO was shifted by 50 pixels both downward and leftward as shown in Figure 8. The column 1 and row A were also shifted accordingly. This configuration is more similar to that of Logan and Sadler (1996) than the configuration of Experiment 1. The procedure of the experiment is the same as that of Experiment 1

Figure 10: Spatial template for "migiue (upper right)" (Experiment 2, R=large, L=large)

If our hypothesis is correct, the effect of the RO size and the interaction between the RO and LO sizes would disappear
because the relative position of the LO centroid does not vary even though the RO size changes as shown in Figure 9.

Table 3: Result of four-way (A, R, L, P) ANOVA (Experiment 2)

\hline & \multicolumn{4}{c}{\((* *: p<.01, *: p<.05)\)}
\end{tabular}

Result Figure 10 shows the spatial templates for "upper right" with three different aspect ratios. The other conditions are the same as Figure 3. In this configuration, the participants tend to give very low ratings in the horizontal and vertical aligned cells, i.e. column 1 and row A. This is obviously because these cells are completely located within the good region for "above" and "right".

Analysis and discussion We conducted a four-way ANOVA in the same manner as Experiment 1. Table 3 shows the result of the multivariate ANOVA. As we expected, the main effect of the RO size ( R ) and the interaction between the RO and LO size disappeared. This supports our hypothesis described in the previous section.

\section*{General discussion}

The present study discussed the acceptability of the LO positions for a Japanese diagonal spatial term "migiue (upper right)" based on the empirical data. The data was collected through the experiments taking into account three geometrical factors: the size of RO and LO, and the background aspect ratio. Our findings through the data analysis can be summarised as follows.
- The reference axis of "migiue (upper right)" stays at the direction of \(45^{\circ}\) even though the aspect ratio of the background varies. This seems robust as far as the aspect ratios used in the experiments (5:5, 5:7 and 5:9). However, according to the horizontal extension of the background, the acceptability of the area below the reference axis tends to be higher, and that of the area above the reference axis tends to be lower. This would be the effect by the diagonal line of the background. This tendency is particularly remarkable in the distant area.

Interestingly, this observation is contrary to the finding by Gapp (1995), which claimed that the acceptability was not affected by the distance, although it became slightly higher when the LO was close to the RO within the area where the angular deviation from the reference axis is less than \(45^{\circ}\). In our data, the angular deviation is less than \(45^{\circ}\) in all positions, but the distant positions tend to show higher acceptability. For instance, the pairs of cells A2 and B5, and B1 and E2 have the same angular deviation from the reference axis, about \(\pm 26.5^{\circ}\). As Figure 3 shows, the ratings of the distant positions (B5 and E2) are consistently higher than that of the close positions (A2 and B1) in all aspect ratios. An ANOVA on the average ratings at these four positions showed a main effect of the distance \((F(1,33)=20.2, p<.01)\).
- The acceptability of the diagonal spatial relation is affected by the adjacent orthogonal spatial relations. In our case, the acceptable regions of "above" and "right" interfere with the acceptability of "upper right". This hypothesis was confirmed by the main effect of the RO size, and the interaction between the RO and LO size.

The above-mentioned contradiction between the results of ours and Gapp (1995)'s would be also explained by the interference by the orthogonal relations. The closer the LO is to the RO, the closer the LO is to the reference axis of the adjacent orthogonal relations ("above" and "right") as well, thus the acceptability would be affected more by the orthogonal relations.

Considering these findings together, we would say that the acceptability of diagonal spatial terms is determined by the interaction among four axes, namely, the horizontal axis, the virtical axis, the diagonal axis at \(45^{\circ}\) and the diaglonal axis of the background. Among these axes, the two orthogonal axes are most dominant as past studies suggested. The diagonal axis of the background seems most recessive but still affects the diagonal axis at \(45^{\circ}\).

Future research directions include the evaluation of existing computational models for spatial relations against the diagonal spatial relations. According to our preliminary experiments in which the Proximal and Centre-of-mass model and Attention Vector Sum model (Regier \& Carlson, 2001) were applied to our data for "upper right" with setting its reference axis at \(45^{\circ}\), these models fit quite well to the data. We found, however, the deviation from the data enlarged as the deviation of the diagonal axis of the background from the reference axis at \(45^{\circ}\) increased. As described above, these two diagonal axes should be taken into account in these computational models for diagonal spatial terms. We need further investigation to determine the quantitative effect of the interaction of these axes on the acceptability of the diagonal relations for building a computational model.

\begin{abstract}
In this paper, we present two experiments that investigate how intonation can constrain pragmatic inference. While prior research has shown that intonation can increase the likelihood of an inference being made, less is known about how it affects the mechanisms involved in processing of inferences. In the first experiment, listeners had more direct mouse paths towards target responses for stronger interpretations after hearing utterances with referents with pitch accents than without. In the second experiment, we replicate the finding of the first study and found more direct mouse paths towards weaker interpretations after hearing de-accented referents Our findings suggest that intonation constrains the online processing of pragmatic inference by increasing the availability of stronger interpretations.

\section*{Introduction}

The rapid nature of human communication requires speakers and listeners to be as efficient as possible. To help achieve this, listeners often rely on context to help disambiguate between different linguistic structures and meanings. However, often what a speaker intends to say is not always directly retrievable from a linguistic form; rather listeners must infer it. One issue concerning pragmatic inference is whether the processor can keep up with the task demands of conversation. Some have argued that linguistic inference must be quick and "cheap" (Levinson, 2000; Piantidosi, Tily, \& Gibson, 2012), however others have experimentally demonstrated that some linguistic inferences can be quite costly in terms of processing (Bott \& Noveck, 2004; Huang \& Snedeker, 2009). In this paper, we discuss one aspect of the linguistic signal that has the potential to make certain costly pragmatic inferences quicker and more efficient: prosody. We report the findings from two experiments that test different accounts about how prosody affects the processing of pragmatic inferences.

\section*{Pragmatic inferences and language processing}

Traditionally, linguists have treated pragmatic inferences as the interpretative process in which a speaker must reconcile how speaker's literal sentence meaning differs from his or her intended meaning. Grice (1967) initially distinguished between two types of pragmatic inferences
(particularized implicatures): conventional implicatures and conversational implicatures. Conventional implicatures roughly amount to inferences about a speaker's intended meaning that can be made without accessing the conversational context. Conversational implicatures, however, require that listeners must first consider the literal sentence meaning, compare it against the context and then potentially enrich it in order to arrive at a speaker's intended meaning. Neo-Griceans have proposed an inference type that falls somewhere between Grice's original distinction: default inferences (Levinson, 2000). Default inferences are inferences that are computed on every occasion, but can be cancelled later. Always deriving the inference avoids costly pragmatic computations that would delay obtaining the speaker's intended meaning. According to this process, inferences are heuristic-based and therefore can become "cheap" in regards to processing resources.

Researchers in experimental pragmatics have tested whether certain implicatures classes are indeed understood as default inferences. One case that has caused some debate is the case of scalar implicatures. For these inferences, listeners can choose between either a weak or a strong interpretation depending on what they think the speaker intended to communicate. For example, a sentence such as "I drank some of my friend's beers last night" could either be taken to mean that I drank (1) at least one (and possibly all) of the beers or (2) at least one and not all of the beers. The difference between interpretations (1) and (2) is that to interpret "not all" in (2), the listener must infer that had the speaker meant "all," they would have said so. In other words, the listener would need to make a pragmatic inference to access the stronger interpretation. Several experimental studies have shown that understanding upper bound meanings of some, as in (2), takes substantially longer than the meaning in (1) (Bott \& Noveck, 2004; Huang \& Snedeker, 2009). As such, a default implicature account of scalar implicatures is not borne out by the majority of these findings because of the processing cost for (2). However it might be the case that this processing cost can be diminished in the right context (Grodner, Klein, Canbary, \& Tannenhaus, 2010; Degen \& Tannenhaus, 2011), i.e. making (2) more available or active earlier on in processing. Our studies seek to examine how processing costs can be diminished and what this means for processing accounts of pragmatic inferences. Specifically, we examine
how one prominent cue, intonation, affects the availability and integration of various sources of information during the processing of conversational implicatures.

\section*{Intonation and Pragmatic Inferences}

Many studies have shown that intonation interacts with pragmatic processes in general, specifically those having to do with the integration of prior context to help disambiguate anaphoric reference, e.g. reference resolution, via information structure. For example, Dahan, Chambers, \& Tannenhaus (2002) found that pitch accents ( \(\mathrm{H}^{*}\) ) can rapidly disambiguate referents by integrating prior discourse mention of a referent. What is less clear is whether intonation affects pragmatic processes above that of explicatures, e.g. reference resolution, namely at the level of implicatures. For example, scalar implicatures are generally thought to be defeased in the antecedent of a conditional (if some of the...) and under negation (see e.g., Chierchia, 2004, for a review). Scalar implicatures therefore require the integration of semantics and pragmatics in a way that other pragmatic phenomena do not (see Horn, 2006). How and at what level of interpretation intonational information is intergrated into the processing of scalar implicatures is therefore an open question.

From a processing perspective, intonation could affect implicatures in at least two ways. First, it may alter how likely people are to derive an implicature. Secondly, it may also affect the speed with which people derive them. The difference is important because it allows us to understand in more detail how intonation interacts with other processing mechanisms. In particular, intonation might act merely as a cue to derive the implicature, or it may alter the process more fundamentally. In the next section we discuss previous findings related to prosody and pragmatic inferences, before specifying our hypotheses in more detail.

The one study that has specifically investigated prosody and scalar implicatures was Chevallier et al. (2008), who tested the effects of contrastive stress on the disjunction, or. Disjunctions can be optionally enriched from an inclusive reading, one or the other and possibly both, to an exclusive reading, one or the other but not both. Chevallier et al. tested whether contrastive stress on "or" affected the enrichment. For example, whether sentences like, "You can have the meat course or the fish course," was interpreted differently to, "You can have the meat course OR the fish course." While they found the stress on "or" greatly increased the proportion of exclusive readings, response times for the exclusive readings were identical regardless of whether contrastive stress was used or not. This study then, found that while intonation altered how the sentence was understood, it did not alter the time-course for the inference.

While our study is primarily concerned with conversational implicatures, other studies on intonation and different sorts of pragmatic inferences are clearly relevant. These studies have produced mixed results as to the effects of intonation on the speed of inference derivation, however, and it is often difficult to see whether intonation is affecting
speed of derivation or probability of derivation. For example, Dennison (2010) found that contrastive pitch accents in conjunction with final rises increased the likelihood that upon hearing "the pencil WAS sharp", listeners were more likely to infer that pencil is now not sharp, i.e. dull. This did not, however, affect the time course of processing relative to explicit negation: listeners spent as much time looking at pictures of the affirmative state (a sharp pencil) before fixating on the intended meaning (a dull pencil) as with explicit negation. Similarly, Sedivy et al. (1999) found no difference in looks to a referent disambiguated by a non-stressed adjective, "Click in the tall glass," vs. "Click on the TALL glass". In contrast, Ito \& Speer (2008) found that contrastive pitch accents ( \(\mathrm{L}+\mathrm{H}^{*}\) ) rapidly constrain the reference resolution of an upcoming noun. When listeners heard a prior mention of a referent (green ball), listeners were more likely to make anticipatory eye-movements upon hearing a contrastive pitch accent on BLUE to an object (ball) that had a contrasting item in the set (a blue ball vs. a red ball vs. a blue star).

The literature reviewed above suggests that intonation affects how likely implicatures are to be generated, but it is unclear whether it speeds up the process of making the inference. In our experiments we test the former hypothesis, namely whether a particular intonational pattern, focus intonation, speeds up the process of making conversational implicatures. One possibility is that because enrichment is optional, focus intonation could make it more likely that the procedures used to derive an implicature would be triggered (e.g., exhaustivity operator, (van Rooj and Schulz, 2004); or an only operator, (Chierchia, 2004); or reasoning about Gricean maxims, (Grice, 1975). If this is the only effect of the focus however, processing speed will not be altered and could even be delayed, e.g. more alternatives could be generated and considered. Focus would be one more cue to derive the implicature, but would not alter any of the procedures needed to perform the implicature computations. This account is consistent with the findings from Chevalier et al. (2008) and Dennison (2010). The other possibility is that focus intonation changes how the implicature is computed, which could happen several ways. For example, focus intonation might act like an explicit only in the sentence. This would remove the need to consider whether the speaker was informed and reliable (Sauerland, 2004). Removing this stage would speed up processing (Bott et al., 2012, demonstrate that scalar implicatures are computed more slowly than similar sentences with an explicit only). A final possibility is that focus might also encourage people to start deriving the implicature earlier on in the sentence; either because the pitch accent strengthens the assertive content of the proposition, e.g. the speaker is not leaving the topic open, or because the listener recognizes that a speaker is in a position to place a pitch accent on the referent.

\section*{Overview of experiments}

In this paper, we present two experiments investigating how prosody affects the processing of conversational
implicatures. At issue is whether prosody, in this case intonation, speeds up the process of making implicatures.

We used a picture-speech matching paradigm. Participants were presented with a visual display showing diverse objects. For example, a candle in one part of the screen and a dog in the other. They then heard a sentence assigning Mark ownership of one set of objects, and clicked on the image that best captured the object owned by Mark. For example, they might hear, "Mark has a candle" and then had to click on the candle image. In the critical trials, participants heard a sentence involving one object, "Mark has a candle (A)," but were presented with one image containing a candle (A), and one image containing a candle and a candy (AB). Now, in these trials, both options were logically permissible - there is a candle in both images; it is only by generating an implicature that the participant can chose the candle-only option ("the speaker must mean that Mark only has a A, and not AB, because otherwise they would have said so"). Thus, if the participant selected the candle-only option, they must have derived the implicature. We refer to the candle-only option(A) as the strong interpretation because it is informationally stronger than the candle and candy option (AB) (the weak interpretation).

Most importantly, we manipulated intonational focus on the referent. Participants heard either "Mark has a candle," or "Mark has a CANDLE." If focus intonation facilitates the derivation of the inference, the mouse-paths towards the stronger interpretation targets (CANDLE) should be more direct for stressed vs. unstressed referents when the twoobject picture is the competitor target.

\section*{Experiment 1}

In Experiment 1, the visual display involved two targets, one on the left and one on the right. Participants heard one of four types of experimental conditions, as shown in Table 1. Conditions 1 and 2 were the critical conditions described above, and conditions 3 and 4 were control conditions designed to eliminate low-level, perceptual explanations of any effects we might observe. If intonation speeds up the pragmatic process of deriving the implicature, we would expect a larger effect of intonation in conditions 1 and 2 than in conditions 3 and 4.

\section*{Method}

Twenty six undergraduate students in the School of Psychology at Cardiff University participated in this experiment for either course credit or a 3 pound Sterling reimbursement. The experiment took roughly 15 minutes to complete. All participants were debriefed upon completion.
Stimuli The same auditory stimuli were used for both experiments (except for the addition of prepositional phrases in Experiment 2). An utterance had the stem "Mark has a" and either had one referent (A)or two referents (AB) (see Table 1). Roughly half of the stimuli ( 24 items) were adapted from Dahan, Tannenhaus, \& Chambers (2002) and the other half ( 26 items) were created in order to increase the number of items. Of these items, half of the sentence and
picture combinations were phonological competitors, e.g. candle vs. camel and the other half were semantic competitors, e.g. pencil vs. eraser. This was done to help disguise the purpose of the experiment. For each item combination, black and white clip art pictures of each referent were constructed. Each item had either a picture of just one of the objects (candle) or both (candle and a camel). Objects were sized equally so that the picture of the object was the same size as when the object was in the two-object picture. This was done to control the salience of a oneobject picture versus a two-object picture. The utterancepicture combinations are also shown in Table 1.

A male speaker of British English with no noticeable regional variety was used to record the sentences. Sentences were recorded in a sound attenuated booth using a unidirectional microphone and digitized with USB sound capture device. All utterances were first recorded in sentence form and then the individual referents were recorded in isolation in both stressed and unstressed forms. A trained phonetician inspected these recordings and made sure that utterances with focus intonation had \(H^{*} \mathrm{~L}-\mathrm{L} \%\) patterns and non-focus intonation utterances had L*L-L\% patterns. Acoustic measurements were conducted so that this and mean F0 were the only significant different between the two versions. Next, objects in isolation were spliced into the sentence frames. In the two referent utterances, the pause between "and" and the second referent "a camel" was reduced to 100 ms so that listeners could not reliably use the stress to detect speaker continuation.

Table 1: Utterance-picture combinations Exp. 1
Utterance (Pitch accent) Picture(s)
Target conditions
(1) Mark has an A (L*) A vs. AB
(2) Mark has an \(\mathrm{A}\left(\mathrm{H}^{*}\right) \quad\) A vs. AB
(3) Mark has an A (L*) A vs. B
(4) Mark has an A \(\left(\mathrm{H}^{*}\right)\) A vs. B

Filler conditions
(5)Mark has an A ( \(L^{*}\) ) and a B ( \(L^{*}\) ) AB vs. A
(6)Mark has an \(A\left(\mathrm{H}^{*}\right)\) and a B ( \(\mathrm{H}^{*}\) ) AB vs. A
(7) Mark has an \(\mathrm{A}\left(\mathrm{H}^{*}\right)\) and a B ( \(\left.\mathrm{L}^{*}\right) \quad \mathrm{C} \mid \mathrm{B}\) vs. \(\mathrm{A} \mid \mathrm{B}\)
(8) Mark has an A (L*) and a B ( \(\mathrm{H}^{*}\) ) A|C vs. A|B

Design \& Procedure In both experiments, participants were were presented with an audio file and clicked on the picture that corresponded to the mentioned referent in the sentence. In the instructions, they were told that they were overhearing a speaker describing to another person which objects Mark has. Response boxes were equally sized and placed at the top left and right and corners of the screen. To begin each trial, participants clicked on START at the bottom center of the screen and then saw the response options for 2000 ms before the audio file was played. Participants could move their mouse and make their response at the onset of the word "has".

Participants were exposed to all conditions. Four experimental lists were generated so that a given participant had only one of the four target conditions for a given item. Filler conditions were added that had both related oneobject pictures as well as non-related one-object pictures. Filler conditions were kept the same across all lists. As mentioned in the stimuli section, all versions of filler picture conditions had utterances with both \(\mathrm{H}^{*} \mathrm{~L}-\mathrm{L} \%\) and \(\mathrm{L} * \mathrm{~L}-\mathrm{L} \%\) accent patterns on initial referents so that listeners would be as likely to hear focus intonation in both one and tworeferent utterance.
The experiment was run with Runner program in the Mousetracker suite (Freeman \& Ambady, 2010). The Analyser program exported responses into 101 normalized time steps. The dependent measure used was the Area under the Curve (AUC), which amounts to the total geometrical area for a mouse trajectory relative to a straight line from the start button to correct target.

\section*{Results}

The average mouse-paths for the target conditions are shown in Figure 1. Figure 1 shows the raw \(x\) - and \(y\) coordinates for the mouse-paths for the various conditions, showing that utterances with unstressed referents in the twoobject competitor condition have delayed mouse-paths towards the response target. Utterances with stressed referents in the two-object competitor condition do not look to be substantially delayed relative to the control conditions.

A mixed model with two predictor variables (focus intonation and competitor type) was used to test the directness of participants mouse paths (AUCs) towards the correct response. Intonation ( \(\mathrm{H}^{*}\) vs. L* pitch accents) and competitor type (weaker interpretation or phonological/semantic cohort) were used as fixed effects (along with an interaction term) and used subjects and items as random effects. In all conditions, accuracy rates were over \(97 \%\). Participants had more direct mouse paths to control condition (Conditions \(3 \& 4\) ) than when the weaker alternative was used as a competitor (Conditions \(1 \& 2\) ), \(t=\) 3.94, \(p<.01\). Across competitor type, focus intonation yielded more direct responses toward the correct target, \(t=\) \(3.31, p<.03\). Critically, the interaction between focus and competitor type was significant, \(t=2.91, p<.05\), suggesting that the main effects were driven by the relative difference of focus intonation between Conditions 1 and 2.

Figure 1: Raw x- on y-coordinates for Experiment 1.

\section*{Discussion}

In the presence of having a picture of the weaker interpretation as a competing target, listeners had more direct responses to the target picture of the stronger interpretation for utterances with a stressed referent than an unstressed referent. This suggests that the pitch accent made the weaker interpretation less accessible. Mouse-paths in Condition 2 were more direct towards the target and quite close to the control conditions. This means that focus seems to have substantially reduced the interference of the weaker interpretation competitor found in Condition 1 almost to the extent that is wasn't present (as in Conditions 3 and 4). These findings suggest that the implicatures have been processed more quickly in the focus condition.

An alternative explanation of our findings is that listeners could be interpreting the focus intonation as a discourse signal that the speaker has finished speaking. This would explain why participants mouse movements were more direct to the signal referent because listeners would be less likely to expect more upcoming speech from the listener. In our second experiment, we seek to eliminate this explanation of our findings.

\section*{Experiment 2}

Gricean maxims explain not only how speakers imply meanings beyond literal sentence meaning, but also provide allow listeners to infer whether a speaker has finished his/her turn. Moreover, research on intonation has shown that listeners interpret falling intonation at the end of the phrase to indicate that a speaker has finished his or her turn (Deruiter, Mitterer, \& Enfeld, 2006). In contrast, phrase final rising intonation can indicate both speaker continuation or uncertainty and this along with durational information can alter listeners' attention to upcoming speech (Tomlinson \& Fox Tree, 2011). Regarding our items in Experiment 1, it is possible that the falling intonation on the referent in phrase final position might have yielded more direct mouse paths to the correct target because listeners inferred that the speaker had finished speaking. To control for this possibility, prepositional phrases were added to each phrase, e.g. "Mark has a candle on the table". Because of this, two more competitor pictures were added to the display, increasing the possible targets from two to four.

Stimuli The same experimental items from Experiment 1 were used. However, a prepositional phrase was added (either "on the table" or "on the shelf") to the existing auditory files. Because of this, two more picture targets were added to each trial. In Conditions \(1 \& 2\), participants were now forced to choose between a picture of a candle and a camel on the table, a candle on the table, along with two distractor pictures (a picture of an apple and a pear on the shelf as well as a picture of an apple on the shelf). Conditions \(3 \& 4\) made use of table/shelf distinction by having participants choose between the single referent on either the table or the shelf along with the distractor pictures. Last, a third experimental condition testing the availability of weaker interpretations in our paradigm. In
this condition, items such as "Mark has a candle on the shelf" would be heard in the context of a picture of only a candle on a table and a picture of both a candle and a camel on a shelf along with the distractor pictures. In this case, participants would need to click on the picture of the weaker interpretation, as the prepositional phrase on the single referent would make the stronger interpretation incompatible with item.

\section*{Results \& Discussion}

The average mouse-paths for the target in conditions 1-2, 3-4, \& 5-6 are shown in Figures 2-4. Conditions \(1 \& 2\) show the same pattern as in Experiment 1, in that the focus intonation helped listeners choose the single referent target in the presence of a two-referent target. However focus did not have a yield a more direct mouse path to the target in the control condition.

Figure 2: Mouse paths for Conditions \(1 \& 2\) in Experiment 2.

Figure 3: Mouse paths for Conditions \(3 \& 4\) in Experiment 2.

Figure 4: Mouse paths for Conditions \(5 \& 6\) in Experiment 2.

A mixed-effect model was used to test AUC values with focus intonation ( \(\mathrm{H}^{*} \mathrm{~L}-\mathrm{L} \%\) vs. L* L-L\% patterns) and implicature type (stronger interpretation, control, weaker interpretation) as fixed effects (along with an interaction term) and with subjects and items as random effects. Accuracy rates were over \(97 \%\) for Conditions 1-4. However accuracy was only \(90 \%\) for Conditions 5-6. Overall, participants' responses to correct targets for control items (Conditions \(3 \& 4\) ) were more direct than both stronger interpretations (conditions \(1 \& 2\) ), \(t=4.07, p<.03\), and weaker interpretations (conditions \(5 \& 6\) ), \(t=7.44, p<.01\). Across all conditions, focus intonation was not a significant predictor of AUCs, \(t=1.29,=.31\). Critically, focus intonation yielded more direct mouse paths towards the correct target for stronger interpretations than for control conditions, \(t=2.79, p=04\). The opposite pattern was found for weaker interpretations: focus intonation yielded less direct mouse paths to correct targets compared to the control condition, \(t=2.03, p<.05\).

In sum, Experiment 2 replicated our findings from Experiment 1: focus intonation helps listeners exclude competition from weaker alternatives when selecting strong interpretations of an utterance. The added prepositional phrase and visual context suggests that the focus intonation is integrated incrementally. This also suggests that the finding from Experiment 1 did not result from listeners exclusively interpreting the focus intonation as a signal that the speaker has finished his or her turn. In addition, focus intonation made it more difficult for participants to choose weaker interpretations upon hearing an item with a single referent. This further suggests that the focus intonation is helping reinforce the "only" operator in such utterances.

\section*{Conclusion}

In two experiments, we sought to better understand how prosody, pitch accents, affects the interpretive processes of pragmatic inference. In our first experiment, focus intonation reduced the processing cost of understanding a stronger interpretation (Mark has only a candle) in the presence of a weak interpretation competitor. The second experiment replicated the findings from Experiment 1 in that focus intonation helped listeners exclude weaker interpretations when clicking on the correct target. Also, focus intonation introduced more competition for single referent pictures when choosing weaker interpretations.

We now discuss our findings as they relate to how and when prosody is integrated incrementally into utterance meanings. At first glance, our findings might suggest that focus intonation acted as an explicit only. This effect could arise by the focus intonation being initially decoded into at a phonological level and then fed forward into a focus operator into pragmatics via information theoretic relationships (Pierrehumbert \& Hirschberg, 1990; Büring 2007). Semantic accounts of focus might also explain our results (Krifka, 1999; van Rooij \& Schulz, 2004; Rooth, 1993). Such accounts hold that focus marking is integrated into utterance interpretations by triggering a search for
lexically available alternatives. As a result of the information structure, the constituent can take on additional meanings due to its elevated status relative to alternatives.

However, our findings only partly support this idea of intonation working at the level of information structure by ruling out contextually available alternatives. Because both stronger and weaker alternatives were visually available, listeners could not use the intonation to create or search out alternatives based on linguistic information. This suggests that listeners were integrating non-linguistic information into these interpretations e.g., visual information and/or speaker specific information, and that focus intonation sped up this integration. In other words, a more plausible explanation might be that focus intonation allowed listeners to start deriving the inference earlier on in the sentence.

Future work is needed to better tease apart these possibilities. One way forward would be to dovetail on a recent investigation by Breheny, Ferguson, \& Katsos (2013), which examined the rapid integration of speakers’ perspectives when processing ad hoc, conversational implicatures. In their study, listeners' eye movements were sensitive to speaker information when generating the "nothing else" implication, suggesting that information structure is necessary, but not sufficient for rapidly inferring "nothing else" implications: initial early biases toward the "nothing else" interpretation disappeared when listeners believed that the speaker's viewpoint of the objects was obscured. Although their confederate speakers in the look and listen experiment did not reliably use pitch accents when communicating the "nothing else" implication, an open question is whether focus intonation on the referents in their study would have reduced the delay in the speaker ignorance condition. We are conducting ongoing research to test this possibility, which can better adjudicate at what level intonation affects pragmatic inference.

\title{
The visual motion aftereffect from mental imagery depends on speed
}

\begin{abstract}
When we imagine a train snaking through a desert, does information about the train's speed make it into our visual mental image? In this paper, we make use of the motion aftereffect illusion (MAE) to test whether the speed of imagined visual motion modulates transfer of adaptation to a subsequent visual motion discrimination task. We compared the effects of viewing slow, medium, and fast motion on the magnitude of the MAE (Experiment 1) with the effects of simply imagining the same motion stimuli (Experiment 2). In Experiment 1 we found that increasing the speed of real visual motion from slow to medium produced a corresponding increase in the magnitude of the MAE, but increasing speed from medium to fast did not. Likewise, imagining slow motion produced a smaller MAE than did imagining medium motion, but the effect leveled of between medium and fast motion. These findings suggest that our mental imagery of motion is specific to the speed of the moving objects, and highlight areas of overlap between mental imagery and visual perception.
\end{abstract}

Keywords: Mental imagery; Motion aftereffect; Embodiment

\section*{Background}

When we imagine a car racing by, how visual is the process of creating the mental image? Do the representations we generate include information about how fast the car appears to be going? Or are they invariant to this property of visual motion perception? In this paper, we make use of the motion aftereffect illusion (MAE) to test whether the speed of imagined visual motion modulates transfer of adaptation to a subsequent visual motion discrimination task.

Researchers have long debated just how similar imagining a visual scene is to actually witnessing it (Kosslyn, 1981; Pylyshyn, 1973). Previous work examining the metric properties of imagined static scenes has found that information about size (Kosslyn, 1975), distance (Kosslyn, Ball, \& Reiser, 1978), and structure (Kosslyn, 1973) is indeed persevered in mental imagery. For example, Kosslyn et al (1978) found that the distance between objects in a mental image is proportional to the physical distance between their real-world counterparts. Participants in their study memorized a fictional map containing several landmarks, and were later asked to "scan" between pairs of landmarks in their mental image of the map. Results showed that the greater the distance between two landmarks on the physical map, the longer it took people to mentally scan between them.

Other work has shown that people are capable of mentally performing metric transformations on images of static objects (Finke, Pinker, \& Farah, 1989; Shepard \& Metzler, 1971). In a study by Shepard and Metzler (1971), participants judged whether pairs of geometric objects were identical to one another or mirror reversed. The authors reasoned that if people solved this task by mentally rotating one object until it aligned with the other, their reaction time should depend on the physical angular disparity between objects. Indeed, participants took longer to mentally rotate objects that would take longer to physically rotate, and vice versa.

The metric properties of mental imagery for dynamic scenes have not been studied as widely as for static scenes. One feature of visual motion that has been found to make it into mental imagery is motion direction. Winawer, Huk, \& Boroditsky (2008) demonstrated that imagining visual motion in a particular direction is sufficient to produce direction-selective adaptation in the visual system (i.e., produce a visual motion aftereffect illusion). After imagining upward motion, participants were more likely to see a subsequent dynamic stimulus as moving downward, and vice versa. Transfer of adaptation from mental imagery to perception suggests that a common neural mechanism underlies both processes. However, the degree of adaptation from mental imagery was considerably weaker compared to that from real visual motion perception, which sets a limit on the overlap between these two processes.

The adaptation paradigm used by Winawer and colleagues provides a unique testing ground for discovering other motion properties preserved in dynamic mental images. In this paper, we ask whether the magnitude of the visual motion aftereffect from mental imagery depends on the speed of imagined motion. If so, does motion speed modulate the MAE from imagery in the same way as speed modulates the MAE from real visual motion perception? That is, is speed yet another feature common to both mental imagery and perception, or is it an area in which internallygenerated motion representations abstract away from their externally-generated counterparts?

To test these questions, we first measured the effect of speed on the MAE from real visual motion (Experiment 1), and compared that with the MAE from imagining the very same motion stimuli (Experiment 2). In Experiment 1, subjects viewed videos of moving stripes (upward or downward) in three within-subject conditions: slow, medium, and fast. Following each video, participants indicated the direction in which a set of dynamic dots appeared to move. We found that increasing the speed of
visual motion from slow to medium produced a corresponding increase in the magnitude of the MAE, but increasing speed from medium to fast did not.

In Experiment 2, participants simply imagined the videos from Experiment 1 prior to completing the dot discrimination task. We found that imagining motion produced a reliable MAE (albeit weaker than from viewing real visual motion). We also found that viewing and imagining motion produced the same relative pattern of results across conditions. As in Experiment 1, imagining slow motion produced a smaller MAE than did medium or fast motion, but there was no difference between the medium and fast conditions.

\section*{Experiment 1}

How does motion speed modulate the magnitude of the MAE from real visual motion?

\section*{Methods}

Participants 30 Stanford undergraduate students participated in this study in exchange for payment.

Stimuli \& Procedure The task design, procedure, and visual stimuli used were modeled on those used by Winawer and colleagues (2008) and Dils and Boroditsky (2010). On each trial participants judged the direction of dot motion after viewing real visual motion. Trials were presented in 6 blocks: 3(speed: fast, medium, or slow) by 2(adaptation direction: upward or downward). The upward and downward versions of each speed were presented in succession. Block order was otherwise randomized across participants. Participants adapted to 60 seconds of motion in the first trial of each block. The adaptation phase of each subsequent trial lasted 6 seconds. There were 24 total trials per block.

Adapting stimuli. Participants watched videos of drifting black-and-white horizontal stripes. The videos showed a sine grating with a spatial frequency of 3.44 cycles per degree of visual angle drifting either upward or downward. In the medium condition, the grating drifted at 4.77 degrees per second. The slow grating drifted at half the speed of the medium grating ( 2.39 degrees per second), while the fast grating drifted at twice the speed of the medium grating ( 9.54 degrees per second). A flickering fixation cross was superimposed at the center of each video. The cross flickered at the same rate that the grating drifted. This feature was included to equate stimuli between Experiments 1 and 2, and it was task-irrelevant in the current study.

Test stimuli. Following the adaptation portion of each trial, participants judged the direction of motion coherence in a field of moving dots, without feedback. One hundred round dots were placed within a round aperture 10 degrees in diameter. The dots were light gray on a dark gray background, and each dot was 0.10 degrees in diameter. The dots moved at 12 degrees per second within the aperture, and any dots whose \(x-y\) coordinates exceeded the boundary of the aperture were randomly placed within the
aperture on each frame. A light gray static fixation dot 0.15 degrees in diameter was placed at the center of each dot display. Dot motion was always presented for 1 second, at which point the dot display disappeared from the screen. Participants pressed " f " if the dots appeared to move upward, and " j " if the dots appeared to move downward.

Each dot display had net motion coherence either up or down. For each subject, three coherence values were sampled 24 times in each direction. The values were tailored to each participant's dot motion sensitivity threshold (as assessed in a baseline task described below). They were selected to be \(12.5 \%, 25 \%\), and \(50 \%\) of the coherence necessary for each individual to detect the direction of motion in a dot display with \(99 \%\) accuracy. Coherence and direction of motion were fully crossed and balanced across trials and participants.

Baseline Motion Sensitivity Task. During the baseline motion sensitivity measurement, participants viewed 192 dynamic dot displays in succession and on each trial had to indicate the direction of motion coherence, upward or downward. Participants pressed the ' \(F\) ' key on a keyboard to indicate upward motion and the ' J ' key to indicate downward motion. The percentage of dots that moved coherently varied from trial to trial. In the baseline task, 12 coherence values were tested \((99 \%, 66 \%, 44 \%, 29 \%, 20 \%\), \(13 \%, 9 \%, 6 \%, 4 \%, 3 \%, 2 \%, 1 \%\) ), and each coherence level was sampled 8 times in each direction (upward / downward). A logistic function was fitted to each participant's data at the end of the baseline task, and the fit was used to compute the participant's threshold (the percentage of dot coherence required for \(75 \%\) accuracy). The threshold was then used to compute the coherence values to be used in the main experimental task, namely, values corresponding to \(50 \%, 25 \%\), and \(12.5 \%\) of the coherence necessary for asymptotic performance. These values were selected to be sufficiently difficult yet discriminable for participants. We refer to these 'normalized coherence' values rather than the actual subject-specific values in all references of motion coherence in reporting results.

Analysis. Participants who did not reach asymptotic performance on the baseline motion sensitivity test were excluded from all analyses ( 5 people). A logistic model was fitted to each participant's data from the main adaptation task. The regression models used a maximum likelihood algorithm to generate the fits and included a bias term, a term for motion coherence of the test stimulus, and three terms for the direction of the adapting stimulus (slow, medium, and fast motion). We computed the shift in the motion response functions as a function of adaptation direction for each level of motion speed. We used this analysis (1) to ensure that there was a reliable MAE in the full sample, and (2) to subsequently exclude participants who did not show an overall trend in the direction of an MAE after viewing real visual motion (4 participants). Since the aftereffect from real visual motion is typically large and robust, we reasoned that participants who did not
at least numerically respond in the direction of adaptation were likely not following task instructions. Even if they were engaged in the task, the absence of an aftereffect would prevent us from being able to assess its dependence on speed in those individuals.

Data from the remaining 21 participants was submitted to a mixed-models logistic regression. The model included fixed-effect parameters for coherence of the test stimulus, direction of adaptation, speed of the adapting stimulus (Helmert coded), and trial number. The model also included terms for the interaction between adaptation direction and motion speed, as well as adaptation direction and trial number. This last interaction term was included to account for longitudinal shifts in the aftereffect due to accumulation of adaptation and fatigue. Finally, the model included random slopes by participant for the full fixed-effects structure.

\section*{Results}

Figure 1 shows the raw, unfitted means across participants for upward and downward adaptation separately (including participants whose data was not in the direction of an MAE). In this inclusive sample, participants showed a \(164.5 \%\) shift between the motion response functions in the direction of adaptation. This difference was highly significant, \(\beta=-4.63, Z=-7.37, p<0.00001\).

Next we tested whether speed modulated the magnitude of the aftereffect in people who responded in the direction of adaptation overall. Indeed, viewing slow motion produced a smaller MAE than did viewing medium or fast motion ( \(\beta=-2.31, \mathrm{Z}=-4.68, p<0.00001\) ). This corresponded with a \(12 \%\) per deg/s increase in the probability of experiencing an MAE on a given trial. However, the increase in the MAE from viewing fast motion compared to medium motion was much smaller ( \(0.65 \%\) per \(\mathrm{deg} / \mathrm{s}\) ), and this shift did not reach significance \((\beta=-0.17, Z=-0.38\), \(p>0.5\) ). The predicted means from this analysis are plotted in Figure 2.

\section*{Discussion}

We asked whether the MAE from real visual motion perception depends on motion speed. We tested for MAEs following slow, medium, and fast visual motion, and we found that increasing speed from slow to medium or fast resulted in a corresponding increase in the magnitude of the MAE. However, we found no additional boost from increasing adaptation speed from medium to fast.

This pattern of results is consistent with previous findings on the relationship between speed of an adapting stimulus and the MAE (Ashida \& Osaka, 1995; see Mather, Verstraten, \& Anstis, 1998 for a review). For example, Ashida and Osaka found that the magnitude of the MAE for a given subject increases with speed until it peaks between 5-10 degrees per second. It then begins to decrease as speed continues to increase. The slow and medium conditions in the present study fall squarely within the rising phase of this
trajectory, but the fast condition falls early in the falling phase for most individuals.

In Experiment 2, we ask whether speed of imagined motion modulates the MAE in the same way as does speed of real visual motion.

Figure 1. Mean proportion UP responses after viewing real visual motion (upper panel) and after imagining visual motion (lower panel). Upward adaptation is plotted in red, and downward adaptation is plotted in blue. Error bars denote \(\pm 1\) s.e.m.

\section*{Experiment 2}

Does speed modulate the magnitude of the MAE from imagined motion? If so, is the pattern of results similar to what we observed from viewing real motion?

\section*{Methods}

Participants 30 Stanford undergraduate students participated in this study in exchange for payment.

Stimuli \& Procedure The stimuli and procedure for this experiment were identical to Experiment 1, except that participants imagined the drifting gratings during the adaptation portion of each trial rather than viewing them.

Before each block, participants were shown upward and downward examples of the grating videos that they would need to imagine during the block. Participants viewed each
video twice for 30 seconds before each block in which a new motion speed was being introduced. They viewed each video twice for 6 seconds before all other blocks. We made sure the visual motion presented during this familiarization phase did not interfere with our results during the main experimental task in three ways. 1. Participants were familiarized with both upward and downward motion, creating no net bias in either direction. 2. The familiarization was followed by at least 30 seconds of verbal instructions, a longer delay than necessary for an MAE from this duration of exposure to real visual motion stimuli to dissipate (Hershenson, 1989). 3. The direction of motion adaptation in the first experimental block following familiarization was chosen randomly.

At the beginning of each trial, an upward or downward facing arrow superimposed on a static image of the grating indicated the direction in which participants were to imagine the stripes moving. This cue faded over the course of a second. Once the cue disappeared completely, a flickering fixation cross appeared at the center of the screen. Participants were instructed to fixate on the cross while imagining the stripes and to use the rate of the flicker to help them remember how fast the stripes should move. Participants were also instructed to use the fixation cross as a cue for when to start and stop imagining motion.

Analysis. All analyses described in Experiment 1 were applied in the same way to the data from Experiment 2, including limiting our main analysis to participants who showed a motion aftereffect illusion. We know from previous work that there is considerable variation across individuals in the magnitude and direction of the aftereffect from internally-generated visual motion (Dils \& Boroditsky, 2010). Some individuals show a large MAE from mental imagery, others show a small MAE, and a small number shows priming and not adaptation. While the causes of these individual differences are not yet known, the variation itself is systematic. People who show an aftereffect from mental imagery also show an aftereffect from other forms of internally-generated visual motion such as linguistic descriptions of motion. The predictions we drew from Experiment 1 about how participants in Experiment 2 should behave only apply to people who showed an MAE overall, as we did not have enough participants who showed priming from real visual motion to create a set of predictions for this subgroup. Further, we did not have enough individuals who showed priming in Experiment 2 to measure the effect of speed on priming from imagined visual motion. Therefore, after first confirming that there was a reliable aftereffect from visual motion imagery in the entire sample, we limited the primary speed analysis of this paper to those participants whose responses at least numerically trended in the direction of a motion aftereffect.

We excluded 1 participant from all analyses for failing to reach asymptotic performance in the baseline sensitivity task. We excluded 5 participants from the main analysis whose results did not trend in the direction of adaptation. Additionally, we conducted a mixed-models analysis testing
for the presence of an interaction between experiments (Nieuwenhuis, Birte, \& Wagenmakers, 2011). This analysis included all previously described predictors plus a term for the concreteness of the adapting stimulus (real versus imagined visual motion), as well as the full factorial 3-way interaction between concreteness, adaptation direction, and motion speed.

\section*{Results}

Figure 1 shows the raw, unfitted means across participants for upward and downward adaptation separately (including participants whose data was not in the direction of an MAE). In this inclusive sample, participants showed a \(9.89 \%\) shift between the motion response functions in the direction of adaptation. This difference was reliable, \(\beta=-\) \(0.42, \mathrm{Z}=-2.13, p<0.05\).

Next we tested whether speed modulated the magnitude of the aftereffect from imagined motion in people who responded in the direction of adaptation overall. Indeed, viewing slow motion produced a smaller MAE than did viewing medium or fast motion ( \(\beta=-0.59, \mathrm{Z}=-2.08, p<0.05\) ). This corresponded with a \(4.97 \%\) per deg/s increase in the probability of experiencing an MAE on a given trial. However, the increase in the MAE from viewing fast motion compared to medium motion was much smaller ( \(0.60 \%\) per \(\mathrm{deg} / \mathrm{s}\) ), and this shift did not reach significance ( \(\beta=-0.04, Z=-0.13, p>0.5\) ). The predicted means from this analysis are plotted in Figure 2.

Finally, we asked whether the magnitude of these effects differed between real and imagined visual motion. The overall magnitude of the motion aftereffect illusion was greater for real visual motion than it was for imagined visual motion ( \(\beta=-3.30, \mathrm{Z}=-8.11, p<0.00001\) ). Also, the increase in the MAE from slow to medium and fast motion adaptation was significantly steeper for real visual motion than it was for imagined motion ( \(\beta=-1.74, \mathrm{Z}=-3.46\), \(p<0.001\) ).

Figure 2. Model estimates of the effect of speed on the degree of adaptation for real and imagined visual motion for average (zero)
coherence and average trial. Positive values are consistent with a motion aftereffect illusion.

\section*{Discussion}

In this study, we asked whether speed of visual motion is preserved in mental imagery. Specifically, we tested whether imagining slow, medium, and fast motion would differentially affect the magnitude of the motion aftereffect from mental imagery. We found that imagining motion indeed made people more likely to perceive a subsequent dynamic test stimulus as moving in the direction opposite the adapting motion. However, this effect was not constant across all speeds we tested. Increasing the speed of visual motion from slow to either medium or fast produced a corresponding increase in the magnitude of the MAE from imagery. However, increasing the speed of visual motion from medium to fast did not result in any additional increase in the MAE.

We also asked whether the relative effects of speed on the MAE from imagery would pattern like those from perception. Indeed both viewing and imagining motion produced a similar rise and then leveling off of the MAE as a function of speed. However, the initial rise was reliably steeper for real visual motion perception than for mental imagery.

\section*{General Discussion}

We started this paper by asking just how similar the representations generated in the service of mental imagery are to those generated during actual visual perception. We indeed found evidence of considerable overlap. First we replicated previous work showing that simply imagining motion is sufficient to produce a motion aftereffect illusion. This suggests that perception and mental imagery recruit, at least in part, the same direction-selective neural mechanisms in the visual system (Dils \& Boroditksy, 2010; Winawer, Huk, \& Boroditsky, 2008). Further, we found that visual motion speed modulates the MAE from both perception and imagery. The relative shape of the effect of speed is similar for internally- and externally-generated visual motion. This pattern suggests that the mechanisms recruited by both perception and mental imagery are in fact speed-specific.

However, we have also identified some key differences between visual motion processing and mental imagery. The effects of imagining motion on subsequent visual perception are considerably smaller overall than those from viewing real motion. Moreover, increasing visual motion speed produces a disproportionately smaller increase in the MAE from imagery relative to perception before it levels off. These findings call for a more nuanced view of how and when the processes that underlie mental imagery and perception interact, and when they diverge.

This work replicates and extends previous findings on the motion aftereffect from mental imagery (Dils \& Boroditsky, 2010; Winawer et al., 2008). The present findings help to rule out concerns that the MAE from internally-generated
motion results from a high-level cognitive bias and not from direction-selective adaptation of visual mechanisms. Cognitive bias should not depend on metric visual properties such as speed. Even if there were reason to predict such a relationship, it seems unlikely that it would lead to the specific pattern of results we observed. After all, we found that the very fastest imagined motion condition did not produce the largest MAE. Conversely, the real visual motion study provided a useful set of predictions about how speed should modulate the MAE from imagery.

While our findings suggest that speed is a feature of realworld visual motion that is preserved in mental imagery, it may be the case that our participants were particularly likely to create speed-specific mental images simply because it was one of the few differentiating features of our motion stimuli. Had our speed manipulation been subtler, perhaps we would not have seen it modulate the MAE from mental imagery. Future work aims to address whether features of visual motion such as speed, contrast, and spatial frequency creep into mental images automatically and irrespective of context, or whether they are represented in a more contextspecific way.

A further set of questions concerns speed represented in linguistic descriptions of motion. If we hear about a train racing versus crawling through the desert, do the resulting mental images contain some of the implied speed information? In previous work, it has been shown that speed implied in linguistic passages can have consequences for cognitive processing. For example, Matlock (2004) demonstrated that people are faster to process sentences describing fictive motion (e.g., The highway runs through the valley) after reading a story that describes fast motion compared to a story that describes slow motion. Future work can examine whether differences in the speed of implied motion described in language can also have visual consequences (e.g., in the size of the MAE) in addition to the speed of processing effects discovered by Matlock (2004).

\begin{abstract}
Context effects - preference changes depending on the availability of other options - have wide ranging implications across applied and theoretical domains, and have driven the development of new dynamic models of multi-attribute and multialternative choice. We propose the Multi-attribute Linear Ballistic Accumulator (MLBA), a new dynamic model that provides a quantitative account of the co-occurrence of three context effects - attraction, similarity, and compromise - not only in traditional paradigms involving choices among hedonic stimuli but also of recent demonstrations of these effects with non-hedonic stimuli. The MLBA model has analytical solutions making it computationally easier to apply than previous dynamic models.
\end{abstract}

Keywords: Decision-making, multi-alternative choice, preference reversal, context effects, dynamic models

\section*{Introduction}

Individuals are often faced with the problem of choosing a single option from a large set of possible alternatives where the options have several features. For example, when purchasing a new cell phone, there are numerous phones from which to choose and each phone has many different features. A robust finding in the choice behavior literature is that preferences are subject to "context effects". That is, preferences for existing alternatives can be influenced or even reversed by the addition of new alternatives. For example, an initial preference for a cheap, low quality cell phone over an expensive, high quality phone could be reversed when a third expensive phone of low quality is also considered.

Three important context effects are the attraction (Huber, Payne, \& Puto, 1982), similarity (Tversky, 1972), and compromise (Simonson, 1989) effects. The standard experiment for the effects involves choices among three alternatives which each have two attributes. For example, three different cell phones with attributes of price and quality. Figure 1 graphically represents the positions of various options within a two dimensional space defined by two attribute values.

\section*{Three context effects}

The attraction effect refers to the enhancement of an option through the inclusion of a similar but slightly inferior decoy alternative. For the choice set \(\{X, Y\}\), let \(A_{X}\) and \(A_{Y}\) be similar to \(X\) and \(Y\) respectively but slightly inferior to each. For example, \(X\) might be a cheap, low quality cell phone and \(A_{X}\) might be the same quality as \(X\) but more expensive. The attraction effect occurs when people show
greater preference for \(X\) when \(A_{X}\) is included in the choice set \(\{X, Y\}\) as compared to when \(A_{Y}\) is included (and vice versa for \(Y\) ). Mathematically, the attraction effect occurs when \(\operatorname{Pr}\left[X \mid\left\{X, Y, A_{X}\right\}\right]>\operatorname{Pr}\left[X \mid\left\{X, Y, A_{Y}\right\}\right]\) and \(\operatorname{Pr}\left[Y \mid\left\{X, Y, A_{X}\right\}\right]<\) \(\operatorname{Pr}\left[Y \mid\left\{X, Y, A_{Y}\right\}\right]\).

Figure 1: Various options plotted in a two dimensional attribute space. Preferences between \(X\) and \(Y\) can be affected by the presence of other options.

The similarity effects refers to the enhancement of a dissimilar option when two similar options compete with one another. For the choice set \(\{X, Y\}\), let \(S_{X}\) and \(S_{Y}\) be similar and competitive to \(X\) and \(Y\) respectively. For example, if \(X\) is a cheap, low quality cell phone, then \(S_{X}\) might be a little more expensive and have slightly higher quality than \(X\). The similarity effect occurs when people show greater preference for the dissimilar option \(Y\) when \(S_{X}\) is included in the choice set \(\{X, Y\}\) as compared to when \(S_{Y}\) is included (and vice versa for \(X\) ). Mathematically, the similarity effect occurs when \(\operatorname{Pr}\left[X \mid\left\{X, Y, S_{X}\right\}\right]<\operatorname{Pr}\left[X \mid\left\{X, Y, S_{Y}\right\}\right]\) and \(\operatorname{Pr}\left[Y \mid\left\{X, Y, S_{X}\right\}\right]>\operatorname{Pr}\left[Y \mid\left\{X, Y, S_{Y}\right\}\right]\).

The compromise effect refers to the enhancement of an option when it is presented as a compromise between two other alternatives. For the choice set \(\{X, Y\}\), let \(C_{X}\) and \(C_{Y}\) be extreme options that make \(X\) and \(Y\) take the middle ground respectively. For example, if \(X\) is a cheap, low quality cell phone, then \(C_{X}\) might be drastically cheaper and extremely
lower quality than \(X\). The compromise effect occurs when people show greater preference for \(X\) when \(C_{X}\) is included in the choice set \(\{X, Y\}\) as compared to when \(C_{Y}\) is included (and vice versa for \(Y\) ). Mathematically, the compromise effect occurs when \(\operatorname{Pr}\left[X \mid\left\{X, Y, C_{X}\right\}\right]>\operatorname{Pr}\left[X \mid\left\{X, Y, C_{Y}\right\}\right]\) and \(\operatorname{Pr}\left[Y \mid\left\{X, Y, C_{X}\right\}\right]<\operatorname{Pr}\left[Y \mid\left\{X, Y, C_{Y}\right\}\right]\).

The three context effects are theoretically important because they violated the simple scalability property (Krantz, 1964; Tversky, 1972) which is a property of most utility models of choice including Luce's (1959) ratio of strengths model. To show a violation, consider the attraction effect. According to simple scalability, the inequality \(\operatorname{Pr}\left[X \mid\left\{X, Y, A_{X}\right\}\right]>\operatorname{Pr}\left[X \mid\left\{X, Y, A_{Y}\right\}\right]\) implies that the strength of \(A_{X}\) is less than the strength of \(A_{Y}\). However, the inequality \(\operatorname{Pr}\left[Y \mid\left\{X, Y, A_{X}\right\}\right]<\operatorname{Pr}\left[Y \mid\left\{X, Y, A_{Y}\right\}\right]\) implies that the strength of \(A_{Y}\) is less than the strength of \(A_{X}\). Both statements obviously cannot be true so the property is violated. The similarity and compromise effects produce similar violations.

\section*{Dynamic models of context effects}

Because utility models cannot account for context effects due to violations of simple scalability, researchers have turned to dynamic models to explain the effects. There are two predominate dynamic models of the effects: multi-alternative decision field theory (MDFT) (Roe, Busemeyer, \& Townsend, 2001) and the leaky competing accumulators (LCA) model (Usher \& McClelland, 2004). Even though these models have provided great insight into multi-alternative choice, they are not without flaws. First, both models require time intensive simulations for fitting data with internally controlled stopping times (the experimental procedure commonly used in context effects tasks in which participants control when they make decisions as opposed to an experimenter controlled deadline). Thus, it is difficult to fit the models to human data and evaluations of the models have relied on qualitative analyses such as showing that all three effects can be obtained using a single set of parameters. There has not been a quantitative comparison of the models and it remains unknown whether or not they can account for human data.

Further, the LCA model assumes that the attraction and compromise effects are the result of loss aversion. The loss aversion assumption seems reasonable for situations where the options have hedonic attributes such as consumer products with attributes of price and quality. However, there is recent evidence that context effects are a general feature of choice behavior and not specific to options with hedonic attributes. Trueblood (2012) demonstrated the three effects in an inference paradigm involving scenarios about criminal suspects. In these experiments, subjects were asked to infer which suspect out of a set of three was most likely to have committed a crime based on eye-witness evidence. Trueblood, Brown, Heathcote, and Busemeyer (in press) also showed the three effects in a simple perceptual task where subjects were asked to select the largest rectangle out of a set of three. Choplin and Hummel (2005) found the attrac-
tion effect with ovals and line segments in a similarity judgment paradigm and Tsetsos, Usher, and McClelland (2011) obtained the similarity effect using time-varing psychophysical stimuli. These experiments all suggest that the effects are not due to loss aversion because there is no notion of gains or losses along the attributes.

This paper introduces a new dynamic model, the multiattribute linear ballistic accumulator (MLBA) model, to account for context effects in multi-alternative choice. The MLBA model is easier to fit to data than MDFT and the LCA model because of its computational tractability. Also, it does not rely on loss aversion to explain the effects and thus can be applied to both hedonic and non-hedonic choices.

\section*{Precursors to the MLBA model}

The MLBA model is an extension of the linear ballistic accumulator (LBA) model (Brown \& Heathcote, 2008) that takes into account multiple attributes of options. The LBA models choice and response times with independent accumulators that race to a threshold \(\chi\). Each accumulator corresponds to a different option and the accumulator that first reaches the threshold is selected. Within a single trial, the accumulators are both linear and deterministic leading to mathematically tractable solutions for choice and response times. Each accumulator starts at a randomly determined amount of evidence selected from a uniform distribution \([0, A]\). The accumulators increase at speeds defined by the drift rates which are drawn from a normal distribution on each trial. Typically, the normal distributions have freely-estimated mean values \(d_{1}, d_{2}, d_{3} \ldots\) and a common standard deviation \(s=1\).

Figure 2: Connectionist network interpretation of MDFT.

The MLBA model also incorporates some of the cognitive mechanisms used in MDFT. MDFT assumes an individual's preferences are determined by a series of comparisons and evaluations of the alternatives that evolve across time. The preferences continue to evolve until one of the preference states, associated with one of the options, reaches a threshold and is selected. Preference states are determined by va-
lences for each option and lateral inhibition among the options. The valences are constructed from three components: subjective values, stochastic attention weights, and a comparison mechanism. The strength of the lateral inhibition is determined by the distance between two options in an "indifference/dominance" space (Hotaling, Busemeyer, \& Li, 2010).

MDFT can be interpreted as a connectionist network (Roe et al., 2001; Busemeyer \& Johnson, 2004), as illustrated in Figure 2. At each moment in time, attention can be allocated to attribute \(P\) (e.g., price) or attribute \(Q\) (e.g., quality), as illustrated in the first layer. The second layer shows each option weighted by the attributes. This layer instantiates the comparison mechanism and projects valences to the third layer. The valences are subject to the distance-dependent lateral inhibition process in the fourth layer, which outputs preferences.

\section*{The MLBA model}

The MLBA model adds to the LBA model by explicitly specifying how drift rates arise from the evaluation of attributes. It is assumed that mean drift rates are an increasing function of the valences of the options, where valences are defined in a similar manner to MDFT. Specifically, valences are determined by three components: subjective values, attention weights, and a comparison mechanism.

In determining the mean drift rates, each option is associated with a valence that represents the advantages or disadvantages of the option. For a set of options such as \(\{X, Y, Z\}\), the valences can be described by the vector \(V=\left[v_{X}, v_{Y}, v_{Z}\right]^{\prime}\). Let \(P\) and \(Q\) be attributes where \(P_{i}\) and \(Q_{i}\) denote the value of option \(i\) on each dimension. It is assumed that decisionmakers evaluate the subjective value of each option on each attribute producing the matrix of evaluations:
\[
M=\left[\begin{array}{ll}
m_{P 1} & m_{Q 1}  \tag{1}\\
m_{P 2} & m_{Q 2} \\
m_{P 3} & m_{Q 3}
\end{array}\right]
\]

In MDFT, the values \(m_{P i}\) and \(m_{Q i}\) represent an individual's subjective evaluation of the attributes. However, the exact form of this evaluation is not given. In the MLBA model, we constrain this form. We assume that the psychological \(m_{P i}\) and \(m_{Q i}\) values result from a local rescaling (i.e., within a single trial) of the experimentally defined attribute values, \(P_{i}\) and \(Q_{i}\). Wedell (1991) argued that context effects should be considered as local rather than global phenomena. Also, Gonzalez-Vallejo (2002) postulated a local rescaling of options in her proportional difference model.

There are at least three ways the local rescaling can be implemented. One possible rescaling arises from dividing the experimental values by the smallest values on attributes \(P\) and \(Q\) for a given set of options so that \(m_{P i}=P_{i} / \min (P)\) and \(m_{Q i}=Q_{i} / \min (Q)\). Another possibility is dividing the experimental values by the largest values on attributes \(P\) and \(Q\) for a given set of options so that \(m_{P i}=P_{i} / \max (P)\) and \(m_{Q i}=Q_{i} / \max (Q)\). The third option is to divide the experimental values by the average value of the attributes \(P\) and \(Q\)
for a given set of options so that \(m_{P i}=P_{i} / \frac{1}{3}\left(P_{1}+P_{2}+P_{3}\right)\) and \(m_{Q i}=Q_{i} / \frac{1}{3}\left(Q_{1}+Q_{2}+Q_{3}\right)\).

As in MDFT, the second component of the valence vector is the attention weights. We assume the decision-maker allocates a certain amount of attention to each attribute. The attention weight \(w_{P}\) represents the amount of attention allocated to the \(P\) attribute across the trial and \(w_{Q}\) represents the amount of attention allocated to the \(Q\) attribute across the trial. It is further assumed that \(w_{Q}=1-w_{P}\). The two attention weights are used to define the attention vector:
\[
W=\left[\begin{array}{ll}
w_{P} & w_{Q} \tag{2}
\end{array}\right]^{\prime} .
\]

The third component of the valence vector is a comparison mechanism. Like MDFT, this comparison process determines the relative advantage or disadvantage of each option on each attribute. The comparison process can be represented by a contrast matrix:
\[
C=\left[\begin{array}{ccc}
1 & -\frac{1}{2} \alpha_{12} & -\frac{1}{2} \alpha_{13}  \tag{3}\\
-\frac{1}{2} \alpha_{21} & 1 & -\frac{1}{2} \alpha_{23} \\
-\frac{1}{2} \alpha_{31} & -\frac{1}{2} \alpha_{32} & 1
\end{array}\right]
\]

Using this matrix, which assumes that \(\alpha_{i j}=\alpha_{j i}\), we can define the valence vector in a similar manner as in MDFT by the matrix product
\[
\begin{equation*}
V=C M W \tag{4}
\end{equation*}
\]

The weights \(\alpha_{i j}\) in the contrast matrix are defined by the indifference/dominance distance function developed by Hotaling et al. (2010) to determine the strength of the lateral inhibition in MDFT. Consider a pair of options \(\left(P_{i}, Q_{i}\right)\) and \(\left(P_{j}, Q_{j}\right)\). Define the distance between these two options as \((\Delta P, \Delta Q)=\left(P_{i}-P_{j}, Q_{i}-Q_{j}\right)\). These distances are then mapped to the corresponding coordinates in the indifference and dominance space: \((\Delta I, \Delta D)=1 \sqrt{2} \cdot((\Delta Q-\Delta P),(\Delta Q+\) \(\Delta P)\) ) where \(\Delta I\) is the difference along the indifference dimension and \(\Delta D\) is the difference along the dominance dimension. Using these coordinates, the distance function that weights changes more in the dominance dimension than the indifference dimension is defined as
\[
\begin{equation*}
\text { Dist }_{i j}=\sqrt{(\Delta I)^{2}+\beta \cdot(\Delta D)^{2}} \tag{5}
\end{equation*}
\]
where \(\beta \geq 1\). The distances are converted into similarities by the Gaussian function:
\[
\begin{equation*}
S_{i j}=\exp \left(-\phi \cdot D_{i s t} t_{j}\right) \tag{6}
\end{equation*}
\]

Using the similarities, we define the \(\alpha\) parameters as dissimilarity measures:
\[
\begin{equation*}
\alpha_{i j}=1-S_{i j} \tag{7}
\end{equation*}
\]

This mapping allows for options that are dissimilar to be weighted more in the comparison process. Finally, the valences are mapped into mean drift rates using a logistic function:
\[
\begin{equation*}
d_{i}=\frac{10}{1+\exp \left(-\gamma \cdot v_{i}\right)} \tag{8}
\end{equation*}
\]

In total, the model uses four free parameters to define the mean drift rates: the attention weight \(w_{P}\), the dominance weight \(\beta\), the similarity parameter \(\phi\), and the logistic parameter \(\gamma\). The model also has a starting point parameter \(A\), a threshold parameter \(\chi\) and a drift rate noise parameter \(s\) which are fixed when only modeling choice probabilities. For the current application, the noise parameter is assumed to the be the same for each accumulator. This assumption could be relaxed in other circumstances.

As with MDFT, the MLBA model can also be interpreted as a connectionist network as illustrated in Figure 3. For a given trial, a certain amount of attention can be allocated to attribute \(P\) and to attribute \(Q\) as illustrated in the first layer of the network. The second layer shows each option weighted by the attributes. This layer applies the contrast process and projects valences into the third layer. The valences are transformed into mean drift rates by a logistic function (f) in the fourth layer. Unlike MDFT, there is no lateral inhibition.

Figure 3: Connectionist network interpretation of MLBA.
The MLBA model accounts for the similarity effect through the local rescaling of the attribute values used to determine the \(M\) matrix. This local rescaling process results in more favorable subjective values for the dissimilar option. The model accounts for the attraction and compromise effects through the comparison process captured by the \(C\) matrix.

\section*{Combined Inference Experiment}

Context effects are typically tested using different groups of subjects for different effects. Thus, it remains an open question whether the attraction, compromise, and similarity effects can be found within a single experiment using the same subjects. This experiment investigates whether all three effects can be observed within the same experiment using the inference paradigm developed by Trueblood (2012). Data
from this experiment will be used in the subsequent section to compare MDFT and the MLBA model.

In Trueblood (2012), the three effects were tested in separate experiments using an inference paradigm involving decisions about criminal suspects. The experiments tested how people infer which suspect out of a set of three is most likely to have committed a crime based on two pieces of evidence. The evidence was described as strength ratings from two different eyewitness testimonies where the ratings ranged from 0 to 100 with a rating of 0 corresponding to very weak evidence for guilt and a rating of 100 corresponding to very strong evidence for guilt. In these crime scenarios, the suspects represent the different choice options and the eyewitness testimonies represent the two attributes in a similar manner as a consumer product with attributes of quality and price.

\section*{Method}

Sixty-eight undergraduate students from Indiana University participated for course credit. Participants were told they would see three suspects of a crime on each trial and were instructed to select the suspect that seemed most likely to have committed the crime based on the strengths of two different eyewitness testimonies. Participants were also told that the testimonies of both eyewitnesses were equally valid and important and that the strengths of the testimonies were equated. Participants did not receive feedback.

The suspects and eye-witness strengths were presented in a table format with different suspects in different rows. In the attraction effect experiment, for example, participants might have seen strength ratings of 63 (eyewitness 1) and 33 (eyewitness 2) for the suspect in row one, strength ratings of 32 (eyewitness 1) and 64 (eyewitness 2) for the suspect in row two, and strength ratings of 61 (eyewitness 1 ) and 31 (eyewitness 2) for the suspect in row three. In this example, the third suspect acts as the dominated decoy for the first suspect.

Each participant completed 240 trials which were divided into three blocks of 80 trials. The three blocks were used to test the three effects and were randomized across participants. Within each block, participants saw 40 trials testing one of the effects and 40 filler trials. The presentation order of the trials within each block was randomized. Filler trials where one alternative was clearly superior were used to assess accuracy throughout the experiment. The trials used to test for context effects were subdivided so that the decoy was placed near one alternative for some trials and near the other alternative for other trials. For example, the attraction effect was analyzed by comparing the choice sets \(\left\{X, Y, A_{X}\right\}\) and \(\left\{X, Y, A_{Y}\right\}\) as illustrated in Figure 1. The similarity effect was tested in two regions of the attribute space using a total of four ternary choice sets as in Trueblood (2012).

\section*{Results}

For data analyses, three participants were removed because their accuracy was two standard deviations lower than the average accuracy on the filler trials. Figure 4 shows the mean choice probabilities for focal and non-focal alternatives in the
attraction, similarity, and compromise effect trials. For the similarity effect, the focal option refers to the dissimilar alternative because this is the one enhanced by the decoy. For the attraction effect trials, the choice probability for the focal alternative \((M=0.548)\) was significantly larger than the choice probability for the non-focal alternative ( \(M=0.419\) ) \((\mathrm{t}(64)=3.141, \mathrm{p}=0.002)\). The similarity trials also showed that across all four choice sets the choice probabilities were significantly larger for focal options \((M=0.429)\) than nonfocal options \((\mathrm{M}=0.362)(\mathrm{t}(64)=2.578, \mathrm{p}=0.012)\). For the compromise effect, the choice probability for compromise alternatives \((M=0.466)\) was significantly larger than the choice probability for extreme alternatives \((M=0.407)\) \((\mathrm{t}(64)=2.172, \mathrm{p}=0.034)\).

\section*{Comparing MDFT and MLBA}

We fit MDFT and the MLBA model to the average choice probabilities across subjects from the combined inference experiment discussed above. We did not fit individual choice probabilities because there were not enough data from each subject. The two models were fit to choice probabilities only rather than choice probabilities and response times. In previous literature, multi-alternative choice models have only been analyzed with respect to choice probabilities. Future work could use response time measures to further test the models.

Because MDFT does not have analytical solutions for internally controlled stopping times, fitting the model requires computationally intensive simulations. To avoid this computational difficulty an approximate method developed by Hotaling et al. (2010) was used, where we fit the model using an externally controlled stopping procedure with a large stopping time. We fit the model by allowing four parameters to vary freely. One of the parameters determines the attention weight in the first layer of the model shown in Figure 2. The other three parameters are used in calculating the strength of the lateral inhibition. We fixed the decision time to the large value, \(t=1001\) used by Hotaling et al. (2010) and the withintrial variability parameter to 1 . Because the attribute values for the experiment were associated with eyewitness testimony strengths ranging from 0 to 100 , we used the attribute values divided by 10 for the subjective values.

The MLBA model was fit by numerically integrating over decision times as discussed in Hawkins et al. (submitted). For the MLBA model, we allowed the four parameters used to define the mean drift rates to vary freely and fixed the starting point parameter to \(A=1\), the threshold parameter to \(\chi=2\), and the drift rate noise parameter to \(s=1\). We fit three versions of the model corresponding to the three possible local rescalings: minimum, maximum, and average.

We fit a total of 24 choice probabilities arising from the eight ternary choice sets used in the experiment. The attraction and compromise effects each involved two ternary choice sets corresponding to the two possible locations of the decoy alternative. There were four ternary choice sets used for the similarity effect as described above. The models were fit
by minimizing the sum of squared error (SSE) between the model predictions and the data. When fitting mean probabilities, the SSE will approximate the maximum likelihood estimate. Table 1 gives the mean squared error (MSE) and the \(R^{2}\) values for the models.

Table 1: MSE and \(R^{2}\) values for MDFT and three versions of MLBA.
\begin{tabular}{lcc}
\multicolumn{1}{c}{ Model } & MSE & \(R^{2}\) \\
\hline MDFT & 0.037 & 0.251 \\
MLBA (minimum rescaling) & 0.030 & 0.400 \\
MLBA (maximum rescaling) & 0.016 & 0.684 \\
MLBA (average rescaling) & 0.029 & 0.414
\end{tabular}

The MLBA model using the maximum rescaling is able to account for about \(68 \%\) of the variability in the data as indicated by the \(R^{2}\) value. Substantially poorer performance was obtained for the MLBA model with minimum and average rescaling, although both still performed much better than the MDFT model. Future work could examine the differences between the three rescalings in more detail. We doubt MDFT's poor fits are due to the externally controlled stopping time procedure, as Hotaling et al. (2010) found that the externally controlled stopping time model with long stopping times produced essentially the same results as internally controlled stopping times.

\section*{Discussion}

Multi-alternative choice models such as MDFT and the LCA model have provided great insight into choice behavior, but these models have some drawbacks. They both required time intensive stimulations to fit data. Further the LCA model uses loss aversion to explain the attraction and compromise effects. The assumption that asymmetry between losses and gains is the underlying cause of these effects is problematic because the effects arise in paradigms were there are no losses or gains. The MLBA model overcomes these problems and provides a new psychological theory of context effects.

The MLBA model consists of two components: a frontend process that compares options along their attributes and a back-end process that determines the probability that a particular option will be selected. The back-end process is the LBA model developed by Brown and Heathcote (2008). This paper develops the front-end attribute processing component. The coupling of front-end and back-end processes is not new. The SAMBA model (Brown, Marley, Donkin, \& Heathcote, 2008) of choice and response times in absolute identification tasks proposes a front end to the Ballistic Accumulator model (Brown \& Heathcote, 2005). We suggest this pairing can be viewed as the front-end process modulating action selection in the back-end process. Models incorporating such modulation are common in the neurophysiological literature. For example, Frank (2005) developed a model in which the striatum modulates motor actions and working memory updating

Figure 4: Mean choice probabilities with error bars showing the standard error of the mean for the attraction, similarity, and compromise effects from the combined inference experiment.
in frontal cortex. We do not argue that our model can be mapped to specific brain regions, but speculate that the gating of actions by a front-end process could have a neural explanation.

\begin{abstract}
In two experiments we examined the effects of training on auditory perception bias (Experiment 1), the relationship between auditory perception bias and global-local processing (Experiment 2), as well as the relationship between globallocal auditory processing, empathy and self-construal (Experiment 2). The present findings are discussed in relation to their implications for research in auditory perception and the perception of others' emotional states.
\end{abstract}

\section*{Introduction}
"C'est quoi, le pitch?" used to be the favorite question of the famous French TV talk show host, Thierry Ardisson, when he was interviewing writers, film makers and politicians alike. Knowing what the pitch is may not just be important on French television but plays an important role in our development of linguistic abilities as well. Starting in early infancy, our early auditory ability to process pitch and detect pitch contour deviations appears to be tightly linked to our ability to extract linguistic rules (Mueller, Friederici, \& Männel, 2012). Pitch pattern perception has been shown to be an important predictor of reading performance both in skilled readers and children with developmental dyslexia (Foxton et al., 2003; Ziegler et al., 2012) and to play a role in L2 acquisition (Wong \& Perrachione, 2007). However, pitch processing and production play an important social role in two ways: First, pitch modulation is a carrier of information about speakers' emotions and attitudes (Scherer et al., 1991; Juslin \& Laukka, 2003). Second, pitch imitation is exploited in promoting social convergence and status accommodation (Gregory, 1983; Gregory \& Hoyt, 1982; Gregory, Webster, \& Huang, 1993; Gregory \& Webster, 1996; Gregory, Dagan, \& Webster, 1997; Gregory \& Gallagher, 2002) and expressing ingroup-outgroup bias (Babel, 2009). In sum, an early assessment and training of a listener's ability to process rapid pitch changes in the speech signal could contribute to the development of tools for diagnosis and remediation of different types of language and communication disorders.
What makes pitch detection difficult? Pitch is, roughly, the perceptual correlate of fundamental frequency, produced primarily by the vibrations of vocal chords. It is both the most prominent and most elusive component of the complex sound produced by human articulators because its
perception is influenced both at the level of primary auditory mechanisms in the ear (which, mainly due to the nonlinearities in the cochlea, may supply input in the fundamental frequency region; Moore, 2003) and at the level of neural processing in the auditory cortex (Schneider et al., 2005). Interestingly, the way complex sounds are perceived seems to differ systematically between individuals: Some listeners - known as \(\mathrm{f}_{0}\) or synthetic/holistic listeners - focus primarily on the region between \(50-500 \mathrm{~Hz}\), the region where the fundamental frequency can be found. Others - known as spectral/analytic listeners - rely on analyzing the harmonic constituents of the sound and focus on the spectrum "as a whole" (e.g. von Helmholtz, 1885). A neurological basis has been suggested for this difference, according to which there is a leftward vs. rightward asymmetry of the lateral Heschl's gyrus for synthetic and analytics listeners, respectively (e.g. Schneider et al., 2005). The auditory perception bias has been almost exclusively analyzed in the context of musical training, but the results of individual studies indicate that it may also affect linguistic performance (Wong \& Perrachione, 2007; Wong et al., 2008), as well as pitch imitation (PostmaNilsenová \& Postma, 2012).
Most of the research on the synthetic and analytic listener types suggests that their auditory perception bias is a stable individual difference, possibly caused by genetic factors (Dediu \& Ladd, 2007; Wong, Chandrasekaran, \& Zheng, 2012). However, musical competence and training can affect the listening mode and lead to a shift from spectral to fundamental listening (Seither-Preisler et al., 2007). Also, repeated exposure to stimuli with a missing fundamental frequency over the course of several months appears to facilitate the synthetic listening mode and thus, presumably, to improve pitch perception (Seither-Preisler et al., 2007; Postma-Nilsenová \& Postma, 2012).

In the first part of our study, we explore the possible effect of training on auditory perception bias. More specifically, we aim to find out whether training subjects into perceiving changes in pitch direction according to changes in fundamental frequency or changes in the spectrum can affect their subsequent listening mode. In the second part of the study, we explore the link between the auditory perception bias and listeners' sensitivity to local
and global pitch changes, roughly mirroring local and global perception in the visual domain (Ziegler et al., 2012).

Simply put, global processing refers to the perception of a stimulus as a whole, whereas local processing corresponds to the perception of its parts. With respect to auditory stimuli, global processing corresponds to the perception of the pitch direction or contour, while local processing stands for the perception of the intervals between the notes comprising a sound (Bouvet et al, 2011; Justus \& List, 2005; Sanders \& Poeppel, 2007). Research in the visual domain has provided some support for stronger right hemisphere activation during global processing and stronger left hemisphere activation during local processing (e.g. Fink et al, 1996). So far, the link between auditory local and global processing and the auditory perception bias has not been explored experimentally.

\section*{Global vs. Local Precedence and its Correlates}

In the visual domain, processing at the global level usually takes precedence over processing at the local level, a tendency described as the Global Precedence Effect (GPE) (Navon, 1977). A similar pattern has been demonstrated in the auditory domain as well (Bouvet et al., 2011; List, Justus, Robertson \& Bentin, 2007). Contrary to this general effect, processing at the local level can also precede global processing when stimuli features are altered (e.g. Kimchi, 1992), or, even more importantly, in case of developmental differences. For instance, in the auditory domain, children with developmental dyslexia show a stronger tendency for local auditory processing (Ziegler, Pech-Georgel, George, \& Foxton, 2011); in the visual domain, individuals diagnosed with Autistic Spectrum Disorders, such as autistic children (Jollife \& Baron-Cohen, 2006) and women diagnosed with Anorexia Nervosa (Southgate et al, 2008) show a local processing bias as well. In the case of autism, Baron-Cohen (2002) describes the tendency for local processing as systemizing and differentiates it from empathizing, which reflects the ability to share others' mental and emotional states. Autistic children perform poorly in tasks requiring Theory of Mind (ToM) and show empathic deficits from a very early age (Baron-Cohen, 1995; Yirmiya, Sigman, Kasari, \& Mundy, 1997, a.o.). Impaired ToM is also itself associated with low empathy scores (Shamay-Tsoory et al., 2005). The above findings indicate that the presence of a local processing bias is, in autism at least, accompanied by the presence of impaired empathy. A more direct examination of the link between global-local visual processing and empathy in normal subjects has shown, on the contrary, a link between local processing and greater empathy (Woltin, Corneille, Yzerbyt, \& Förster, 2011). This last finding was attributed to the facilitating role that local processing plays in self-other awareness, a prerequisite for the experience of empathy (Decety \& Jackson, 2004).

In the present research, we also aim to examine the relationship between empathy and global-local auditory processing. In the auditory domain, personal distress, an affective component of empathy, has been associated with
the ability to perceive prosody (Aziz-Zadeh, Sheng, \& Gheytanchi, 2010). Prosody perception is impaired in children diagnosed with the Asperger syndrome (Korpilahti et al., 2007). Furthermore, autistic children have difficulties in inferring mental states from the other's voice (Rutherford, Baron-Cohen, \& Wheelwright, 2002). If we take into account the processing preferences of autistic individuals, impaired prosody perception and decreased empathy seem to accompany the local processing bias. Considering that similar processing types are exhibited across modalities, we might expect a local processing preference to be accompanied by impaired prosody perception and empathy in the auditory domain as well.

To strengthen the proposed relationship between globallocal processing and empathy, we will also examine the role of self-construal (Markus \& Kitiyama, 1991). Interdependent self-construal has been associated with global processing, whereas independent self-construal with local processing (Kühnen \& Oyserman, 2002; Lin et al, 2008, 2009). Moreover, interdependent self-construal is related to higher empathy (Cross et al., 2000). In addition to these two types of self-construal, we are also considering the relational-interdependent self-construal, a type of interdependence found in rather individualistic cultures (Cross et al., 2000). According to the above, we expect interdependent and relational-interdependent self-construal to be positively related to global auditory processing and empathy, while independent self-construal to be negatively related.

\section*{Current Study}

\section*{Experiment 1}

\section*{Participants}

Sixty-eight students ( 15 males and 54 females) from Tilburg University were recruited for an experimental session in exchange for course credit. Participants' age ranged from 17 to 27 years old (mean \(=22.2, \pm 2.6\) ). One participant reported non-normal hearing ability; the participant was not excluded from the analyses given that (s)he performed similarly to the rest of the participant group. The participants were randomly divided into the three betweenparticipant experimental conditions.

\section*{Stimuli and procedure}

A total of 72 pairs of complex harmonic tones consisting of two, three or four harmonics were constructed for the pitch discrimination task, following the procedure described in Laguitton et al. (1998), including the addition of noise in order to minimize the effects of combination tones (which arise at the cochlear level and may interfere with the measurements of individual differences on the neural level). Thirty-six tone pairs were ambiguous, meaning that the second tone sequence would be judged as higher vs. lower than the first one depending on the participant's listening mode. For 18 ambiguous tone pairs, the second sequence would be judged as lower-higher based on a fundamental
frequency listening mode. For the rest of 18 tone pairs, the second sequence would be judged as higher-lower based on a spectral listening mode. The remaining 36 tone pairs were unambiguous and were used as control stimuli. Each tone pair was 2000 ms long. All stimuli were displayed using EPrime (Psychology Software Tools, Inc., www.pstnet.com).

Training phase: During the training phase, participants were presented with 36 ambiguous tone pairs. They were instructed to listen to the tone pair and were asked to indicate whether they perceived the tone pair as rising or falling. After each response, they were provided with feedback about the tonal progression, aiming to train their listening mode. In the fundamental frequency mode condition, participants were told that the tone pair was rising (falling) according to rises (falls) of the fundamental frequency. In the spectral listening mode condition, the feedback depended on rises (falls) of the spectrum. In a control condition, no feedback was provided. The response key order was counterbalanced between the participants.

Testing phase: During the testing phase, participants were presented with 18 ambiguous and 18 non-ambiguous tone pairs. Similarly to the training phase task, they were instructed to indicate whether they perceived the tone pair as rising or falling, they were not provided with feedback about the tonal progression.

\section*{Measurements}

Based on the participants' answers, we calculated their individual 'Coefficient of Sound Perception Preference' \(\left(\partial_{p}\right)\) using the formula \(\partial_{p}=(\mathrm{F}-\mathrm{Sp}) /(\mathrm{F}+\mathrm{Sp})\), where F is the number of virtual fundamental classifications and Sp the number of spectral classifications in the testing phase. We calculated the 'Listener Attention Coefficient' \(\left(\partial_{A}\right)\) as the proportion of correctly categorized unambiguous stimuli.

Figure 1: Distribution of the Coefficient of Sound Perception Preference across the three experimental conditions.

\section*{Results}

A one-way analysis of variance showed no effect of training on the Coefficient of Sound Perception Preference in the testing phase. The participants in the fundamental frequency mode condition, the spectral mode condition and the control condition also did not differ with respect to their mean reaction times and correct responses to the non-ambiguous stimuli. The distribution of the \(\partial_{p}\) values across the three conditions is shown in Figure 1.

\section*{Discussion}

The results of the first experiment indicate that simple feedback is not sufficient to train participants in such a way that they focus either on the fundamental frequency in the signal or on its harmonic components. The results confirm the findings of Ladd et al. (2013) and others who found that auditory perception bias is robust in test-retest. Contrary to their study, we found a relatively normal distribution of listener types in our experimental group, compared to the prevalence of holistic (fundamental) listeners in their experiment. The difference is most likely due to the use of masking noise in our stimulus material which helped to exclude effects of combination tones (Plomp, 1976).

\section*{Experiment 2}

\section*{Participants}

Forty-nine students (7 males and 42 females) from Tilburg University, drawn from the same participant group as in Experiment 1, were recruited for an experimental session in exchange for course credit. Participants' age ranged from 18 to 27 years old (mean \(=22.5, \pm 1.8)\).

\section*{Stimuli and procedure}

Auditory global-local processing task
To measure global-local auditory processing, a total of 96 pairs of 4-tone sequences ( 48 same and 48 different) stimuli were used. The stimuli were constructed following the procedure suggested by Ziegler, Pech-Georgel, George, \& Foxton (2011). The sequences contained pure tones, each of 250 ms duration with 20 ms gating windows, with frequencies from an atonal scale taken from a division of an octave into seven equally spaced logarithmic steps. The starting frequencies were taken from the interval between 250 to 354 Hz . The third or fourth note in the second sequence was altered so that it was two steps lower or higher than the note in the first sequence (see Figure 2). In the local stimuli, the second sequence would remain rising/falling, in the global stimuli, the global melody would change. Each tone pair was 1000 ms in duration. All stimuli were displayed using E-Prime (Psychology Software Tools, Inc., www.pstnet.com) in a random order.

\section*{Auditory affective processing task}

To measure participants' performance in auditory affective processing, we used the Montreal Affective Voices stimuli (Belin, Fillion-Bilodeau, \& Gosselin, 2008). The corpus includes 90 vocal affect bursts (expressed as the vowel \(/ \mathrm{a} /\) ),
which express the emotions of anger, disgust, fear, happiness, pain, pleasure, sadness, surprise and a neutral expression. Participants heard each vocal expression once and were asked to select one of the above emotions.

Figure 2: Illustration of the local and global types of stimuli used in Experiment 2 (from Ziegler et al. (2011)).

\section*{Empathy measurement}

To measure empathy, we used the Interpersonal Reactivity Index, developed by Davis (1980). It measures individual differences in empathy and consists of four dimensions (perspective taking, fantasy scale, empathic concern and personal distress) each one tapping a different aspect of empathy. Participants were asked to indicate, on a five-point scale, to what extent each statement described themselves.

\section*{Self-construal measurement}

To assess the role of self-construal, we used the SelfConstrual Scale developed by Singelis (1994). The scale consists of 24 items which measure the interdependent and independent images of the self. We also included the relational-interdependent self-construal scale (Cross et al., 2000). The scale consists of 11 items. For both measures, participants were asked to indicate their agreement or disagreement on a seven-point scale.

\section*{Measures}

Following Ziegler et al. (2011), we used d' measures to calculate the participants' performance in the auditory global-local pitch processing task ( \(\mathrm{d}_{\mathrm{G}}\) and \(\mathrm{d}_{\mathrm{L}}\), respectively). Both measures were not normally distributed with \(M d_{G}=\). 427, \(M d_{L}=.312\). For the auditory affective processing task, we calculated the scores as the total number of correctly identified emotions (Aff). The mean score of correctly identified emotions (90 in total) was 61.6 ( \(S D=9.3, M d=\) 64); the distribution of answers was not normal with most participants performing above chance \((t(47)=36.56, p<\). 001). For the empathy measurement, the Cronbach's alpha coefficient was .73 ; the items were reduced to a single empathy score (Emp) for further calculations. For self-
construal, we constructed three subscales: relational selfconstrual (Cronbach's alpha (11) = .76), interdependent selfconstrual (Cronbach's alpha (12) \(=.47\) ) and independent self-construal \((\) Cronbach's alpha \((12)=.73)\).

Table 1: Nonparametric Spearman's correlations for measures collected in Experiment 1 and 2.
\begin{tabular}{lccccccccc} 
& \(\mathrm{d}^{\mathrm{G}}\) & \(\mathrm{d}^{\mathrm{L}}\) & \(\partial_{\mathrm{p}}\) & \(\partial_{\mathrm{A}}\) & Aff & Emp & Rel & Inter & Indep \\
\hline \(\mathrm{d}_{\mathrm{G}}\) & \(.45^{* *}\) & .10 & -.02 & \(.34^{*}\) & -.02 & .07 & .11 & .06 \\
\(\mathrm{~d}^{\prime} \mathrm{L}\) & & & -.02 & -.03 & .07 & -.07 & -.04 & .06 & -.06 \\
\(\partial_{\mathrm{p}}\) & & & .04 & .07 & .24 & .03 & -.02 & -.98 \\
\(\partial_{\mathrm{A}}\) & & & & -.15 & -.04 & -.15 & -.13 & -.19 \\
Aff & & & & & & -.04 & -.30 & .06 & .00 \\
Emp & & & & & & .10 & \(.39^{* *}\) & -.08
\end{tabular}

Note: \({ }^{*} p<.05,{ }^{* *} p<.001\)
\(d^{\prime}{ }_{G}=\) Global pitch processing \(\left(d^{\prime}\right), d^{\prime}{ }_{L}=\) Local pitch processing ( \(d^{\prime}\) ) , \(\partial_{p}=\) Coefficient of Sound Perception Preference, \(\partial_{A}=\) Listener Attention Coefficient, Aff \(=\) Affective Voices, Emp = Empathy Measurement, SC = SelfConstrual.

\section*{Results}

The Shapiro-Wilk test of normality showed a significant non-normal distribution for several of the measures, therefore, we used non-parametric tests throughout. In Table 1 , the results of nonparametric correlations for the measures of global and local pitch perception, emotion perception, affective empathy and self-construal are reported, including the Coefficient of Sound Perception Preference collected in the first experiment. The analysis shows a significant relation between global pitch perception processing and the auditory affective processing measure: participants who were better in perceiving changes in the global pitch contour were also better in identifying vocalized emotions.

\section*{Discussion}

The results of the second experiment indicate that global auditory processing is related to auditory affective processing. This suggests that being able to identify emotions in voice is associated with the ability to perceive pitch globally.

\section*{General discussion and Conclusion}

The present studies aimed to: a) investigate the possibility of altering individuals' auditory perception bias through training, b) to illustrate experimentally the existence of a relation between auditory global-local processing and auditory perception bias, and c) to examine the link between global-local auditory processing on one hand and empathy and self-construal on the other hand. Our findings show that auditory perception bias cannot be altered by simple training/feedback. This finding adds to the existing evidence
according to which the mode of listening (synthetic or analytic) constitutes a rather stable individual difference. With respect to its relation with auditory global-local processing, our findings cannot support an association between processing type and perception bias. We do find, though, an association between global auditory processing and auditory affective processing. To put it differently, perceiving the contour in sounds is related to the ability to recognize emotions in voice. No evidence is provided for the link of empathy with processing when using self-report measures. It is quite possible that, especially for perceived emotions, behavioral measures of emotional empathic responses may yield different results.

\begin{abstract}
Keeping track of things as they move in space and time is a task common to scientists, marketers, spies, coaches, and more. Visualizations of complex information aid drawing inferences and conclusions but there are manv wavs to represent data. Here we show that the kinds of inferences people draw depend on the kind of visualization, boxes in tables or lines in graphs. Lines link and boxes contain; they both direct attention and create meaning.
\end{abstract}

Keywords: diagrams; information visualization; inference; data displays.

\section*{Introduction}

People are always on the move. So are other living things, and even inanimate things, not just tangibles like packages, airplanes, and lava but also slang, fashion, music, rumors. Tracking and understanding movements of things in space and time is a task shared by scientists, historians, football coaches, paparazzi, marketers, physicians, spies, Facebook, event planners, Foursquare, police, culture mavens, advertisers, gossip columnists, friends, and more. The movements of beings and things through space over time are valuable data to be explained by theories. Why do people or things cluster in one place or avoid another? Why did person X see Y and then Z ? Why did they meet there? Why is this place popular at one time and not at another? Speculating about the movements of people or things over time is endlessly fascinating, and the number of queries, hypotheses, and explanations that can be generated enormous.

Making sense of complex data like the movements of things in space and time is made easier by organizing it spatially into diagrams. Diagrams are composed of simple geometric forms, dots, lines, boxes, and more that both carry meaning and direct attention (e.g., Tversky, 2011; Tversky, Zacks, Lee, \& Heiser, 2000). Lines direct attention by drawing the eye from place to place, point to point, connecting the dots. Lines create meaning by conveying relationships, connections from one place or point to another, as in route maps or networks or line graphs. Boxes also direct attention, by bringing the eye to the contents of the boxes. Boxes are containers, they enclose one set of elements and separate them from
elements in other boxes. Boxes create meaning by creating categories. They indicate that everything within the box is similar, sharing features, and different from everything outside the box. Lines and boxes, like other simple geometric marks, are replete with meaning. They alter conclusions, inferences, and interpretations. The same data, height of 8 and 10 year olds or height of women and men, are interpreted as trends when displayed as lines and as discrete comparisons when displayed as bars (Zacks \& Tversky, 1999). For example, when lines connected the height of men and women, some people said, "As you get more male, you get taller."

Lines and boxes should also bias data exploration and inferences from displays of people, place, and time. Previous research evaluated production, preference, and performance of displays of people, place, and time (Kessell \& Tversky, 2010). When asked to create ways to keep track of movements of people across space and time, most participants created matrices or tables; a minority connected people over time with lines. Preference by other participants followed the same pattern. Overall, matrices with people as cell entries and time and place in rows and columns respectively were most commonly produced and preferred. This format has good foundations. Place and time are fixed, immutable, but people can move from cell to cell. Performance was assessed by the time to verify many kinds of inferences from the data. Lines facilitated inferences about time, but all other kinds of inferences were faster from tables.

Displays of people, place, and time are frequently used for data exploration, to generate conclusions from the data and inferences about the underlying processes. Here, we investigate the roles of lines and boxes in the spontaneous generation of inferences from data displays. Because lines connect people over time, lines should bias conclusions and inferences about people, and secondarily about time. Boxes emphasize their contents, the confluence of people, place, and time, and should support a greater variety of conclusions and inferences.

\section*{Method}

\section*{Participants}

Eighty-one people, 39 of them men, participated through Amazon's Mechanical Turk website. Their ages ranged from 18 to 75 , with a mean of 30.9. Forty-six percent had a Bachelor's degree or higher, 39.4\% had some college education, \(12.2 \%\) went to high school, and 2.5\% did not specify education level. Most (93.4\%) were native English speakers.

\section*{Stimuli}

The stimuli (Figures 1 and 2) were taken from Kessell \& Tversky (2010). Both showed the locations of four students at four times of day with time horizontal, place vertical, and people as cell entries. For the boxes condition (Figure 1) people were color-coded dots. For the lines condition (Figure 2), people were coded as colored lines going from cell to cell. Note that both conditions have boxes, but in the box condition, they are filled with the individuals. In the line condition, the boxes are empty, in the background, acting as points that are connected by lines.

Figure 1: The box stimulus display

Figure 2: The line stimulus display

\section*{Procedure}

Participants were randomly assigned to the box or line condition. For both, the first screen, seen in Figure 3, showed an example of a data display, a bar graph, along
with several possible conclusions and inferences that could be drawn from the display.

Figure 3. Example used in the instructions.
The sample inferences given were: "The population in both California and New York grew from 1900 to 2000. In 1900, the population was greater in New York than in California. In 2000, the population was greater in California than in New York."
Then either the box (Figure 1) or line (Figure 2) diagram was presented and participants were directed: "Please study the following graph and use the space below to draw as many inferences as possible." After this task, participants were asked for demographic information.

\section*{Results}

Participants typically generated many inferences, often several in a single phrase, complicating the coding and the counting. Consequently, inferences and interpretations were coded and analyzed in two ways: the primary and secondary organizer used; and the number of different types of statements/inferences produced. Two people coded; in the few cases where they disagreed, they discussed the cases and came to agreement.

\section*{Primary and secondary organizers}

In order to capture the overall structure of the organization of the interpretations and to compare the organization produced for each diagrams, we coded the primary organizer and secondary organizer for each participant. The inferences could be organized by Time People, or Location. Here is an example with People as primary organizer and Time as secondary organizer:
"David went to the dorm in the morning, stayed at the dorm until noon, went to the library at the afternoon, and ended up at the bookstore at evening. Justin went to the dorm in the morning, the bookstore at noon, the gym in the afternoon and back to the bookstore at evening. Alex went to the library in the morning, the bookstore at noon, the gym at the afternoon and to the dorm at evening. Sammy went to the gym in the morning, to the bookstore and noon, to the dorm at the afternoon, and stayed at the dorm until the evening."

The results of this coding are shown in Figures 4 and 5. The distribution of primary organizers differs between the two conditions, \(\chi 2(2 ; \mathrm{n}=81)=5.815, \mathrm{p}=.043\); However,
the secondary organizers did not differ between conditions: \(\chi 2(2 ; \mathrm{n}=81)=2.489, \mathrm{p}=.288\).

Figure 4. Distribution of primary organizer by condition.

Figure 5. Distribution of secondary organizer by condition
For both box and line displays, the default primary organizer was People, followed by Location and then Time. However, people dominated far more for lines than for boxes. The dominant secondary organizer for lines was Time, whereas the dominant secondary organizer for boxes was Place.

\section*{Number of statements/inferences}

As the previous example illustrates, the inference statements were organized and structured. Careful examination of the protocols revealed that most statements could be categorized as follows.

Single statement: a statement that referred to a single cell of the matrix, i.e., one person, one time and one place. For example, "David is in the dorm in the morning."

Parallel: a set of related statements in the same format, that is, organized by the same features in the same way. Parallel statements contain many inferences, that is, they refer to information in many cells. For example, the following statement is counted as one parallel statement: "Justin went to the dorm in the morning, the bookstore at noon, the gym in the afternoon and back to the bookstore in the evening." Parallel statements invite repetition, and were often repeated.

Generality: any statement that involves more than one person, time, or place (but is not a parallel statement). For example, "The bookstore is the most consistently visited places for the guys" and "David and Sammy spent more time in the Dorms that the others." Generalities also include many inferences.

Leap: any interpretation that went beyond the information given. For examples, "David and Sammy are friends," "David is probably unfit," "Alex manages his time well and gets everything done," and "Since Justin does not return to the dorm in the evening I would infer that he is probably dating a student who works at the bookstore and spends evenings at her place."

Negation: a negative statement from information given in the diagrams. For examples, "David never goes to the gym," "No one goes to the bookstore in the morning," and "Students are not required to use the library or gym."

The mean numbers of statements in each category are given in Figures 6 (error bars indicate standard error).

Figure 6. Frequencies of kinds of inferences given to box and line displays.

Differences in the frequencies of the statement categories between the two displays were examined by a generalized linear model with a Poisson distribution for each dependent variable. The results ( \(\chi 2\) statistics and pvalues) are shown below in Table 1.

Table 1. Tests of differences between conditions
\begin{tabular}{|l|l|l|}
\hline Inference type & Wald \(\chi 2(1)\) & p -value \\
\hline Single & 17.828 & \(<.001\) \\
\hline Parallel & 14.608 & \(<.001\) \\
\hline Generality & 15.156 & \(<.001\) \\
\hline Leaps & 0.771 & .380 \\
\hline Negation & 20.86 & \(<.001\) \\
\hline Word Count & 30.413 & \(<.001\) \\
\hline
\end{tabular}

The analyses confirm that the box displays yielded more single statements, generalities, and negations than the line displays, and that the line displays yielded more parallel statements than the box displays. There was no significant difference in number of leaps.

Because of the diversity of statements, there is no sensible way to count and compare the total number of inferences drawn from each display. Some brief statements summarized many information cells, and other
statements conveyed none. However, the word count was higher for lines (mean=90) than boxes (mean=79); this may be due to the large quantity of parallel statements, which are relatively long, for lines.

\section*{Discussion}

Diagrams of complex information use marks and place on the page to convey information effectively (e.g., Tversky, 2011; Nickerson, Corter, Tversky, Rho, Zahner \& Yu, 2013). Such diagrams are meant to spur a wide range of conclusions, inferences, and hypotheses. Designers of displays are faced with many decisions for portraying the data, and those choices affect the kinds of inferences that viewers make. In particular, data points can be connected by lines or enclosed in boxes. Lines suggest relationships and links whereas boxes contain and suggest contrasts with other boxes.

Here, information about movements of people in place and time were organized with lines or boxes, corresponding to two common diagrammatic formats, line graphs and tables. Participants were asked to make as many inferences as they could from one of the displays. Overall, participants produced a large number of generalities that linked information that was separated in the data, showing that they did attempt to integrate the information. In general, People was the dominant organizer of inferences. As predicted, the two spatial organizations of data, lines and boxes, had dramatic effects on the kinds of inferences drawn from the data, movements of people in space and time. Lines connected people over space and time. Although People was the dominant organizer in both cases, People was far more dominant when lines connected each person's movements over time, and Time was the dominant secondary organizer. Lines also encouraged more parallel inferences, inferences with the same structure and format. These are sets of inferences structured in the same way: \(X\) went to \(A\) at time 1, to B at time 2, etc. With boxes, people dominated as first organizer, but Place rather than Time dominated as secondary organizer. Boxes also encouraged more statements about single features of the information, more generalities involving many features, more leaps that went far beyond the information given, and more negations, that is, statements about empty cells.

Displays of this information are used for exploration and understanding of the underlying phenomena driving the movements as well as conveying them to others. Visuospatial characteristics of information displays affect the kinds of inferences drawn from the information, factors like position in space, marks such as lines and boxes, and content of the dimensions. People, place, and time are three-dimensional data, and three-dimensional displays are famously difficult to comprehend, biased toward the variables on the axes (e. g., Carpenter \& Shah, 1998). Based on previous research (Kessell \& Tversky, 2010), we chose the consensus arrangement of the three variables, time on the Y axis, place on the X axis, and
people as cell entries. Time and space are fixed dimensions (place was not located dimensionally here, but commonly is, in maps). Only people are movable, perhaps the reason they were selected for the cell entries.
People was by far the most popular organizer for inferences. This is most likely due to that fact that people are agents, for the most part, they decide where to go and when. People is also preferred to Place or Time for organizing both episodic (e. g., Taylor \& Tversky, 1997) and autobiographical memory (e. g., Wagenaar, 1986). In both cases, organization of memory is multiple and flexible, but organization by People is privileged. Location and time, like people, can be good predictors of activities, but people are agentive, and for that and a variety of other reasons, are better and preferred as organizers of memory.

The display format, line graph or table, affected both quantity and quality of inferences. The different patterns of inferences suggest that tables and line graphs induce different strategies for exploring the data. Those presented with tables seemed to focus on the cells, producing more single statements that described single cells. They noticed when cells had many entries, producing relatively more generalities, such as the crowd at the bookstore at noon. They also noted empty cells, producing negations that observed the absence of people in the bookstore in the morning or the gym at night. By contrast, those presented with lines used the lines to explore the data, focusing on each person's movements in turn across cells. Lines led the eye and the mind from cell to cell; matrices led the eye and the mind to the cells.
Which is better? Like almost everything, it depends. If you are tracking parcels or thieves or spies or consumers or celebrities, then lines will focus you on the important information. On the other hand, if you're entertaining many hypotheses, then use tables. Just be aware that what you choose makes a difference.

\begin{abstract}
In this paper, we empirically investigate whether people understand irony from computers in order to test the recent argument for an egocentric tendency in irony comprehension. In the experiment, participants took a timed math test comprising 10 questions of 3 -digit by 2 -digit multiplication. After that, they received a feedback comment on their performance (including potentially ironic sentences) from either an intelligent evaluation system with an AI engine (AI condition), a nonintelligent automatic evaluation system (Auto condition), or a human judge connected via the network (Human condition). The result was that the participants in the AI and Auto conditions understood the comment as ironic as those in the Human condition, and the participants in the AI condition perceived more sarcasm than other participants. Because people know that computers cannot think just as humans do, these results can be regarded as evidence for the egocentric tendency in irony comprehension, indicating that participants understood irony egocentrically from their own perspective without taking into account the mental state of the ironic speaker. These findings are also consistent with the "media equation" theory, from which we can suggest implications for the media equation, anthropomorphism, and computer-mediated communication of irony.
\end{abstract}

\section*{Introduction}

Verbal irony is a kind of nonliteral language that implicitly conveys the opposite of the literal meaning. \({ }^{1}\) To interpret irony, people must infer the speaker's beliefs and intentions including not only the first-order belief that the speaker does not think that the utterance is literally true, but also the secondorder belief that the speaker thinks that the hearers do not think so. For example, imagine that you are rushing to a movie theater, where your friend is waiting for you so that you can see the movie together. When you arrive there about 30 minutes late and you miss the first part of the movie, your friend says to you, "You are always so punctual!" You can easily understand that this utterance is ironic, but you have to know beforehand many things about your friend's belief and intention. First of all, you must be sure your friend does not think that you are always punctual because you are late for the movie. Furthermore, in order to recognize the speaker's ironic intention, you must know that your friend thinks that you think this utterance is literally false, because your friend does not intend to convey his/her criticism using irony unless he/she is convinced that you can understand the utterance is literally false.

This property of irony leads to the widely accepted assumption that irony interpretation requires a "Theory of Mind" (henceforth, ToM), which refers to the ability to infer the mental states of others (e.g., Happé, 1993; Sperber \& Wilson, 2002).

A large number of recent empirical studies have demonstrated the validity of this assumption. For example, developmental studies have revealed that typically developing children below 5-years of age, who do not completely acquire ToM, cannot understand irony (e.g., Creusere, 2000; Filippova \& Astington, 2008; Pexman, 2008). It has also been found that people with pervasive developmental disorder (PDD) such as autism and Asperger syndrome have difficulty understanding irony, and this difficulty has been attributed to impaired ToM (Happé, 1993; Kaland et al., 2002; Wang, Lee, Sigman, \& Dapretto, 2006). Hence, irony has been used as a benchmark for testing PDD and discriminating PDD from attention deficit hyperactivity disorder (ADHD) (Adachi et al., 2004). Furthermore, recent neuroimaging studies have demonstrated that, as compared to literal sentences, ironic sentences elicited higher activation in the medial prefrontal cortex, which is known to play a central role in ToM (Rapp, Mutschler, \& Erb, 2012; Shibata, Toyomura, Itoh, \& Abe, 2010).

On the other hand, some opposing evidence has been reported suggesting that irony comprehension does not always require ToM; people can interpret irony without considering the speaker's beliefs and intentions (e.g., Akimoto, Miyazawa, \& Muramoto, 2012; Keysar, 1994). Keysar (1994) demonstrated that people perceive an utterance as ironic even when it is obvious to them that the speaker of the utterance does not know the discrepancy between an utterance and reality (and thus, the speaker has no ironic intention). Akimoto et al. (2012) also found that people perceive irony by first attributing their own belief to the speaker automatically and subsequently by adjusting it through an effortful ToM process. These findings suggest that irony can be interpreted automatically by the egocentric process, and when the egocentric interpretation should be checked for errors and time allows \({ }^{2}\), it is checked according to, or made consistent with, the speaker's belief by the allocentric ToM process. For example, in the case of "late arrival" example presented above, you recognize the utterance "You are always so punctual!" as ironic first by considering the discrepancy between the content of the utterance and your own belief that you arrived late and thus you are not punctual. If you have enough time, you may then consider what your friend really thinks in order to check or confirm your own egocentric interpretation. It must be noted that this egocentric view of irony is also supported by a theoretical study of irony, i.e., Utsumi's (2000) implicit display theory of irony. Note also that the egocentric interpretation is not specific to

\footnotetext{
\({ }^{1}\) This "folk" definition of irony has been recognized as problematic by irony researchers, but it is sufficient for the present purpose.
\({ }^{2}\) Indeed, Epley, Keysar, Boven, and Gilovich (2004) found that ironic interpretation was more egocentric in the time-limited circumstance than in the leisurely circumstance.
}
irony; recent empirical studies have revealed that communication in general proceeds in a relatively egocentric manner, with addressees routinely interpreting what speakers say from their own perspective (Birch \& Bloom, 2007; Keysar, 2007).

From these recent empirical findings of the egocentric nature of irony understanding, we also argue that people perceive irony in an egocentric way without resorting to the allocentric process of considering other's beliefs. In this paper, to obtain further evidence for this claim, we propose a different experimental methodology, namely an experiment with "irony generated by computers." The research question to be answered here is: Do people understand irony from computers? We know that computers cannot think just in the same way as humans do, and thus computers do not, or even cannot, intentionally say irony. Hence, it is highly reasonable to assume that people do not attempt to infer the "mental" states of computers, even when they see or hear a potentially ironic utterance generated by computers. It follows that, if irony interpretation essentially involves the allocentric process of inferring the mental state of the speaker, then people do not perceive irony in computer generated utterances. On the other hand, if irony interpretation does not always require the consideration of the speaker's mental states and is governed by the egocentric process, people may see the irony when they are given potentially ironic utterances by computers. In sum, by empirically examining whether people perceive irony in the computer-generated statements, we can obtain the evidence for or against the claim that irony is understood in an egocentric fashion without or before the allocentric ToM process. This is what this study aims to accomplish.

To examine people's reactions to irony from computers, we conducted a laboratory experiment. In this experiment, participants took a timed math test on computer comprising 10 questions of 3-digit by 2 -digit multiplication (e.g., \(768 \times 59\) ). They were instructed that the computer system not only provides a math test, but also (1) evaluates their overall performance on math calculation by an AI engine taking into account multiple information such as the test score, the time it took to calculate, and their behavioral data during calculation collected through Web cameras (AI condition); or (2) evaluates their overall performance on math calculation automatically from the test score and the time for calculation (Auto condition); or (3) displays their overall performance on math calculation evaluated by a human judge who observed their behavior during calculation through Web cameras (Human condition). After finishing the test, they received a highly positive comment on their performance from the computer. This positive comment can be ironically interpreted if participants could not get a satisfactory score.

As we mentioned above, our argument for the egocentric nature of irony interpretation predicts that people understand irony from computers just as they understand irony from humans. Therefore, we can predict that people's understanding of irony does not differ among these three conditions of this experiment. Specifically, supposing that the difference between the AI and Auto conditions may lie in the attributability of humanlike mental states to computers (e.g., people may be more likely or easier to attribute the mental state to intelligent computers with AI technology than non-intelligent computers), no difference between these two "computer irony" conditions
also suggests the egocentric nature of irony comprehension.
Our prediction can also be supported by the "media equation" theory (or "Computers Are Social Actors (CASA)" theory) for human-media interaction (Nass \& Yen, 2010; Reeves \& Nass, 1996). The media equation theory argues that people tend to unconsciously treat computers and other media (e.g., automobiles, cellphones, robots) as if they were real people. For example, people behave politely and cooperatively to computers, and attribute personality characteristics to computers. The media equation has been empirically supported by a number of studies demonstrating that the social rules and heuristics guiding human-human communication apply equally well to human-media interaction. Among these studies, Fogg and Nass's (1997) study on computers that flatter is most relevant to our study. They demonstrated that, when receiving a "flattery" feedback from a computer, people reported the same effects of flattery (e.g., more positive affect and evaluations on computers) as flattery from humans. Likewise, it is reasonable to assume that the media equation predicts that people understand irony from computer just as they understand irony from others, thus suggesting that the answer to the question "Do people understand irony from computers?" is yes. It must be noted here that our study can also be regarded as an empirical study on the media equation, and we can point out the relationship between the media equation and the egocentric communication, which will be discussed later in this paper.

\section*{Method}

\section*{Participants}

Fifty-three undergraduate and graduate students participated as volunteers. Note that the recruitment of participants continued until valid data were obtained from 45 participants (i.e., 15 participants for each of the three conditions).

\section*{Design}

This experiment had three conditions: AI, Auto, and Human conditions. These conditions were manipulated by the instruction given to the participants and the time it took to provide feedback to them (i.e., to display the truth of their answer for each math question, and to display a final comment on their performance), except for which the three conditions were identical.

\section*{Procedure}

The experiment was conducted using a computer system comprising a Windows PC, an LCD monitor, and two Web cameras. After arriving at the laboratory, participants seated in front of the computer system, and were given an explanation of the purpose of the experiment and an overall instruction of the task they had to perform. Specifically, participants were instructed that the purpose of the experiment was to test and evaluate a computer system in front of you that we were developing, and that this system not only would provide a math test, but also (1) would evaluate their overall performance on math calculation by an intelligent AI engine taking into account multiple information such as the test score, the time it took to calculate, and their behavioral data during calculation collected through Web cameras (AI condition); or (2) would evaluate their overall performance on math calculation automatically from the test score and the time for calculation (Auto
condition); or (3) would display their overall performance on math calculation evaluated by a human judge who observed their behavior during calculation through Web cameras (Human condition). Note that actually the computer system made no evaluation in all the conditions and no human judge evaluated the participants in the Human condition; the system simply displayed the same comment we prepared beforehand, independently of participants' performance. Note also that no humanlike agents were displayed on the monitor.

After the instruction, participants took a timed multiplication test comprising 10 questions of 3-digit by 2 -digit multiplication (e.g., \(768 \times 59\) ). Multiplication questions were randomly generated so that they did not differ in complexity. In order to make more errors and thus to be more likely to perceive irony, participants were requested to calculate as quickly as possible and complete each multiplication within 30 seconds. If 30 seconds passed since they started each question, they received a warning from the system. Multiplication questions appeared on the monitor one at a time and remained there until participants typed the answer. Participants calculated a given multiplication on paper and typed the answer. The truth of the answer was then presented on the monitor one seconds (in the AI and Auto conditions) or three to five seconds (in the Human condition) after the answer was typed.

After finishing the test, participants received from the system a highly positive comment on their performance, together with summary statistics including the number of correct and incorrect answers, the mean answering time, and the number of questions they took more than 30 seconds to answer. The comment was that "You have a perfect calculation performance. You were very careful not to make a mistake. The time you took to calculate is also excellently fast." In the comment, the first and last sentences were potentially ironic, if participants' performance is not satisfactory.

After receiving the comment from the computer system, participants were asked to answer a questionnaire. The questionnaire comprised six questions with 7 -point Likert scales. The questions that we use in the analysis were: "Do you perceive irony in the comment?" (irony rating; \(7=\) ironic, \(1=n o t\) at all ironic), "Do you perceive sarcasm in the comment?" (sarcasm rating; \(7=\) sarcastic, \(1=\) not at all sarcastic), and "Do you think the comment is intentional?" (intentionality rating; \(7=\) intentional, \(1=\) not at all intentional). Other questions were: "Does the comment literally include praise or criticism?", "Is your performance satisfactory?," and "Is the evaluation given by the system appropriate?" At the close of the experiment, participants were told the true purpose of the experiment and debriefed. None of the participants were suspicious of the true purpose of the experiment.

\section*{Result}

Whether the comment presented to the participants was understood as ironic greatly depends on their performance on the calculation test. Therefore, in the analysis, we did not use the data of eight participants who correctly answered all the multiplication questions within 30 seconds, because they were very unlikely to perceive irony in the comment. In other words, in order to collect the valid data of 15 participants per condition (and thus a total of 45 participants), we had to recruit 53 participants.

Figure 1: Mean irony and sarcasm ratings for the three conditions

In order to confirm that the likelihood of perceiving irony in the comment did not differ among three groups of participants, we analyzed the difference in the number of incorrect answers and answering time. The total numbers of incorrect answers were 31,20 , and 17 for the AI, Auto, and Human conditions, respectively; the difference did not reach the level of statistical significance, but was close to it, \(\chi^{2}(2, N=450)=5.65\), \(p=.059\). This result suggests that we must regress out the effect of incorrect answers in the following analysis. On the other hand, the mean answering times per question were 26.8, 26.1, and 26.8 seconds for the AI, Auto, and Human conditions, respectively; they did not significantly differ, \(F(2,42)=0.17\), \(p>80\).

\section*{Irony and Sarcasm Ratings}

First of all, we examined whether the mean irony and sarcasm ratings differ among the three conditions, as shown in Figure 1. Concerning irony ratings, the participants in the AI condition appeared to perceive the comment as more ironic than other participants. A one-way, between-participants ANOVA showed that the difference among the three conditions was marginally significant, \(F(2,42)=2.08, p=.08\). However, an ANCOVA with the number of incorrect answers as the covariate revealed that this difference was no longer significant, \(F(2,41)=1.55, p=.22\). This means that, when the number of incorrect answers was statistically controlled, the adjusted irony ratings did not differ among the three conditions; as predicted, people understood irony from computer just as they understood irony from humans.

The mean sarcasm rating was also higher in the AI condition than in the other two conditions, and this difference reached the level of statistical significance, \(F(2,42)=6.06\), \(p<.01\). An ANCOVA with the number of incorrect answers as the covariate also revealed that this main effect was reduced, but remained significant, \(F(2,41)=4.91, p<.05\). Pairwise comparisons ( \(p<.05\) ) confirmed that the participants in the AI condition perceived the comment as significantly more sarcastic than the participants in the other two conditions. In particular, it is surprising that the mean sarcasm ratings in the Auto and Human conditions were very low, suggesting that the participants in these conditions did not perceive sarcasm. Possible reasons of this result will be discussed in the section of discussion.

In addition, we analyzed the correlation between irony and sarcasm ratings. In general, "blame-by-praise" irony, such as ones used in this experiment, accompanies a sarcastic effect (Kreuz \& Glucksberg, 1989). Therefore, we can confirm from this analysis that participants' judgment on irony and sarcasm was not arbitrary, and consequently the above result was reliable. The correlations between irony and sarcasm ratings were .51 (AI condition), 83 (Auto condition), and .77 (Human condition), and they were all significant ( \(p<.05\) ). This result clearly indicates that the participants who interpreted the comment as ironic also perceived sarcasm in the comment, and thus the obtained result on irony and sarcasm ratings was reliable.

\section*{Intentionality Rating}

First of all, we analyzed the mean intentionality ratings for the three conditions. The mean intentionality ratings were \(4.00(\mathrm{SD}=1.73)\) for the AI condition, \(3.93(\mathrm{SD}=1.75)\) for the Auto condition, and \(3.40(S D=1.96)\) for the Human condition. They did not significantly differ both in the ANOVA analysis, \(F(2,42)=0.49\), and in the ANCOVA analysis with the number of incorrect answers as the covariate, \(F(2,41)=\) 0.58 . The participants perceived the same low degree of intentionality involved in the comment, regardless of whether the speaker was a computer or a human. This result suggests that people may interpret the comment egocentrically.

Next, we examined the correlations between the intentionality and irony ratings. If people interpret irony by allocentrically thinking about the speaker's beliefs and intentions, they recognize the intentionality of the speaker in an ironic comment. Meanwhile, if people interpret the comment literally, they do not (or do not have to) recognize the intentionality behind the literal comment because it simply states the fact. Therefore, the allocentric view of irony understanding predicts a positive correlation between the irony and intentionality ratings. On the other hand, if people interpret irony egocentrically, they do not have to recognize the intentionality of the speaker, and thus the egocentric view of irony understanding predicts no correlation between the irony and intentionality ratings. The correlations between irony and intentionality ratings were \(r=.11\) (AI condition), \(r=-.05\) (Auto condition), and \(r=.08\) (Human condition). All these correlations were not at all significant, thus providing additional evidence for the egocentric view of irony understanding.

\section*{Discussion}

\section*{Anthropomorphism and Egocentric Comprehension}

The design of the experiment in this paper is premised on the assumption that people consciously know that computers do not have minds and thus cannot think as humans do. However, many researchers criticize this assumption on the empirical grounds that people tend to attribute human characteristics, beliefs, intentions, or emotions to nonhuman agents and objects (e.g., Epley, Waytz, \& Cacioppo, 2007). This tendency is known as anthropomorphism. According to the anthropomorphic explanation, people do not think of computers as mindless, and as a result our finding that people understand irony from computers does not imply the egocentric view of irony comprehension. Against this criticism, we defend our position as follows. A number of researchers have discussed a
variety of anthropomorphic experiences, which can be classified into two types: a strong, mindful anthropomorphism and a weak, mindless anthropomorphism (Kim \& Sundar, 2012). Considering a number of existing empirical findings on anthropomorphism, we deny the possibility that the participants of our experiment anthropomorphized computers mindfully (i.e., in a strong, mindful sense). A weak, mindless anthropomorphism might occur, but it implies that people's reasoning about the "mental states" of computers is quite egocentric.

Mindful anthropomorphism refers to the tendency to infer the mental states of nonhuman agents or objects from an allocentric perspective. For example, some pet owners perceive and speak of pets as being thoughtful and considerate. This anthropomorphic process is often conscious and seems to require ToM. Recent research demonstrates that whether people mindfully anthropomorphize nonhuman agents and objects depends on two properties, i.e., agency (the capacity to plan and act) and experience (the capacity to sense and feel) (Gray, Gray, \& Wegner, 2007). Indeed, Krach et al. (2008) demonstrated through a fMRI experiment that activation of the brain regions (i.e., the medial frontal cortex and the right temporo-parietal junction) known to be associated with ToM was correlated with the degree of agency or humanlikeness (i.e., a human partner, a highly humanlike robot, a functional robot, and a non-humanlike computer, in descending order of agency). The computer system used in our experiment had no humanlike appearance and displayed no humanlike characters, and thus is very low in both agency and experience. Hence, we can safely say that the participants of our experiment did not anthropomorphize the computer system mindfully; this indicates that our assumption that people think of computers as mindless holds true for the experiment.

Mindless anthropomorphism refers to the tendency to automatically attribute human mental states to nonhuman agents or objects without much consideration of whether nonhuman targets have mental states (Kim \& Sundar, 2012). Many of the studies on anthropomorphism have used the term "anthropomorphism" to refer to this mindless version. For example, Epley et al. (2007) state, "Using one's own mental states and characteristics as a guide when reasoning about other humans is egocentrism. Using one's own mental states and characteristics as a guide when reasoning about nonhuman agents is anthropomorphism (ibid., p.868)." Their notion of anthropomorphism clearly indicates that mindless anthropomorphism is egocentric. Hence, even if the participants of our experiment mindlessly anthropomorphized computers during the experiment, they did not directly infer the "mental states" of computers. It follows that the finding that they perceived irony from computers implies that they did so egocentrically, as we argue in this paper.

It must be noted that the media equation is consistent with mindless anthropomorphism; in other words, the media equation is primarily due to the egocentric nature of communication. Nass and Moon (2000) have argued that the notion of mindlessness provides a robust explanation for the media equation. As have been observed in a variety of social situations, people mindlessly apply social rules and expectations to computers. This phenomenon completely coincides with mindless anthropomorphism. Although they reject an anthropomorphic explanation of the media equation, but the
anthropomorphism they rejected is the mindful version of anthropomorphism. Egocentric, mindless anthropomorphism is a main cause of mindless behavior observed in a variety of media equation studies.

\section*{Egocentric and Allocentric Comprehension of Irony}

This paper has provided empirical evidence for the egocentric view of irony processing in a novel approach of using computers as ironists. People understand irony from their own perspective, and this leads to the obtained result that people understand irony from computers in the same way as they understand irony from humans. However, the egocentric view seems to be inconsistent with the strong relationship between the ability to understand irony and the ToM ability, which has been justified by a large number of empirical studies. Of course, the egocentric view does not imply that ToM (and the allocentric process) is unnecessary for irony processing, but the argument that people can understand irony without considering the mental states of others from the speaker's perspective seems to be inconsistent with the empirical findings that people with a ToM deficit cannot understand irony. How can the egocentric view explain these incompatible findings?

One possible explanation would be given from a developmental perspective; ToM is a prerequisite for acquiring the concept of irony (i.e., what is irony), but once people (i.e., children) know what is irony, they increasingly do not take into account the mental state of the speaker. The concept of irony essentially involves the speaker's intention of being ironic, which is motivated by a certain situational setting (which is referred to as ironic environment by Utsumi's (2000) implicit display theory) where the speaker's expectation has not been fulfilled and the speaker has a negative attitude toward it. Therefore, to acquire the concept of irony, children must be able to infer the mental state of the speaker. In general, children below 5years of age cannot distinguish between what they know and what others know, and behave egocentrically as if their own beliefs are shared by others, from which it naturally follows that they cannot be aware of irony. Typically developing children at around 5 years of age can increasingly distinguish what others know from what they know, and they come to understand some aspects of irony. Children's appreciation of irony continues to develop into adolescence. As demonstrated by a number of developmental studies on irony, in this development period children's performance on irony understanding is correlated with their (allocentric) ToM ability, because they are acquiring the concept of irony with the help of their developing ToM ability. Adults, who completely acquired the concept of irony and have experienced a number of ironic communication, develop the egocentric tendency again, and increasingly do not take into account the mental state of the speaker (Keysar, 2007), mainly to shortcut the burdensome process of allocentric comprehension.

\section*{Irony in Computer-Mediated Communication}

The experiment of this paper was conducted through computer-mediated communication. One may argue that our findings are specific to computer-mediated communication and should not be generalized to irony understanding in ordinary face-to-face communication. In other words, it may be pointed out that our finding is an artifact of computermediation communication and allocentric comprehension is
always required in face-to-face communication. We basically reject this possibility, but at the same time point out that there may be some truth in it.

Some empirical evidence against this possibility was obtained. Hancock (2004) found that comprehension of irony did not differ between computer-mediated communication and face-to-face communication. More important is their finding that a misunderstanding rate of irony did not differ between these two communication modes, and it was equal to the estimate (i.e., approximately 5\%) given by Gibbs (2000). Considering Keysar's (2007) argument that egocentric understanding can provide a systematic reason for misunderstanding, this finding may suggest that people understand irony in computer-mediated conversation as egocentrically as in face-to-face conversation; this clearly rejects the specificity of computer-mediation communication, thus indicating that the finding of this paper is not an artifact of computer-mediated communication. Note also that, in almost all empirical studies of irony, participants of the experiment were asked to understand irony from the addressee's perspective, but they were not the addressees of irony. On the other hand, our participants were literally the addresses of irony, and thus we may safely say that the experiment of this paper was conducted in a more realistic setting, which is more similar to face-to-face communication.

At the same time, some positive arguments for the specificity of computer-mediated communication can be pointed out concerning irony production. Hancock (2004) also revealed that speakers in computer-mediated conversation produced more irony than face-to-face speakers. Furthermore, it is pointed out that sentences created via social media such as blogs and Twitter include more irony, which motivates recent NLP studies on automatic recognition of irony (e.g., Reyes, Rosso, \& Veale, 2013). These findings are concerned with the production of irony, but appear to suggest that irony comprehension in computer-mediated conversation may be somewhat different. For example, a younger generation, who is familiar with blogs and Twitter, may be likely to interpret utterances in computer-mediated conversation as ironic. In addition, micro-bloggers in Twitter often use the hashtag \#irony or \#sarcasm to clearly indicate their ironic intention. It is a very characteristic property of irony in microblogs, because in general ironic intention should not be explicitly expressed so that irony does not lose its effect. This specific property of Twitter may possibly induce the younger generation (including the participants of our experiment) to understand irony more egocentrically in computer-mediated communication. This may be a potential reason for the result that the mean sarcasm rating was higher in the AI condition, assuming that the perceived agency of the AI condition is most similar to that of micro-bloggers. On the other hand, the participants in the Auto condition might perceive little agency. The participants in the Human condition might be aware of more humanity in an imaginary human judge than in micro-bloggers because they were told that the human judge was observing their behavior throughout the math test.

\section*{Concluding Remarks}

The experiment reported in this paper demonstrated that people perceived the comment as ironic regardless of whether the
speaker of irony is a computer or a human. The experiment was based on the "Computers Are Social Actors" or "CASA" paradigm, which is a novel approach for the study of irony. The obtained finding provided empirical evidence in favor of the egocentric tendency in irony comprehension, because if people understand irony by routinely considering the mental state of the speaker, they could not perceive irony when a computer is the speaker of irony. Through the study of this paper, we have also discussed some features of irony comprehension in computer-mediated communication and the relationship among egocentric communication, anthropomorphism, and media equation. It is worth pursuing these issues for further research.

\begin{abstract}
This study extends the learning and use of affordances on robots on two fronts. First, we use the very same affordance learning framework that was used for learning the affordances of inanimate things to learn social affordances, that is affordances whose existence requires the presence of humans. Second, we use the learned affordances for making multi-step plans. Specifically, an iCub humanoid platform is equipped with a perceptual system to sense objects placed on a table, as well as the presence and state of humans in the environment, and a behavioral repertoire that consisted of simple object manipulations as well as voice behaviors that are uttered simple verbs. After interacting with objects and humans, the robot learns a set of affordances with which it can make multi-step plans towards achieving a demonstrated goal.
\end{abstract}

\section*{Introduction}

Motor competences of robots operating in our environments, is likely to remain inferior to ours on most fronts in the near future. In order to complete tasks that require competences beyond their abilities, the robots will need need to interact with humans in the environment towards compensating these deficiencies. The inspiration for our study comes from babies and small children who can compensate the lack of their physical competences through the use of adults via social interaction. For instance, for a child, the reachability of a candy on a high shelf becomes possible only in the presence of an adult, as long as he can "manipulate" him properly using his social behaviors.

In this paper, we extend an affordance framework proposed for robots towards learning interactions with inanimate objects, to learning interactions with humans. The notion of affordances, proposed by Gibson (Gibson, 1986), emphasized the interaction between the agent and the environment, as opposed to the agent or the environment only, and provided a unifying frameworks for the study.

\section*{Contribution}

This study extends the learning and use of affordances on robots on two fronts. First, we use the very same affordance learning framework that was used for learning the affordances of inanimate things to learn social affordances \({ }^{1}\) (viz. affordances whose existence requires the presence of humans). Second, we use learned affordances to make multi-step plans.

In our earlier studies, we had proposed a framework that allowed the robot to learn affordances such as traversability of an environment (Ugur \& Şahin, 2010) or graspability

\footnotetext{
\({ }^{1}\) We would like to note that the term, social affordances has been used in different contexts, e.g., for the possibilities emerging from social networks (Wellman et al., 2003), or the affordances of an environment and properties of people that facilitate social interaction in a group of people (Kreijns \& Kirschner, 2001).
}
(Ugur, Şahin, \& Oztop, 2009), liftability of objects (Dag, Atil, Kalkan, \& Sahin, 2010) and showed how one can make multistep plans using the learned affordances.

In this paper, we argue that robots can use the very same framework to learn what a human may afford. Moreover, we enhance our prior study on multi-step planning (Ugur et al., 2009) via a new form of prototypes for effect representation.

Specifically, we equipped the humanoid robot iCub with a perceptual system to sense tabletop objects, as well as the presence and state of humans in the environment, and a behavioral repertoire that consisted of simple object manipulations and voice behaviors that uttered simple verbs. After interacting with objects and humans, we show that the robot is able to learn a set of affordances with which it can make multi-step plans towards achieving a demonstrated goal.

\section*{Related Work}

The notion of affordances provides a perspective that puts the focus on the interaction (rather than the agent or the environment) and was formalized as a relation \(a\) between an entity or environment \(e\), a behavior \(b\) and the effect \(f\) of behavior \(b\) on \(e\) (Şahin, Çakmak, Doğar, Uğur, \& Üçoluk, 2007; Montesano, Lopes, Bernardino, \& Santos-Victor, 2008):
\[
\begin{equation*}
a=(e, b, f) \tag{1}
\end{equation*}
\]

For example, a behavior \(b_{\text {lift }}\) that produces an effect \(f_{\text {lifted }}\) on an object \(e_{\text {cup }}\) forms an affordance relation ( \(\left.e_{\text {cup }}, b_{\text {lift }}, f_{\text {lifted }}\right)\). Note that an agent would require more of such relations on different objects and behaviors to learn more general affordance relations.

The studies on learning and use of affordances have mostly been confined to inanimate things, such as objects (Fitzpatrick, Metta, Natale, Rao, \& Sandini, 2003; Detry, Kraft, Buch, Kruger, \& Piater, 2010; Atil, Dag, Kalkan, \& Şahin, 2010; Dag et al., 2010) and tools (Sinapov \& Stoytchev, 2008; Stoytchev, 2008) that the robot can interact with. In these studies, the robot interacts with the environment through a set of actions, and learns to perceptually detect and actualize them. Moreover, with the exception of few studies (Ugur et al., 2009; Williams \& Breazeal, 2012), the robots were only able to perceive the immediate affordances which can be actualized with a single-step action plan.

Formalizations, such as 1 , are proved to be practical with successful applications in navigation (Ugur \& Şahin, 2010), and manipulation (Fitzpatrick et al., 2003; Detry et al., 2010; Ugur et al., 2009; Ugur, Oztop, \& Şahin, 2011), conceptualization and language (Atil et al., 2010; Dag et al., 2010; Yürüten et al., 2012), and vision (Dag et al., 2010). However,
in these studies, the environment is limited to objects only, excluding the possible diversities or use-cases that might arise due to the existence of humans in addition to the objects.

Human-assistance has been incorporated in (Montesano et al., 2008; Dag et al., 2010; Ugur, Oztop, \& Şahin, 2011) using the same affordance formalization (1) to learn object affordances by imitation and emulation. However, the role of the human is limited to teaching affordances as part of the training phase, and he is out of the loop during execution of actions for possible assistance in creating a certain effect in the environment to extend robot's motor capacities.

Robot's motor capacities are extended by learning the affordances of tools in (Sinapov \& Stoytchev, 2008; Stoytchev, 2008). However, these studies are focused on learning affordances of tools while the objects are kept fixed, hence the affordances of objects themselves couldn't be captured.

In most of the HRI or social robotics studies, the robots are intended to collaborate with their human partners and they are "active learners" that learn from their partners the correct way to execute and sequence actions for achieving a goal (see, e.g., (Fong, Thorpe, \& Baur, 2003; Breazeal, 2004; Weber, 2008; Cakmak, DePalma, Arriaga, \& Thomaz, 2010) for a review). This way, one can teach a robot to learn complicated sequences of actions (e.g., dancing with a human partner (Kosuge \& Hirata, 2004)) using several mechanisms like scaffolding (Ugur, Celikkanat, Sahin, Nagai, \& Oztop, 2011; Saunders, Nehaniv, Dautenhahn, \& Alissandrakis, 2007) or demonstration (Pastor, Hoffmann, Asfour, \& Schaal, 2009; Argall, Chernova, Veloso, \& Browning, 2009; Akgun, Cakmak, Jiang, \& Thomaz, 2012). Similarly, affordances are also utilized in planning (Ugur, Oztop, \& Şahin, 2011) over action possibilities, but human is not a part of the plan. However, in (Williams \& Breazeal, 2012), humans are important part of the plan, yet their participation is limited with the experiment scenario, and participants are priorly acknowledged about the type of assistance they are going to provide to the robot.

For a similar goal, affordances (called "interpersonal affordances") that emerge from coordinated joint actions of two robots are investigated (Richardson, Marsh, \& Baron, 2007; Marsh, Richardson, \& Schmidt, 2009); e.g., two robots learning the interpersonal affordance of lifting a table which, otherwise, is liftable by neither of them. Our approach differs from these studies in the sense that the human is seen as part of the environment (with no special status) and uses the very same framework to learn social affordances as the physical affordances of objects.

\section*{Research Platform}

\section*{Perception and Environment Representation}
iCub perceives its environment through two Kinect cameras ( K 1 and K2). K1 is used to extract table and tabletop objects. K2 -accompanied with a motion capture system (Visualeyez II VZ4000)- is used to detect human's body posture and gaze direction. For gaze direction detection, participants are provided with a hat with active LEDs on top. Overall interaction

Figure 1: Visualization of the interaction environment. (a) Robot is on the left, and the human is on the right. (b) Object related features. From top left to bottom right: raw RGBD point cloud of an object on a table, table and extracted tabletop object with its oriented bounding box and id, surface normals, min curvatures, max curvatures, shape indices. [Figure best viewed in color]
environment is represented as a feature vector containing the following features:
Surface features are surface normals (azimuth and zenith), principal curvatures (min and max), and shape indices. They are represented as a 20 -bin histogram in addition to the min, max, mean, standard deviation and variance information.

Spatial features are bounding box pose ( \(x, y, z\), theta), bounding box dimensions ( \(x, y, z\) ), and object presence.
Social features are human torso pose ( \(x, y, z\), roll, pitch, yaw), human gaze direction (roll, pitch, yaw), and human presence, all with respect to robot's own coordinate system shown as coordinate axis in Fig. 1a.

Figure 2: The interaction objects. From left to right; balls, boxes, cylinders, mugs, and irregular objects.

\section*{Behaviors and Effect Representation}

The robot is equipped with six behaviors (push-left, pushright, push-forward, pull, top-grasp, side-grasp) and some voice behaviors ("pass me", "hello", "come", "sit down", "stand up", "bye", "push right", "push left", "take").

Effects -in their raw form- are computed as the difference between the final and the initial state of the environment (viz. difference between the feature vectors representing the environment before and after the behavior performance).

Effects are supervisedly matched to an effect category chosen from a set of effects such as grasped, knocked, no-
change \({ }^{2}\), disappeared, moved right, moved left, moved forward, pulled, sat down, stood up, got attention, got closer.

Effect categories are compactly represented as a vector of " 0 ", " + ", "-", and "*" to represent changes in certain feature value as unchanged (mean close to zero, small variance); consistently increased (positive mean, small variance), consistently decreased (negative mean, small variance); and inconsistently changed (large variance), respectively. This prototype-based effect representation is claimed to correspond to verb concepts in our earlier studies (Atil et al., 2010). For extracting the prototypes for each effect cluster, we analyze the mean and variance values for each element of the features in the cluster. Specifically, we apply unsupervised clustering (RGNG, (Qin \& Suganthan, 2004)) on the meanvariance space. RGNG finds four clusters naturally formed. From the obtained effect consistencies, we determine the prototype of each effect cluster.

\section*{Methodology}

\section*{Data Collection}

We used 35 objects (Fig. 2) that are chosen to be in different colors, and shape complexities (from primitive cubes, spheres, cylinders to mugs, wine glasses, coke cans etc.), easily identified as "cylinder", "ball", "cup", "box", while some of them had irregular shapes to show generalization ability of the system.

We had iCub interact with objects and with humans by using all of the behaviors precoded in its behavior repertoire. In order to collect social interaction data, we have worked with 10 participants of different genders ( 4 female, 6 male), ages (20-40) and professions (4 undergrad, 2 grad students, 4 researchers with non-CS background). They were asked to respond naturally to a random sequence of voice behaviors enacted by iCub. Some of the voice behaviors were accompanied by simple movements (nodding head, waving arm, etc.).

\section*{Affordance Learning}

We collected 413 triplets of \((e, b, f)\) (Eqn. 1) for object interactions and 150 triplets for human interactions, and used them to train a Support Vector Machine (SVM) classifier for each behavior to predict the effect label given an entity. During training, we normalized the feature vectors with respect to the range of values each feature can take.

\section*{Planning with Forward Chaining}

Since we trained SVMs for predicting the effect of each behavior on an object, iCub can do forward chaining to find the set of behaviors leading to a goal state. Since the effect labels are represented by effect prototypes, the similarity between the goal state (which is an effect instance) and the predicted

\footnotetext{
\({ }^{2}\) The no-change label denotes that the applied behavior did not produce any notable change on the object. For example, when iCub asks a participant to stand up who was already standing, the participant would not change his position. This yields negligibly small changes in the feature vector.
}
effect prototype is needed and we use the Mahalanobis distance, which is calculated by taking the mean \(\mu_{E_{i}}\) of first effect cluster \(E_{i}\) (if the first \(E_{i}\) is an effect instance, we take the effect instance as \(\mu_{E_{i}}\) ) and using the second effect cluster's \(E_{j}\) mean \(\mu_{E_{j}}\) and variance \(\sigma_{E_{j}}\) :
\[
\begin{equation*}
d\left(E_{i}, E_{j}\right)=\sqrt{\left(\mu_{E_{i}}-f_{\text {proto }, E_{j}}^{+,-, 0}\right)^{T} S_{j}^{-1}\left(\mu_{E_{i}}-f_{\text {proto }, E_{j}}^{+,-, 0}\right)} \tag{2}
\end{equation*}
\]
where \(S_{j}\) is the covariance matrix of the second effect cluster \(E_{j}\). In computing the Mahalanobis distance, the features marked inconsistent in the prototype are disregarded (denoted by \(f_{\text {proto }, E_{i}}^{+,-, 0}\) for the effect prototype \(f_{\text {proto } E_{i}}\) of an effect cluster \(E_{i}\) ), as those correspond to an unpredictable/inconsistent change in the feature elements.

Finding the effects Planning toward achieving the goal is found using a breadth-first tree search. Starting with the initial state, we construct a tree such that it contains all the possible effect sequences with length \(n\) (empirically chosen as 3 ). The plan is made as the goal is matched with the predicted states after applying a sequence of behaviors.

In the first step of future state calculation (Fig. 3), the current state of the object is fed to the trained SVM for each behavior. Then, the predicted effect's prototype is determined. The mean value of this effect is added to the initial features, with the exception of the inconsistent features, and the predicted future state is found. After this application, the predicted future state can be compared with other states; but the inconsistent features of the applied effect (denoted as black columns in predicted after-state) is excluded from the comparison calculations.

Figure 3: Future state prediction.

Application of effects Given the object, we can obtain from the trained SVMs the behavior that can achieve a desired effect with the highest probability. Thus, we obtain the behaviors required for each step in the planned effect sequence, forming a sequence of behaviors. If the obtained effect at any step in the behavior sequence does not match with the expectation, then the planning restarts. Fig. 3 and 4 respectively exemplify how a sequence of effect prototypes for reaching a desired effect is sought and how a behavior that produces an effect on an object is found. The system executes the planned behavior sequence. If, at any step, the predicted effect is not achieved (including overshoots or undershoots), the planning restarts from the current object state.

Figure 4: A simple depiction of how the planning is performed using the combinations of effects in the repertoire. At each step, the prediction block described in Fig. 3 is applied for each behavior. Once a future state close enough to goal state is obtained, the search is terminated.

\section*{Results}

\section*{Social Affordance Learning}

Fig. 5 shows some of the effect prototypes that lead us to interesting observations. In the first place, some effects can apparently be produced both by social and non-social behaviors. An obvious example is "say push to your left" and pushright (causing the moved right effect most of the time). Furthermore, we observe that in some cases, social behaviors can be a better option for goal emulation. For instance, when the object is far enough from the robot, the predicted effect for pull behavior is no change; whose effect prototype has only *'s and 0's (features with inconsistent change and negligible change), whereas the predicted effect for "pass me" behavior is pulled, the effect whose prototype denotes consistent decrease in object's distance to the robot (x-position). In emulating a goal to pull this object towards itself, Eq. 2 yields that pulled effect brings the object closer to the goal, hence iCub chooses to ask a human to pass the object.

The effects got attention and got closer turned out to be ambiguous effect labels - their corresponding clusters did not have any consistently increasing or decreasing features. This might also be related with our feature set. Similar results were observed for the effects clustered as sat down and stood up, although they were unambiguously interpreted by the participants. The amount of standing and sitting of our experiment participants has had a high variance. The participants had two major interpretations for the "pass me" behavior: they either (i) pushed the object towards the robot (causing pulled effect) or (ii) tried to pass it to robot's hand (Fig. 6). Similar response was also observed when the voice behavior "take this" was applied: while most of the participants took the object and removed it from the scene (causing the disappeared effect), some of the participants just dragged the object towards themselves (causing moved forward effect). We were expecting that when iCub enacted the voice behavior "bye",
the participants would leave the scene. However, participants mostly kept their positions and responded by waving back.

Figure 5: Some of the results obtained from unsupervised clustering of feature mean and variances. Vertical axis represents some of the effects (E1: moved-right, E2: moved-left, E3: moved-forward, E4: pulled and E5: disappeared) and the horizontal axis represents some of the features detected as consistently increasing (red upwards arrow) or decreasing (blue downwards arrow) in the given effects (F1: position-x, F2: position-y, F3: human presence))

Figure 6: Some different reactions by experiment participants when the robot uses the "pass me" voice behavior.

Both social and non-social behaviors contribute to these results. For example, pulled can be produced both from pull and "pass me" behaviors. Note that some of the features, which were inconsistently changed (marked with star) or negligibly changed (marked with circle), grouped into one column for brevity.

\section*{Social Affordances and Multi-step Planning}

We demonstrate social affordances in three scenarios:
1- Multi-step planning without human presence In this scenario, the object is placed in front of iCub as the initial position, and the target position is shown with red circles (Fig. 7a). After initial and final positions are shown to iCub, it plans without a human present in the environment; i.e., it cannot make use of "social affordances". According to the plan, the effect sequence is determined as moved forward, moved left, moved forward. After a successful push-forward behavior, the object is moved-forward (Fig. 7b), then with a push-left behavior, the object reaches close to the target position (Fig. 7c). Appropriate behaviors to end up with the last moved-forward effect may have been push-forward behavior or "pass me" voice behavior. Since there is no human across
the table and because the object is too far to be moved forward to its target position, iCub figures out that it is impossible for the object to reach its final position (Fig. 7d) and stops at this stage.

Figure 7: Scenario \#1: The robot cannot reach the target position and cannot fulfill the goal due to absence of a human.

2- Multi-step planning with a human - using "pass me" voice behavior This scenario demonstrates a case for successful planning. As the initial position, the object is placed closer to the human and the target position is shown with a red circle (Fig. 8a). After planning, the effect sequence pulled, pulled, moved left is determined to reach the target position. For the first pulled effect, since the object is placed far from iCub and with the contribution of human presence, "pass me" voice behavior has the highest probability and is executed (Fig. 8b). For the remaining pulled and moved-left effects, pull (Fig. 8c) and push-left (Fig. 8d) behaviors are executed respectively. As a result, each planned effect is achieved and the object reaches its target position (Fig. 8e).

Figure 8: Scenario \#2: The robot can use human's affordances when stuck, by using the "pass me" voice behavior.

3- Multi-step planning with a human - using "take" voice behavior This scenario shows a demonstration in which iCub finds a valid plan but because of a behavior which results with an unexpected effect, iCub re-plans. For this scenario, the object is placed close to iCub and the target position is shown with a red circle (Fig. 9a). The planner finds out the required effect sequence as moved forward, moved right, moved forward. The first two effects are achieved using the push-forward (Fig. 9b) and then push-right behavior (Fig. 9c). For the last effect, push-forward behavior is executed. However, instead of a moved-forward effect, moved-right effect occurs (Fig. 9d). Because of this unexpected effect, iCub needs a re-planning (Fig. 9e). This re-planning results with
a new effect sequence of moved left, moved forward. This re-planned effect sequence is achieved by using push-left behavior (Fig. 9f) and "take" voice behavior (Fig. 9g) and object reaches its target position (Fig. 9h).

Figure 9: Scenario \#3: The robot can use human's affordances when stuck, by using the with "take" voice behavior.

From these 3 different scenarios, we conclude as follows: (i) After iCub executes a behavior, if it observes an unexpected effect, it re-plans. (ii) iCub executes its behaviors by planning (and re-planning if necessary) until the object reaches the target position or iCub decides that it is impossible for the object to reach the target position. (iii) If there is a human, iCub may benefit from the affordances offered by the human to get a desired effect. (iv) If there is no human and the desired effect requires a human, iCub can realize that it is impossible for the object to reach the target.

\section*{Conclusion}

In this paper, we used the very same affordance learning framework developed for discovering the affordances of inanimate things to learn social affordances, that is affordances whose existence require the presence of humans. We demonstrated that our humanoid robot can interact with objects and with humans (using simple verbal communication) and from these interactions, it can learn what the objects as well as the humans afford. Moreover, we showed that the robot can ask for human assistance whenever it is required while executing multi-step plans to satisfy demonstrated/given goals.

Our approach towards learning the social affordances is in line with the findings that affordances at different levels (intra-level and inter-level) share the same intrinsic constraints and organizations (e.g., (Richardson et al., 2007)).

\title{
Linguistic cued attention in children: Words organize attention to shape in a visual search task
}

\begin{abstract}
By one account of early word learning, children become proficient word learners as a result of environmental regularities: Learning words tunes the child to the regularities offered by the language being learned, orienting attention to those regularities. We test one core claim of this account, that count nouns should cue attention to the shape of the objects. Using a visual search task we present evidence that hearing the name of the object narrows children's attention to the objects in the array that have the same shape. Future steps and the implications of these results are discussed.
\end{abstract}

Keywords: attention; language and cognition; visual search; word learning.

\section*{Introduction}

Using past experience to select what to attend to is a powerful feature of human cognition. If exposed to environmental regularities, infants (Kirkham, Slemmer and Johnson, 2002; Saffran, Aslin \& Newport, 1996) and adults (Chun \& Jiang, 1998; Zhao, Ngo, McKendrick, \& TurkBrowne, 2011) readily attend to the current events that better match the underlying structure of their previous experience.

This ability to selectively attend to the most reliable sources of information as a result of past experience has been proposed as a mechanism underlying early word learning. Not only do children learn a large amount of words in the first years of life, but they also seem to do so in very smart ways. For example, by 2.5 years children use shape to generalize new noun categories - if given a novel named object, children will selectively attend to shape over color or texture when extending the novel name to new exemplars (the shape bias; Booth \& Waxman, 2002; Jones \& Smith, 2002).

Because in English many count nouns map to object categories well organized by within-category shape similarity, learning individual word-object mappings could create a top-down process that would organize future learning. According to the attentional learning account of the shape bias, it is the co-occurrence of nouns and shapes that creates an attentional bias to shape over other features when generalizing a new object category. Although there is evidence supporting the attentional account (GershkoffStowe \& Smith, 2004; Jones, 2003; Smith, Jones, Landau, Gershkoff-Stowe, \& Samuelson, 2002), the specific
mechanisms through which nouns cue object shape have not been directly tested. In the traditional shape bias task, children are asked to generalize a new object category in an untimed forced-choice procedure. The fact that children tend to select the shape match could be do to attentional processes or to much later decision processes. Indeed, competing theories of the attentional learning account have suggested that the shape bias reflects more conceptual theories about how words refer to objects (Waxman \& Gelman, 2009).

The purpose of this paper is to empirically test a core claim of the selective attention account: That words cue children's attention to the shape of the objects. To this end, we use a visual search task - a well-documented attentional task in which participants are asked to find a particular object (the target) amidst distractor objects. In the visual search literature with adults (Treisman \& Gelade, 1980) and children (Gerhardstein \& Rovee-Collier, 2002), when the target and the distractors differ by just one feature, search is almost effortless and does not depend on the number of distractors. When the target and the distractors have overlapping features, finding the target becomes a serial search - and response times depend on the number of distractors. The intercept and the slope of the search function are also indicators of the attentional processes involved. While the slope reflects the per item search time (i.e. how long it takes per item to decide if it is the target), the intercept is thought to reflect pre-search processes, including the representation of the search target in working memory (Vickery, King \& Jiang, 2005; Woodman, Vogel and \& Luck, 2001).

To investigate the role of labels in visual attention we use a visual search task to compare children's performance when they were cued with both the spoken name and a picture of the target versus then they were cued with just a picture of the target.

\section*{Experiment 1: Do labels cue attention to shape?}

Finding a target requires keeping a representation of the target in working memory. Research with adults has suggested that more robust working memory representations of the target result in overall decrease in search times (i.e. intercept changes). Because visual attention is biased
towards elements in the array that match the contents of working memory, stronger working memory representations would effectively suppress attention to nonmatching elements in the search array (Kristjansson, Wang \& Nakayama, 2002; Soto \& Humphreys, 2007; Vickery, King \& Jiang, 2005), therefore modulating pre-search attentional processes.

Does hearing the name of the target prior to search influence its representation in working memory, and thus search? If hearing the object name results in the enhanced representation of object shape relative to other properties, then the explicit naming of the search target on each trial should effectively narrow search to items in the array with the same shape. This is the hypothesis tested in Experiment 1.

In a conjunctive search task, children were asked to search for a particular colored object (e.g., red bed) in a field of same shape (e.g., green bed) and same color (e.g., red couch) distractors. In the Label condition, children heard the displayed object (but not its color) named (e.g., "bed") prior to each search trial; in the Silent condition, they just saw the displayed target. If storing the name along with the target object in working memory supports processes that automatically direct attention to same shaped items in the array, then overall search time should decrease in the Label condition as participants would preferentially examine the shape matching objects to find the conjunctive match. That is, by hypothesis, in the Label condition children's attention might be automatically attracted to the shape matching items, with attention to the non-shape matching items being dampened. If so, this would effectively reduce the search set and should lead to faster overall search times in the Label than in the Silent condition.

\section*{Methods}

Participants. Thirty-two children ( \(\mathrm{M}=37\) months, range: 31-43 months) were assigned to either the Silent or the Label condition. Ten additional children were recruited but not included in the final sample due to refusal to participate in the study ( \(\mathrm{N}=3\) ), not finishing the familiarization phase ( \(\mathrm{N}=1\) ), or selecting a non-target object on most test trials ( \(\mathrm{N}=6\) ). Children were reported to have no developmental disorders, normal (or corrected to normal) visual acuity and color vision. English was the main language spoken by all families. Parental consent was obtained for all participants in compliance with the IRB of Indiana University.
Stimuli and procedure. Figure 1 shows the experimental set up and the temporal order of events on each trial. The child was seated approximately 35 cm from a \(17^{\prime}\) monitor equipped with a touchscreen (MagicTouch, Keytec, Garland, TX). E-Prime software (PST, Pittsburg, PA) was used to control stimulus presentation and record the latency and the location of each response during the test phase. On each test trial, a "fixation" slide encouraged the child to rest their hands on the table (Figure 1a) before the target object was displayed on the center screen for \(1 \sec\) (Figure 1b).

The search array (with the target object amid distractor objects) was then displayed and the child asked to find the target picture as fast as possible (Figure 1c). Prior to the test phase, children were familiarized with the search procedure, with holding their hands on the table during fixation, and touching the target.

Figure 1: Structure of a trial (left) and child performing the task (right).

Each child was assigned one search target and searched for the same object throughout 32 test trials. Four different objects served between subjects as targets: a red bed, a red couch, a green bed, and a green couch. For each target, the distractors were selected so that half had the same shape and half had the same color as the target (that is, when the target was a red bed, half the distractors were red couches and half were green beds). Each test stimulus was rendered in a 180 x 140 pixel area on a white background. Across trials, the number of distractor objects was manipulated: on each trial, the target object was placed amidst \(2,4,8\) or 12 distractors; eight occurrences of each distractor set size was presented in an order randomly determined for each subject. Sixteen possible locations were used to place the target and the distractors. Across test trials, the target appeared equally often on the left and right side of the screen.

The experimenter started each trial ensuring that the child was looking at the screen; no time limit was set for finding the target. No feedback was given during test phase. In the Label condition, a sound file containing the name of the target object (e.g. "bed") played at the onset of the target (Figure 1b). The audio files were recorded using an artificial speech creator at a sample rate of 16 KHz . No sound file was played in the Silent condition.

\section*{Results and Discussion}

Mean reaction times (RT) per distractor level were calculated for each child. Only correct responses (i.e. when the target object was selected) were included. Although some participants did not complete all test trials, no differences were found between conditions in the total number of trials completed, \(t(30)=-0.37\), n.s., nor in accuracy, \(t(30)=0.14\), n.s. (see Table 1). Figure 2 depicts mean RT for the Silent and the Label conditions as a function of number of distractors. A mixed \(2 \times 4\) analysis of variance with condition as the between-subjects factor and number of distractors as the within-subjects factor yielded a main effect of distractor number \([F(3,90)=27.30, p<\) 0.001 ], reflecting the fact that RT increased as the number
of distractors increased. A main effect of condition was also found \([F(1,30)=4.48, p<0.05]\), reflecting a significant decrease in overall RT for the Label condition. Number of distractors and condition did not interact \([F(3,90)=0.21\), n.s.]. The slopes and intercepts of the linear best-fit lines were also calculated for each child. Independent samples ttests showed that while the slopes of the two conditions were not different \([t(30)=0.39\), n.s.], there was a significant reduction in the intercept of the Label condition when compared to the Silent condition \([t(30)=-2.40, p<\) 0.05].

Figure 2: Mean RT (ms) per number of distractors for the Silent and the Label conditions in Experiment 1. Error bars represent standard errors.

These results are consistent with the hypothesis that hearing the name increases attention to shape matching items and/or decreases attention to non-shape matching distractors - thus decreasing overall search time. The results provide direct evidence for a role of object names in guiding children's attention to object shape. However, presenting the target label did not affect the slope of the search function, which may indicate that the label does not affect the time it takes to make a decision per each attended item. This point will be addressed in the General Discussion section.

Experiment 2 examines an alternative account for the present findings; that it was not the object name per se which enhanced overall search time, but the presence of an auditory signal at the start of each trial.

\section*{Experiment 2: Does any word cue attention?}

A growing literature shows multimodal influences on visual attention and search such that auditory cues may lead to more rapid search (Iordanescu, Grabowecky, \& Suzuki, 2011; Van der Burg, Olivers, Bronkhorst, \& Theeuwes 2008). Thus it is possible that the effects observed in Experiment 1 were due to the addition of a spoken word potentially any word - and not to the target's name nor increased attention to object shape. Accordingly, Experiment 2 replicated the Label condition of Experiment

1 but replaced the target name on each trial with the word "Go."

\section*{Methods}

Participants. Sixteen children between 32 and 42 months of age ( \(\mathrm{M}=37\) months) participated; none of these children had participated in Experiment 1. Eleven additional children were recruited but not included in the final sample due to selecting a non-target object on most test trials. Recruitment and informed consent procedures were the same as in Experiment 1.
Stimuli and procedure. All aspects were the same as in the Label condition of Experiment 1, except that the sound file presented at the onset of the target played the word "Go."

\section*{Results and Discussion}

Mean RT per number of distractors for correct responses was calculated for each child. Children completed 30 trials ( \(\mathrm{SD}=2.98\) ) on average, and mean accuracy was \(83 \%\) (see Table 1). Figure 3 presents RT for correct responses per distractor level for the Go condition. For comparison purposes, results from the Silent condition from Experiment 1 are also shown. A mixed \(2 \times 4\) analysis of variance with number of distractors as within-subjects factor and condition as the between-subjects factor yielded no reliable differences in RT between the Go condition of Experiment 2 and the Silent condition of Experiment \(1[F(1,30)=0.06\), \(p=0.82\) ]. A main effect of distractors number was found [ \(F\) \((3,90)=23.82, p<0.001]\), reflecting the increase in RT as a result of increasing the number of distractors. These two factors did not interact \([F(3,90)=0.41, p=0.75]\). The analyses of the individual slopes and the intercepts confirmed the trends found for RT: No differences were found between the Go condition of Experiment 2 and the Silent condition of Experiment 1 in the slope \([t(30)=0.25\), \(p=0.80]\) or the intercept \([t(30)=-0.38, p=0.71]\).

In brief, an auditory word that is not the name of the target does not result in more rapid search than the presentation of no sound at all, a result that suggests the observed effects in Experiment 1 were not due to an auditory cuing effect but instead reflected the presentation of the object name.

\section*{General Discussion}

Word learning requires selective attention to the right properties - shape is likely to be the right feature if generalizing countable objects, while texture might be a better alternative if generalizing food terms. What processes support the development of these attentional biases? This question is the source of a major dispute in the literature, with some arguing for the role of attended regularities in setting up such attentional biases (Smith, Jones, Yoshida, Colunga, 2003) and others arguing that word learning entails more conceptual and deliberative processes about how categories are formed (Waxman \& Gelman, 2009).

The current results offer support to the first alternative. By showing that words direct attention to the shape of known objects, we offer for the first time direct evidence for a core claim of the attentional learning account. After enough instances of attention being directed to the shape of known objects in the presence of their names, a generalized attentional bias might emerge - any noun, even a novel one, could now cue attention to shape. This is potentially a very powerful learning mechanism, one that enables children to quickly generalize new categories in the presence of new words.

The current results also suggest that the attentional effects of words may be located at the level of working memory hearing an object's name strengthens the shape representation of that object. The finding that hearing the target name on a visual search task influences the intercept of the search function, without changes in the slope, also suggests that the effects of words do not influence the efficiency of search (i.e. how long it took to identify or dismiss each item as the target). However, the present version of the task may not be optimal to test for a potential role of labels in the efficiency of search (as measured by the slope of the search function). In adults, the slope - or per item search time - is affected by the familiarity of the target and distractors (Mruczek \& Sheinberg, 2005; Wang,

Cavanagh \& Green, 1994), by the need or ease of binding the features of individual items in the array into their individual units (Treisman \& Gelade, 1980), and by the discriminability of the target from the distractors (Duncan \& Humphreys, 1989). For young children, providing the basic-level name of the target could, in principle, influence any of these processes - and in so doing increase the role of shape in search in ways that expedite the identification of the target. By this hypothesis, given sufficiently difficult shape discriminations, hearing the object name prior to search might be expected to yield a decreased slope in the search function as well as a decrease in overall search time. This is a critical issue for future research.

What are the implications of the current results? Although more research is needed to further understand the mechanisms involved in the attentional effects of labels in word learning, the evidence presented here suggests that hearing a name activates a representation of certain features of the object - in the case of count nouns, object shape. It follows that hearing an object name will cue attention to that object's shape, and over time this has the potential to not only become a more automatic process, but also to change the nature of the representation (possibly from specific individual features to more abstract shape representations). Moreover, by extension from accounts of these processes in the adult literature (Dahan \& Tanenhaus, 2005; Huettig \& Altmann, 2007; Lupyan \& Spivey, 2010) these labeling effects appear to be rapid and automatic, that is, not under deliberative or conceptual control. Thus, the current results provide a stepping-stone to a mechanistic account of how words organize attention in children - and in so doing, may organize early word learning and the on-line comprehension of words in context.

\section*{Acknowledgments}

This research was supported by a grant from the National Institute of Child Health and Development (HD28675) to LBS and a Graduate Fellowship from the Portuguese Foundation for Science and Technology awarded to CV (SFRH/BD/68553/2010). The authors would like to thank the members of the Cognitive Development Lab at IU for useful discussions, Anna MacKinnon, Blakely Meyer and Tracy Kelsey for their help with recruitment and data collection, and the parents and children who participated in these studies.

\begin{abstract}
Mathematics anxiety negatively affects performance in simple arithmetic tasks. The experiment reported here explored the role of interactivity in defusing the impact of math anxiety on mental arithmetic. Participants were invited to complete additions presented on paper without using their hands or any artefact; in a second, interactive, condition, the same problems were presented in the form of a set of manipulable tokens. Math anxiety was significantly correlated with mental arithmetic performance only in the static condition. The results of a mediation analysis indicated that the effect of math anxiety on mental arithmetic was mediated by working memory capacity in the static condition; in the interactive condition, math anxiety and working memory did not significantly correlate with performance. Interactivity encouraged the coupling of internal and external resources to create a cognitive system that augmented and transformed working memory capacity, diffusing the resource drain caused by math anxiety.
\end{abstract}

Keywords: Mental arithmetic, interactivity, math anxiety, individual differences, distributed cognition

\section*{Introduction}

A person's proficiency in mathematics and an appreciation that effort is a key determinant of math performance will likely have important consequences for his or her educational and occupational opportunities. In addition, a mathematically competent workforce is identified as a strategic driver of economic growth (National Mathematics Advisory Panel, 2008). There are indications in the US and in the UK (National Numeracy Facts and Figures, 2012) that numeracy levels are in decline.

An important factor that impedes math performance and reduces exposure to math-with the inevitably negative impact on the acquisition of math knowledge and skills-is math anxiety. Richardson and Suinn (1972) define math anxiety as "feelings of tension and anxiety
that interfere with the manipulation of numbers and the solving of mathematical problems in a wide variety of ordinary life and academic situations" (p. 551). From a processing efficiency perspective (Eysenck \& Calvo, 1992), math anxiety impairs performance by using up working memory resources to maintain and retrieve negative performance-related thoughts and memories (Ashcraft \& Krause, 2007). As a result, math anxious people deploy limited cognitive resources when working on a math problem, leading to poorer performance, reinforcing a cycle of anxiety and avoidance that perpetuates poor numeracy.

\section*{Mental Arithmetic}

In the absence of pen and paper, mental arithmetic is a quintessential working memory task. Admittedly, for simple problems where the solution draws on long-term memory knowledge of well-rehearsed answers (e.g., \(3+\) 3 ), working memory plays a more limited role (DeStefano \& LeFevre, 2004). However, for more complex problems, such as multiple number additions, working memory resources must be deployed to arrive at a correct answer (Ashcraft, 1995). These resources involve storage of interim totals and place markers as well as executive function skills that direct attention (e.g., which number to add next) or the retrieval of strategies to support more efficient and reliable performance.

The exact nature of the resources recruited depends on the context of reasoning, defined by the features of the external environment in which the problem is presented. For one, the manner of presentation (visual, auditory) would recruit different subsystems of working memory. In addition, if the numbers are visually presented, working memory would be taxed differently depending on whether the presentation is sequential or simultaneous. Even with a simultaneous presentation, the numbers' arrangement in space-columnar, linear, or random-
would also determine the extent of working memory load. More important is the opportunity to manipulate the problem presentation to facilitate thinking: Enabling participants to re-order and group numbers would likely help them remember the numbers already added, identify felicitous sub-totals and interim totals, guide attention, and encourage the development of more efficient arithmetic strategies.

Imagine a participant invited to complete an addition problem involving seven numbers, some single digit, some double digit. In one condition, the problem is presented on a piece of paper as a randomly configured array of numbers; the participant is asked to put her hands palm down on the flat surface on which the problem is presented. The mental effort required cannot be guided and supplemented with complementary actions (Kirsh, 1995) such as pointing and re-arranging. In this context, mental arithmetic performance should reflect the participant's working memory capacity, arithmetic knowledge and skill. Imagine, in turn, the same problem but, this time, presented as a set of number tokens, which the participant is invited to manipulate. The importance of arithmetic knowledge and skills remain; however, now, working memory is augmented by a modifiable problem presentation. Such a dynamic presentation unveils a shifting array of opportunities and possibilities, whether strategically engineered or fortuitously encountered. Thus, working memory is augmented not simply in terms of storage capacity, but also in terms of executive functions. That is, a shifting problem presentation cues certain strategies-for example by grouping certain numbers together-and guides attention. Hence, in a modifiable environment, the strategic control of attentional resources originates, partly, in the world.

\section*{The Present Experiment}

Participants' performance in a mental arithmetic task is likely to be impaired by math anxiety, and this may be particularly apparent when the mental arithmetic task requires a larger commitment of working memory resources, such as in a static context of reasoning where participants cannot interact with numbers that compose a problem. In turn, if reasoners are given the opportunity to couple their working memory resources and arithmetic skills to a dynamic and modifiable problem presentation, the impact of math anxiety might be considerably attenuated. This is because the coupling of internal and external resources creates a more robust and resilient cognitive system that augments the participants' working memory resources, which then can more easily soak up the resource-depleting rehearsal of performance-related thoughts. Arithmetic performance might be positively correlated with math anxiety in a static reasoning environment; however when participants can extend their cognitive resources and let the environment shoulder some of the computational efforts, then accuracy may be
influenced by math anxiety to a lesser extent.
Math anxious individuals cope with math anxiety by limiting their exposure to math, which further limits their levels of numeracy (Ashcraft, 2002). Hence, to get a better window on the influence of anxiety on mathematical cognition, a relatively simple task was developed for this experiment engaging basic arithmetic skills acquired and mastered by university undergraduates. Participants completed the additions in both a static, non-interactive, context and in one where tokens corresponding to the elements of the addition problems could be touched, arrayed, grouped, in whatever manner to support problem solving; hence interactivity was manipulated within-subjects.

Performance was measured in terms of accuracy (absolute error) and efficiency. Thinking efficiency was calculated as the ratio of the proportion of correct solutions for a set of problems over the proportion of time invested by that participant to complete the set out of the maximum time invested by the slowest participants. In the static condition, participants' working memory resources would likely be stretched, particularly by the long additions; in turn the coupling of internal to external resources in the interactive condition could augment the participants' working memory capacity and executive processes.

Participants' working memory capacity was assessed using a computation span task. Math anxiety was predicted to correlate negatively with working memory capacity. More important, the magnitude of error in the mental arithmetic task was predicted to correlate positively with anxiety level and negatively with working memory capacity, but only in the static condition. Thus, a key prediction was that interactivity would defuse the impact of anxiety on calculation error. In a similar manner, math anxiety and working capacity should predict thinking efficiency in the static, but not in the interactive condition. Mediation analyses were conducted to determine the direct and indirect effect of math anxiety on thinking efficiency in both conditions.

\section*{Method}

\section*{Participants}

Forty psychology university undergraduates ( 35 females, overall mean age \(20.8, S D=3.2\) ) received course credits for their participation.

\section*{Material and Measures}

Mathematics Anxiety. Mathematics anxiety was measured using an abridged version of the original 98 -item scale (Suinn, 1972) developed by Alexander and Martray (1989). The abridged version is based on 25 -items for each of which participants used a 5-point scale ( \(1=\) "not at all", 5 = "very much") to describe how anxious the event
described made them feel. The 25 items assessed math anxiety in terms of test anxiety (e.g., "studying for a math test"), numerical task anxiety (e.g., "reading a cash register receipt after your purchase") and math course anxiety (e.g., "watching a teacher work on an algebraic equation on the blackboard"). Math anxiety scores could range from 25 to 125 - the higher the score, the higher the math anxiety; the mean score in the present sample was \(66.0(S D=18.1)\).

Working memory capacity. Working memory was assessed using a computation-span test (Ashcraft \& Kirk, 2001, p. 226). Participants solved simple arithmetic problems in blocks increasing from 2 to 6 problems (e.g., " \(50+7=?\) ?, " \(60 \div 2=?\) ?, " \(19-8=\) ?" was a block of three problems). At the end of each block, participants were prompted to recall in correct order the last number of each problem in that block (for the example above, correct recall would be " \(7,2,8\) "). There were two blocks for each sequence length (e.g., two blocks with sequences of 3 different problems) for a total of 10 blocks. Working memory capacity was measured as the sum of all correct answers across the 10 blocks, for a maximum score of 40 . The mean number of digits recalled by the participants in the present study was \(24.1(S D=7.6)\).

Arithmetic Task. Participants carried out short and long additions, involving either 7 or 11 numbers (see Fig. 1), as fast and as accurately as possible. They completed the problems in blocks, five from the short set first, and five from the long set second. Performance was measured in terms of the mean absolute error and in terms of efficiency. Efficiency was measured as the ratio of accuracy (proportion correct sums) over time invested in doing the sums. The latter was measured as the proportion of actual time to complete the sums divided by the maximum time needed to complete them in that condition; this maximum was determined by taking the average of the top quartile latencies. Inefficient performance is reflected with a ratio smaller than 1 indicating that proportion accuracy was smaller than proportion time invested.

\section*{Procedure}

The mental arithmetic task, working memory span task, and the completion of the 25 -item mathematics anxiety scale were embedded in an experimental session that lasted approximately 40 minutes, and which included other tests of motivation and cognitive skill unrelated to the present experiment. The session always started with participants completing the math anxiety scale. During the mental arithmetic task, participants were presented with the five additions from the short set first. After a \(2-\mathrm{min}\) distractor task (a word search puzzle), participants were presented with the five additions from the long set; the problem order within each set was randomized for each participant. These two sets of sums were presented twice. For one
presentation participants performed the additions with their hands on the table facing them (the static condition) and announced their answer out loud; for the second presentation, square numbered tokens ( 3 cm by 3 cm ) were used, and participants were encouraged to touch, move or group the tokens in whatever manner to help them add the numbers (the interactive condition); as in the static condition, participants announced the solution for each problem out loud. While the long set always followed the short set, the order of condition (non-interactive, interactive) was counterbalanced across participants. With 10 different problems, involving 10 unique configurations of numbers, and 90 numbers across the two sets, it was unlikely that participants remembered the solution to each problem when presented a second time. Still, to prevent direct retrieval of solutions during the second presentation, the participants completed the computation span test between the two presentations of the arithmetic task. Problem set size (with two levels) and interactivity (with two levels) were independent variables that were manipulated in a \(2 \times 2\) repeated measures design.

Figure 1: Examples of additions from the short set (7number additions) and the long set (11-number additions).

\section*{Results}

The correlation matrix involving the anxiety and working memory span measures along with the mental arithmetic performance measures is reported in Table 1. We note, for now, that math anxiety scores were negatively correlated with working memory span, \(r(38)=-.318, p=.045\). The correlations with the different measures of mental arithmetic performance in the static and interactive conditions are described below.

\section*{Absolute Error}

The mean absolute deviation from the correct answer or absolute error for the short and long sums in the static and interactive conditions are reported in the top half of Table 2. Mean absolute error was similar for the short sums across conditions; however, errors increased for the long sums, in a relatively more pronounced manner in the static condition. In a \(2 \times 2\) repeated measures analysis of variance (ANOVA), the main effect of condition was not significant, \(F<1\), the main effect of problem size was marginally significant, \(F(1,39)=4.02, p=.052\), but the interaction was not significant, \(F(1,39)=2.26, p=.141\).

Table 1: Correlation matrix involving mathematics anxiety, working memory capacity, and mental arithmetic performance averaged across all 10 additions in the static and interactive condition \((d f=38)\).

Note: * \(p<.05 \quad * * p<.01\). MARS \(=\) Mathematics Anxiety Rating Scale scores; SPAN = Computation span scores; ERR-S = Average absolute error in the static condition; ERR-I = Average absolute error in the interactive condition; EFF-S = Average efficiency ratio in the static condition; EFF-I = Average efficiency ratio in the interactive condition.

Math anxiety was strongly correlated with absolute error in the static condition averaged across all 10 problems, \(r=.427, p=.006\) (see Table 1), but not in the interactive condition, \(r=.002, p=.989\). To determine the interaction between math anxiety and condition (interactive, static), the difference in the average absolute errors between the interactive and static condition were regressed on the anxiety scores mean deviation form (an alternative to dichotomising anxiety scores with a median split-which reduces power-as recommended by Brauer, 2002). In the absence of an interaction, one would expect that as math anxiety level increased, participants would not benefit from manipulating the tokens-in other words, the difference between the interactive and static condition would be constant across levels of math anxiety. However, the slope of the regression line, \(\beta=-.372\), was significantly negative, \(t(38)=-2.471, p=.018\). This confirms that participants who were more math anxious made errors of a smaller magnitude in the interactive than in the static condition.

Finally, working memory span was marginally correlated with error in the static condition, \(r=-.283, p=\) .077 , but not in the interactive condition, \(r=.030, p=\) . 852.

\section*{Efficiency Ratio}

The mean efficiency ratios are reported in the bottom half of Table 2. Participants’ efficiency exceeded 1 in the static condition for the short problems, but declined for the long sums. In turn, efficiency remained well calibrated and constant across problem size in the interactive condition. The \(2 \times 2\) repeated measures ANOVA revealed that the main effect of condition was not significant, \(F<1\), the main effect of problem size was significant, \(F(1,39)=\)
\(5.24, p=.028\), as was the condition by problem size interaction, \(F(1,39)=5.37, p=.026\).

Table 2: Mean absolute error and efficiency ratio, along with the standard deviation, for short and long sums in the static and interactive conditions.
\begin{tabular}{|c|c|c|c|c|}
\hline \multirow[b]{3}{*}{Condition} & \multicolumn{4}{|c|}{Set Size} \\
\hline & \multicolumn{2}{|c|}{Short} & \multicolumn{2}{|c|}{Long} \\
\hline & M & \(S D\) & M & \(S D\) \\
\hline & \multicolumn{4}{|c|}{Abolute Error} \\
\hline Static & 3.3 & 4.4 & 5.6 & 6.1 \\
\hline \multirow[t]{2}{*}{Interactive} & 3.6 & 4.7 & 4.2 & 3.9 \\
\hline & \multicolumn{4}{|c|}{Efficiency Ratio} \\
\hline Static & 1.2 & 0.9 & 0.9 & 0.8 \\
\hline Interactive & 1.0 & 0.7 & 1.0 & 0.7 \\
\hline
\end{tabular}

Math anxiety was negatively correlated with the efficiency ratio averaged across all 10 problems in the static, \(r=-.306, p=.055\), but not in the interactive condition, \(r=-.230, p=.153\). The average efficiency ratios were not characterised by a significant math anxiety by condition interaction, however. In the regression of the difference in the average efficiency ratios between the interactive and static condition on the mean deviation form of the math anxiety scores, the slope of the regression line, \(\beta=.161\), was not significantly different from zero, \(t(38)=\) \(1.008, p=.320\).

Working memory span was positively correlated with efficiency in the static, \(r=.494, p=.001\) and to a lesser extent in the interactive condition, \(r=.341, p=.031\). In light of the strong correlation between working memory capacity and efficiency, the mediation of the effect of math anxiety on efficiency via working memory capacity in both the static and the interactive condition was analysed using the procedure and SPSS macro developed by Preacher and Hayes (2008). A simple mediation model analysis was run with math anxiety as the independent variable (X), working memory capacity as the mediator ( M ) and average efficiency as the dependent variable (Y); Figure 2 depicts the results of both mediation model analyses for the static (left panel) and interactive condition (right panel). In the case of the static condition, the total effect of math anxiety on mental arithmetic performance (path c) was negative and significantly different from zero. Math anxiety significantly influenced working memory in a negative direction (path a) and working memory significantly influenced efficiency (path b). Finally, the effect of anxiety on efficiency after controlling for working memory (path \(\mathbf{c}^{\prime}\) ) was no longer significant. A bootstrap analysis revealed that the \(95 \%\) bias corrected interval with 5000 resamples

Figure 2: Results of the mediation analysis in the static (left panel) and interactive condition (right panel).
for the size of the indirect effect ( \(-0.58 ; C I[-1.47 ;-0.03]\) ) did not include a zero value and thus can be consider to be statistically significant. A traditional Sobel's test approached significance, \(z=-1.73, p=.084\). Thus, the effect of math anxiety on mental arithmetic efficiency in the static condition was completely mediated by working memory (see Fig. 2, left panel). In the interactive condition, the total effect of math anxiety on efficiency (path c, see Fig. 2, right panel) was negative but not significantly different from zero. Thus, strictly speaking, the condition for mediation analysis was not fulfilled (Baron \& Kenny, 1986). However, it has sometimes been argued that the indirect effect can still be significant, and omitting this analysis could lead to the failure of detecting interesting mechanisms (Hayes, 2009). With this in mind, the mediation analysis was conducted and showed that math anxiety influenced significantly working memory in a negative direction (path a), while working memory marginally influenced mental arithmetic performance (path b). Finally, the effect of anxiety on mental arithmetic performance after controlling for working memory (path \(\mathbf{c}^{\prime}\) ) was not significant. A bootstrap analysis revealed that the \(95 \%\) bias corrected interval with 5000 resamples for the size of the indirect effect ( \(-0.33 ; C I[-0.99 ; 0.02]\) ) included zero and thus cannot be consider to be statistically significant. Finally, the Sobel's test was not significant, \(z=\) \(-1.41, p=.160\). Thus, there was no significant total or indirect path between math anxiety and mental arithmetic efficiency in the interactive condition (see Fig. 2, right panel).

\section*{Discussion}

In this experiment participants completed short and long additions in two different contexts, one which permitted the reconfiguration of the problem through the spatial rearrangement of the number tokens, and one which did not. Participants were generally accurate-although less so for longer additions-and interactivity did not significantly enhance accuracy. However, the significant interaction between problem size and condition for the efficiency ratio measure confirmed that thinking efficiency dropped for the
longer sums in the static condition, but remained stable in the interactive condition. The interaction between problem difficulty and context of reasoning (static, interactive) indicates that determining the benefits of physically reshaping a problem presentation is an exercise done relative to the degree of task difficulty. Thus, with a relatively easy task, interactivity might not benefit the reasoning agent, but interactivity can enhance efficiency when the task is challenging and undertaken on the basis of internal resources alone.

Math anxiety was significantly correlated with working memory capacity. This has been reported previously (Ashcraft, 2002) especially when capacity is gauged with a span test that involves numbers and operations. The more important findings was the significant interaction between math anxiety level and the degree of interactivity: as math anxiety increased, participants made fewer errors in the interactive than in the static condition.

It is important to stress that this experiment employed a repeated measures design: Participants and their levels of maths anxiety were identical in the static and interactive condition. Having said this a post-task measure in each condition might have offered a better measure of how much anxiety was experienced in completing the sums. Manipulating tokens might have altered participants' experience in terms of intrinsic motivation, attentional commitment, and self-efficacy.

In turn, reasoning efficiency, as determined by the ratio of accuracy over time invested in completing the sums, was marginally correlated with math anxiety in the static condition, but not in the interactive condition. The mediation analysis confirmed that the effect of math anxiety on efficiency in the static condition was mediated by working memory capacity. In turn, in the interactive condition, math anxiety had no effect on reasoning efficiency, but working memory capacity marginally influenced performance. According to processing efficiency theory (Ashcraft, 2002) math anxiety exacts working memory resources to maintain performancerelated beliefs and fears. As the static condition put a higher demand on working memory, efficiency was more
directly determined by working memory capacity. In the interactive condition, however, participants have the opportunity to recruit external resources to help them complete the sums. They can group the number tokens to guide and direct attentional resources and identify congenial interim totals that facilitate more efficient addition strategies. The coupling of internal and external resources creates a cognitive system (Wilson \& Clark, 2009) that augments memory storage and distributes the control of executive function in a manner that copes better with the resource drain caused by math anxiety. These findings lend support to the conjecture that for simple mental arithmetic problems, performance improvements are better supported in a learning environment that fosters interactivity.

Future research may explore the role of interactivity in helping reasoners enhance their mental arithmetic performance in contexts that can elicit higher levels of anxiety, such as under time pressured or in situations of greater accountability. One of the recommendations of the National Mathematics Advisory Panel (2008, p. 31) is to determine the etiology of math anxiety and important advances in charting its neurodevelopmental origins have recently been reported (Young, Wu, \& Menon, 2012). In addition, it might be of particular interest to determine whether intervention programmes that are based on interactive training exercises enhance participants' level of instrumentality, efficacy and confidence, reducing math anxiety in more traditional situations, and encouraging greater exposure to mathematics.

\section*{Acknowledgments}

We would like to thank Ellie McCourty, Angie Makri, and Joakim Westh Wiencken for their assistance with the recruitment and running of the participants. Financial support from the Kingston University Faculty of Arts and Social Sciences Research Capability Fund is gratefully acknowledged.

\begin{abstract}
We investigated whether "embodiment" of objects used in a problem-solving task (i.e., whether they have a bodily shape) would have a detrimental effect on learning to solve that problem through practice or through studying video-based modeling examples. A \(2 \times 2\) design with factors Training (Practice/Example study) and Embodiment (Present/Absent) was used ( \(N=80\) ). Results showed a large main effect of Training on effort investment in learning and on retention test performance, with Example study leading to higher scores with lower investment of effort during the learning phase than Practice. Numerically, Embodiment seemed to have an effect, with participants practicing/studying the task with embodied objects (plastic animals) performing worse on retention than participants practicing/ studying with nonembodied objects (discs), but this did not reach statistical significance. A new study with more power and an additional control condition is currently being conducted and results are expected to be available well before the conference.
\end{abstract}

Keywords: problem solving; example study; embodiment.

\section*{Introduction}

A substantial body of research in cognitive science has investigated the effects of a problem's appearance on the acquisition of problem-solving skills. For instance, versions of the Tower of Hanoi task that had the exact same problem space but instead of discs, featured monsters passing globes, or acrobats jumping on each other's shoulders, were found to be much more difficult (Kotovsky, Hayes, \& Simon, 1985; see also findings by Goldstone \& Son, 2005, on effects of concrete vs. idealized object appearance on pattern learning from a simulation). The present study investigated whether the "embodiment" of objects featured in a problem, that is, whether the objects have a bodily shape, would have a detrimental effect on learning to solve a problem either by means of practice or by means of studying digital video-based modeling examples. To the
best of our knowledge, the effects of problem appearance on acquiring problem-solving skills from examples has never been investigated yet.

\section*{Practice vs. Example Study}

For students who need to acquire problem-solving skills but lack prior knowledge of a task, practicing with problem solving is not the most efficient way to acquire those skills. It is far more effective and efficient for novice learners to study examples in which the solution procedure is workedout (worked examples) or demonstrated to the learner (modeling examples; for reviews, see Atkinson, Derry, Renkl, \& Wortham, 2000; Renkl, 2011; Sweller, Van Merriënboer, \& Paas, 1998; Van Gog \& Rummel, 2010). Interestingly, the higher effectiveness and efficiency of example study (possibly alternated with problem-solving) compared to problem-solving practice has not only been found when problems contain no guidance whatsoever, but also when they are tutored problems, on which feedback and hints are provided when errors are made (Salden, Koedinger, Renkl, Aleven, \& McLaren, 2010).

Cognitive load theory explains these beneficial effects of example study compared to problem solving in terms of the underlying cognitive processes and associated cognitive load (Sweller et al., 1998). Problems usually contain only a description of some "givens" and a goal statement, without providing any information on how to move from the givens to the goal state. As a consequence, novices have to figure out the correct solution steps to use by themselves, and often do so by resorting to weak problem-solving strategies such as trial-and-error, or means-ends analysis, which impose a high cognitive load but are not very effective for learning: even though such weak strategies may allow learners to succeed in solving the problem eventually (i.e., good performance), they have been shown to contribute
very little to learning (i.e., good performance of that task at a later moment; Sweller, 1988).

Worked examples prevent the use of such weak problemsolving strategies, by presenting the learner not only with the givens and a goal statement, but also with the workedout solution steps that are to be taken to reach the goal state. The learner can devote all of his or her available cognitive capacity to studying the given solution and constructing a cognitive schema for solving such problems, which can be applied to solve this (or a isomorphic) problem in the future. As such, compared to instruction consisting of problem-solving practice, instruction that relies more heavily on studying worked examples reduces ineffective cognitive load on working memory, and leads to enhanced learning outcomes and often to improved transfer performance (Sweller et al., 1998).
In addition to being more effective for learning, a heavier reliance on examples has also been shown to have beneficial effects on required acquisition time (i.e., lower; see e.g., Sweller \& Cooper, 1985; Van Gog, Paas, \& Van Merriënboer, 2006; Zhu \& Simon, 1987) and cognitive load experienced by students during acquisition (i.e., lower; see e.g., Paas \& Van Merriënboer, 1994; Van Gog et al., 2006) as well as during the test (i.e., lower; see e.g., Paas, 1992; Paas \& Van Merriënboer, 1994).

However, it should be kept in mind that the beneficial effects of worked examples on learning, acquisition time, and cognitive load, seem to apply primarily to novice learners (for advanced learners, an 'expertise reversal effect' occurs, and problem solving becomes more effective; Kalyuga, Chandler, Tuovinen, \& Sweller, 2001; see also Kalyuga, Ayres, Chandler, \& Sweller, 2003), and apply only when the examples are well-designed. That is, following early studies on the worked example effect (Cooper \& Sweller, 1987; Sweller \& Cooper, 1985) it was soon discovered that studying worked examples was not always more effective for learning than problem solving. Rather, the design of the examples played a crucial role in their effectiveness (Tarmizi \& Sweller, 1988). For instance, examples that induced split-attention (Chandler \& Sweller, 1991; Tarmizi \& Sweller, 1988) or included redundant information (Chandler \& Sweller, 1991), did not have beneficial effects on cognitive load and learning.
The present study also addresses the effects of problem and example design on cognitive load and learning, though in a very different manner, that is, by investigating the effects of embodiment of the objects used in the task.

\section*{Problem-solving Task and Design Effects}

The task used in this study is based on a computer-based problem-solving task called Frog Leap (see Van Gog, 2011; Van Gog, Jarodzka, Scheiter, Gerjets, \& Paas, 2009). In this computer-based task, the goal is to switch the sides of three brown frogs on the right and three green frogs on the left by clicking on them. There is an empty space in the middle. The frogs face in the direction of their goal. If they are clicked on they jump one place ahead or jump over one
other frog (they cannot jump over two others, and they cannot go back). The problem can be solved in only one way, in 15 moves.

Prior research has shown the superiority of studying modeling examples (consisting of screen-recordings) over problem solving with this computer-based task. Van Gog et al. (2009) showed that none of the 11 participants in the problem-solving condition managed to solve the problem after practicing twice, and Van Gog (2011) reported pilot data with 7 participants showing the same result even after four practice attempts. In contrast, after studying two examples, the numbers of participants to successfully solve the problem was approximately \(58 \%\) (Van Gog et al., 2009), and the number of moves correctly completed was approximately 10 (out of 15 ; Van Gog, 2011). Effects on transfer were not really explored in these prior studies. A second test task was included on which participants had to start on the opposite side as in the example, which was more difficult because the task had not been practiced or studied starting from this side. Therefore, participants could not simply copy the procedure they had learned, and performance on this second test task was lower than on the first (Van Gog, 2011). However, an even stronger transfer test would be to add an additional component on each side, in which case the solution procedure still relies on the same mechanism, but consists of 24 steps and can only be successfully performed when the mechanism is understood.

A closer look at the task suggests that the errors made during problem solving (both during practice and on the test) seem to result from a failure to carefully consider all possible moves and their consequences. This would explain why test performance strongly improved when participants had the chance to study a video-based modeling example twice, in which the procedure was demonstrated (Van Gog, 2011) or demonstrated and explained (Van Gog et al., 2009).

Based on anecdotal evidence of some participants' responses to the task in prior studies, we began to wonder whether this failure to consider all possible moves could be related to the fact that the objects had a bodily shape, that is, were frogs that had a face and "were headed in a direction". That characteristic seemed to evoke anthropomorphic thinking in some participants (i.e., assigning intentions or goals to the frogs; for a discussion of anthropomorphic thinking, see Epley, Waytz, \& Cacioppo, 2007). Assigning intentions to the objects that need to be moved, might aggravate the tendency to rapidly execute steps that seem to physically reduce the distance of a frog to its goal, without considering the other possible moves (cf. Sweller \& Levine's, 1982, maze learning experiment, in which people who had their left hand on the finish and had to move their right index finger through the maze to get to the finish, continuously made incorrect moves to the left, where they knew their goal was).

If this indeed plays a role, then using the same task but with non-embodied objects should lead to better learning outcomes. To investigate this question, we re-created the
computer-based problem-solving task with real objects, that were either "embodied" (i.e., animals) or "non-embodied" (i.e., discs).

\section*{Hypotheses}

Based on prior research on example-based learning in general (for reviews, Atkinson et al., 2000; Renkl, 2011; Sweller et al., 1998; Van Gog \& Rummel, 2010), and on the computer-based version of this task in particular (Van Gog, 2011; Van Gog et al., 2009), we first of all expected that studying digital video-based modeling examples would also be more effective (result in higher learning outcomes) as well as more efficient (higher learning outcomes attained with less investment of mental effort) than problem-solving practice for this real object version of the task. The open question of whether performance on a transfer task would also be enhanced when an additional object is added on each side, is explored.

Secondly, it was hypothesized that practicing the problem-solving task with "embodied" objects (i.e. animals) would lead to lower performance than doing so with "nonembodied" objects (i.e., discs). The open question of whether this would only be the case for the problem-solving practice conditions (cf. Kotovsky et al., 1985), or also for the examples conditions, was explored. On the one hand, when studying examples and subsequently taking a test with embodied objects, this might not have negative effects on test performance because participants had a chance to learn the correct procedure from the examples. On the other hand, however, participants might still be affected by the objects' embodiment (e.g., fall prey to anthropomorphic thinking) once they start performing the test task themselves.

\section*{Method}

\section*{Participants}

Participants were 80 adults ( \(\mathrm{M}=22.8, \mathrm{SD}=2.61\); 43 women) recruited from the general population. A \(2 \times 2\) design with factors Training (Practice vs. Example) and Embodiment (Present vs. Absent) was used. Participants were assigned to one of the four conditions matched for gender, but otherwise randomly: (1) Embodiment Present Practice ( \(n=20\) ), (2) Embodiment Absent - Practice ( \(n=\) 20), (3) Embodiment Present - Example ( \(n=21\) ), and (4) Embodiment Absent - Example ( \(n=19\) ).

\section*{Materials}

Demographic questionnaire A demographic questionnaire asked for age, gender, level of education, and it also included a check on whether participants were familiar with the learning task (by showing them a picture of the initial state of the problem in the computer-based version discussed above).
Learning task The learning task was based on the computer-based problem-solving task mentioned above (see Van Gog, 2011; Van Gog et al., 2009). In this computer-
based task, three green frogs are sitting on stones on one side of the river, three brown frogs on the other side, with one empty stone in the middle. The goal is to have them switch sides, but frogs can only jump one place ahead if that is free, or jump over one other frog to a free place. They cannot go back or jump over two other frogs. The goal can be reached in 15 steps. In this study, a version of the task was created using real objects (see Figure 1), and the objects consisted either of plastic yellow fishes and green seals (Embodiment Present) or yellow and green discs (Embodiment Absent).
In the practice conditions, participants were given two practice opportunities in which they attempted to solve the problem for 1 min .; if they got stuck, they were allowed to start again. In the examples conditions, participants observed a digital video-based modeling example ( 1 min . duration) twice, in which a human model demonstrated the correct solution procedure with either the animal objects or the discs. The model did not provide any verbal explanations and only the model's hand moving the objects was visible in the video. The digital video was presented on a laptop with a screen resolution of \(1280 \times 720\) pixels at a size of \(28.5 \times 18 \mathrm{~cm}\).

Figure 1: Initial state of the problem in the Embodiment Present (top) and Absent (bottom) conditions

Test tasks The retention test task was identical to the learning task. The transfer test task consisted of the same problem, but with four objects on either side. This task could be solved in 24 steps.
Mental effort After each practice task, each example, and each test task, participants rated how much effort they invested in problem solving or example study on Paas' (1992) 9-point rating scale ranging from (1) very, very low effort, to (9) very, very high effort. This subjective rating scale is widely used in educational research (for reviews, see Paas, Tuovinen, Tabbers, \& Van Gerven, 2003; Van Gog \& Paas, 2008).

\section*{Procedure}

The study was conducted in individual sessions of approximately 10 min . After filling out the demographic questionnaire, the learning phase started. Participants were first instructed about the rules of the task (i.e., an object can only move one space ahead to a free space or over one other object to a free space, moving back or moving over two other objects is not allowed). Depending on their assigned
condition, they subsequently received the instruction to either practice for 1 min ., during which they were allowed to start again if they got stuck, or to study the example presented in the video. After practicing or example study, they rated how much effort they invested in problem solving or example study. Then this sequence was repeated a second time. Depending on their assigned condition, participants practiced with either animals or discs or observed a modeling example with either animals or discs. Immediately after the learning phase, the test phase started, during which all participants were required to solve the problem themselves, first the retention task, which was the exact same problem they had encountered in the learning phase, with three objects on both sides, then the transfer task with four objects on both sides. Depending on their assigned condition, participants performed the test tasks with either animals (when they had practiced/studied the task with animals) or discs (when they had practiced/studied the task with discs). Immediately after each task, they indicated how much effort they invested in attempting to solve the problem. In the test phase, participants' performance was recorded on digital video (zooming in on their hands and the task), to be able to score their performance afterwards.

\section*{Data analysis}

Using the video recordings, each participant's performance on the test tasks was determined by scoring the number of steps correctly executed. For the first test task, this resulted in a maximum score of 15 , for the transfer task, in a maximum score of 24 . For two participants, performance scores were lost due to a technical recording error and two participants failed to fill out an effort rating. Because initial explorative analyses showed that the performance on the test tasks was not normally distributed, a log transformation was conducted (Field, 2009).

\section*{Results}

Data were analyzed using \(2 \times 2\) ANOVAs with betweensubjects factors Training (Practice vs. Example) and Embodiment (Present vs. Absent). For all analyses a significance level of .05 was used and Cohen's \(d\) is reported as a measure of effect size, with \(0.20,0.50\), and 0.80 constituting small, medium, and large effects, respectively.

\section*{Effort Invested in the Learning Phase}

There was a significant main effect of Training on mental effort invested in the learning phase \(F(1,74)=102.09, M S E\) \(=3.08, p<.001\), Cohen's \(d=2.31\), with participants who studied the video-based modeling examples reporting much lower effort ( \(M=2.94, S D=1.63\) ) than participants who practiced problem solving ( \(M=7.00, S D=1.87\) ). There was no significant main effect of Embodiment, nor a significant interaction effect.

\section*{Retention Test Task}

There was a significant main effect of Training, \(F(1,74)=\) \(15.09, M S E=.07, p<.001\), Cohen's \(d=0.87\), which indicated that participants in the Example conditions outperformed ( \(M=0.79, S D=0.30\); non-transformed: \(M=\) \(6.74, S D=5.44\) ) participants in the practice conditions ( \(M=\) \(0.56, S D=0.22\); non-transformed: \(M=3.13, S D=2.49\) ). Although there was a trend towards an effect of Embodiment, with participants in the Embodiment Absent conditions performing better ( \(M=0.72, S D=0.29\); nontransformed: \(M=5.51, S D=4.78\) ) than participants in the Embodiment Present conditions ( \(M=0.63, S D=0.28\); nontransformed: \(M=4.36, S D=4.36\) ) this did not reach significance, \(F(1,74)=2.35, M S E=.068, p=0.129\), Cohen's \(d=0.30\). There was no significant interaction.
A \(2 \times 2\) ANOVA on invested mental effort on the retention test task, showed a significant main effect of Training, \(F(1,76)=9.63, M S E=5.12, p<.01\), Cohen's \(d=\) 0.70 , indicating that participants who had studied examples invested less mental effort in solving the retention test problem ( \(M=5.22, S D=2.60\) ) than participants who had practiced ( \(M=6.82, S D=1.91\) ). There was no significant main effect of Embodiment \(F(1,76)<1\), nor an interaction effect, \(F(1,76)=2.58, M S E=5.12, p=.113\) and indicated that in the Example conditions, the Embodiment Absent condition tended to invest more effort than the Embodiment Present condition on the retention test task, whereas in the Practice conditions, this was the other way around.

\section*{Transfer Test Task}

There were no significant main or interaction effects on performance and invested mental effort on the transfer test task (all \(F<1\) ).

\section*{Discussion}

In line with our first hypothesis, we found a large ( \(d=\) 0.87 ) beneficial effect of example study on test performance. Moreover, the examples conditions reached this higher test performance with less investment of effort during the learning phase (indicating a more efficient learning process), as well as less investment of effort during the retention test (indicating more efficient learning outcomes; Van Gog \& Paas, 2008). This finding is in line with prior studies in other domains that have shown higher learning outcomes with less investment of mental effort during acquisition (e.g., Paas \& Van Merriënboer, 1994; Van Gog et al., 2006) as well as during the test (e.g., Paas, 1992; Paas \& Van Merriënboer, 1994). This effect was limited to the retention test task, though. There were no effects on transfer, which suggests that students in the Example study conditions remembered the procedure (they performed better on the retention test), but did not really understand it sufficiently to be able to adapt it to a new problem situation with an additional object on each side. It would therefore be interesting to investigate whether including verbal explanations by the model, emphasizing the possible options at each step and indicating why the
eventually chosen step is correct and the others are not, would enhance understanding of the solution procedure and thereby, transfer performance.
Regarding our second hypothesis about effects of Embodiment on test performance, we saw a trend in the expected direction, with participants in the Embodiment Absent conditions performing better than participants in the Embodiment present conditions: practicing or studying examples with animal-like plastic objects led to less steps correctly completed on the retention test than practicing or studying examples with wooden discs. However, this difference failed to reach statistical significance ( \(p=.129 ; d\) \(=0.30\) ), possibly due to the relatively low number of participants. Therefore, we will replicate this study with a larger number of participants.

\section*{Second Study}

We are currently conducting a replication study with a larger number of participants to achieve more statistical power. This study will also include an additional condition in which we will control for the effect of direction. That is, because the animals were embodied, they were also headed in a direction. The discs did not imply any direction. So assuming we would find a significant effect of Embodiment when we have more statistical power, this additional condition will allow us to answer the question of whether this is really due to anthropomorphism (assigning goals and intentions to objects that have a bodily shape) or simply a consequence of implied direction. If so, that would still be an interesting finding in terms of understanding factors that might affect problem solving and the acquisition of problem-solving skills through example study. The results of this second study are expected to be available well before the conference.

\begin{abstract}
An experiment examined the effect of 'pure' recognition in the absence of concomitant evaluation - on inferences. In the first stage of the experiment, participants indicated whether they recognized a number of Italian and US cities. In the second stage, they decided which of two cities had the larger population. Crucially, names of the cities were not available in the second stage, but participants could find out whether they had recognized them (yes/no) in the first stage of the experiment (i.e., pure recognition). Additional predictive cues (e.g., presence/absence of a university) were also available. Participants used the recognition cue about \(50 \%\) of the time, rarely examined it first, and used it differently as a function of whether recognition information was binary or continuous. Furthermore, participants used the recognition cue more often if they recognized more items, irrespective of its predictive validity. Implications for theoretical frameworks that view inference as driven by discrete heuristics or processes of evidenceaccumulation are briefly discussed.
\end{abstract}

Keywords: Inference, heuristics, recognition, decision making.

Humans are decision makers. Throughout our lifes, we are constantly confronted with situations that force us to make a choice. Whether it is a preference decision, "Do I take the car or do I walk to work?", or a knowledge decision, "Which soccer team scored more goals last season, Borussia Dortmund or Bayern München?", we are evaluating alternatives.

Gigerenzer and colleagues have proposed a number of relatively simple heuristics that could help us making such decisions. In this paper, we will focus on one of the most prominent examples: the recognition heuristic (Goldstein \& Gigerenzer, 1999, 2002; Gigerenzer \& Goldstein, 2011).

In the original conceptualisation of the recognition heuristic, called take-the-best (TTB; Gigerenzer \& Goldstein, 1996), the first step in deciding which of two response options to choose was to use recognition. So, if a decision maker knows the Bayern München soccer team, but has never heard of Borussia Dortmund, then respond that Bayern München scored more goals last season. When both teams are recognized (thus disabling the use of recognition) the heuristic consults relevant information, or cues, in memory that are indicative of the number of goals scored (e.g., "What was the team's final standing in the national competition?"). These cues should be consulted in descending order of informativeness, starting with the cue that will be most indicative of the
criterion of interest (i.e., number of goals scored). Cue search stops when the decision maker examines a cue that points in one direction (i.e., Borussia Dortmund was first last season, Bayern München was second, so respond Borussia Dortmund).

This proposal for a simple mechanism based on recognition sparked a wide ranging debate about the plausibility, empirical validity, and generality of the recognition heuristic (for recent examples see the papers in the three special issues of the Journal of Judgment and Decision Making - Vol 6 (1) \& (5), 2011; Vol 5 (4), 2010). Much of the debate revolves around some key assumptions about the nature and operation of recognition in inferential judgment.

In the paper that introduced the recognition heuristic as a stand-alone 'tool' (i.e. not just the first step in Take-theBest), Goldstein and Gigerenzer (2002) assume, firstly, that recognition is binary. That is, we either recognize something, or we do not, and there is no room within the heuristic for the distinction between something being vaguely familiar and something being very familiar. Secondly, recognition is assumed to be noncompensatory. That is, when we recognize one option, but do not recognize the other, then we should always go with the recognized option, regardless of any additional information. Lastly, Goldstein and Gigerenzer (2002) make a distinction between familiarity and recognition: "The term familiarity is typically used in the literature to denote the degree of knowledge (or amount of experience) a person has of a task or object. The recognition heuristic, in contrast, treats recognition as a binary, all-or-none distinction; further knowledge is irrelevant." (pp. 77). Thus, according to a strict interpretation of the ( 2002 version of the) recognition heuristic, when deciding whether an Italian city you know has a larger population than an Italian city you do not know, it makes no difference whether the city you do know is Rome or Pisa.

All three of these assumptions have been roundly challenged in the literature on both empirical (e.g., Pohl, 2006; Newell \& Shanks, 2004; Newell \& Fernandez, 2006) and theoretical grounds (e.g., Hilbig, 2010; Newell, 2011). Responding to some of these critiques, Gigerenzer and Goldstein (2011) recast the adaptive use of the recognition heuristic as involving a two-step process: first recognition ("Do I
recognize one object but not the other?") and second, evaluation ("If so, is it reasonable to rely on the recognition heuristic in this situation?"). A view consistent with that is outlined in Newell and Shanks (2004).

While such a conceptualisation is undoubtedly more plausible, it makes the claims about the way recognition aids inference that much more difficult to define and test empirically. Perhaps the trickiest aspect of the problem is that recognition almost always entails further information about the recognized object. If you have heard of Pisa, it is highly likely that you know something else about it (e.g., that it has a leaning tower) which may or may not be relevant to the criterion of interest, in this case population (cf. Oppenheimer, 2003). In other words, it is difficult to isolate the influence of 'pure' recognition - how useful is just knowing that I recognize an object for drawing an inference?

Isolating this 'pure' recognition - recognition without concomitant evaluation - is important because it can shed new light on the distinction between recognition and familiarity, and the extent to which people will rely on recognition even when they cannot directly evaluate their reason(s) for recognising an object. In order to isolate pure recognition we introduced a novel element to the standard task in which participants decide which of two cities has the larger population (e.g., Goldstein \& Gigerenzer, 2002). In our task we created the distinction between recognition and familiarity alluded to by Goldstein and Gigerenzer (2002) by first asking participants to provide recognition data about a pool of response options (city names). We then presented participants with a series of forced choice decisions between two cities about which different pieces of information could be obtained (e.g., presence/absence of a university), but for which the city names were unavailable. Although participants could not discover the names they could - crucially - discover whether or not they had recognized one, both or neither of the cities when they had been presented in the first stage of the experiment. This information was available in the same manner as all the other cues - that is via clicking on relevant buttons ("Did you recognize this city when you were shown its name?") to reveal a yes/no answer (see Figure 1).

A key question here is: How often and when do participants examine the 'pure' recognition cue when drawing an inference? Will recognition remain a primary driver of decisions (cf., Pachur \& Hertwig, 2006) even in the absence of evaluation? In a sense, the use of recognition in this task allows us to gain insight into participants' meta-cognitions about the usefulness of recognition in different environments. For example, do decision makers use recognition more often as they recognize more items in a pool of response categories, irrespective of the informativeness of recognition? To facilitate examining these questions we presented each participant with two decision environments in which we assumed he or she would know a different proportion of the items, thereby allowing us to directly compare response strategies: a US cities environment and an Italian cities environment.

An additional feature of the experiment was that we offered participants (between-subjects) the opportunity to use recognition as a binary (yes/no) or a continuous (slider from 0 to 100) cue. If it is true that recognition operates in a binary fashion, participants should only use the endpoints of a scale when asked to give a continuous rating of their recognition. Similarly, the usage of the recognition cue should not differ between a condition in which it was indicated as binary and a condition in which it was indicated as continuous.

In the next section, we will describe the experiment and each of its conditions in greater detail. Then, we will present some results and conclude on both the tenability of the recognition heuristic, and the use of recognition as an aid to inference more generally.

\section*{Method}

\section*{Participants}

All participants were first year undergraduate students at the University of New South Wales who participated in return for course credit. A total of 100 participants ( 62 females, 38 males), aged 17 to 39 (mean \(=19.5, \mathrm{SD}=2.9\) ) took part in the experiment. They were randomly divided between four between-subject conditions ( \(n=25\) each).

\section*{Material}

The tasks we used for this experiment are based on the German cities task (Gigerenzer \& Goldstein, 1996) in which over the course of consecutive trials, a participant has to decide which of two cities has the larger population. This decision can be made by extracting information on different cues in any order. An example of such a cue could be "Is this city the national capital?". Rather than using German cities, we administered an Italian cities environment and a US cities environment to each participant (see Lee \& Zhang, 2012), expecting to see higher recognition percentages for the US cities than for the Italian cities.

Table 1: The nine cues as used in the Italian and US cities environments. Env = Environment, Val \(=\) Cue Validity, Dis \(=\) Cue Discriminability.
\begin{tabular}{llllll}
\hline Env & Nr. & Cue & Val & Dis \\
\hline Italy & 1 & Is the city the national capital? & 1 & 0.04 \\
& 2 & Dos the city have a railway station? & 0.92 & 0.36 \\
& 3 & Is the city a regional capital? & 0.84 & 0.38 \\
& 4 & Does the city have a football team in the Serie A league? & 0.81 & 0.36 \\
& 5 & Does the city have a university? & 0.80 & 0.55 \\
& 6 & Does the city have an airport? & 0.76 & 0.49 \\
& 7 & Does the city have a football team in the Serie B league? & 0.70 & 0.30 \\
& 8 & Is the city in the Po Valley? & 0.60 & 0.52 \\
& 9 & Did you recognize this city when you were shown its name? & varies & varies \\
\hline US & 1 & Does the city have an airport? & 0.78 & 0.51 \\
& 2 & Dos the city have a sport team? & 0.74 & 0.53 \\
& 3 & Does the city have a metro? & 0.74 & 0.23 \\
& 4 & Does the city have an exposition site? & 0.73 & 0.26 \\
& 5 & Is the city the national capital? & 0.67 & 0.03 \\
& 6 & Does the city have a railway station? & 0.66 & 0.35 \\
& 7 & Is the city a state capital? \\
& 8 & Did you recognize this city when you were shown its name? & 0.59 & 0.34 \\
& & & & \\
\hline
\end{tabular}

In the first stage of the experiment, participants indicate
whether or not they recognize each of the cities used in the subsequent stage of the experiment. In a between participants manipulation, recognition was either measured as a binary or as a continuous variable. Taking the Italian environment as an example, in the binary condition participants were asked "Do you recognize this city in Italy" for a total of 66 Italian cities with response options "yes" or "no". In the continuous condition, participants were asked "How well do you recognize this city in Italy". Answers were indicated on a slider going from 0 ("I am certain that I do not recognize this city") through 50 ("I am not sure whether or not I recognize this city") to 100 ("I am certain that I recognize this city").

In the second stage of the experiment, participants were asked "Which Italian city has a higher population?". The participant could choose between A and B, both of which represented Italian cities the participant had provided recognition data on in the first stage of the experiment. As noted in the introduction, our key focus is on investigating pure recognition without associated knowledge of the response options and thus we effectively disabled internal memory-based search by concealing the names of each city. In order to aid the decision making process, participants were presented with a number of cues on screen for which they can retrieve information. \({ }^{1}\) Crucially, one of the cues the participant could access was the recognition cue of which data was provided in the first stage of the experiment. A screenshot of the second stage of the experiment is provided in Figure 1.

The final manipulation in our experiment consisted of the availability of information on two key aspects of each cue. These are each cues' validity and discriminability. The validity of a cue quantifies the number of times a cue points you to the right answer as a ratio of the times it discriminates between the two response options. For instance, in the Italian cities Environment, the cue "Is the city the national capital?" has a validity of 1 , because whenever one alternative scores positive on this cue, that will be because that alternative is the city Rome and Rome is the largest Italian city. The discriminability of a cue quantifies the number of times a cue discriminates between two response alternatives as a ratio of all possible cue comparisons for each question. The national capital cues does not discriminate very often and therefore has a low discriminability, because this cue will only discriminate when one of the two response alternatives is Rome. In the "+info" condition, cue validity and discriminability was shown on screen, in the "-info" condition, this information was not available to the participant. Note that for the continuous recognition cue, the cue discriminates if both scores are different from eachother. Thus, if one cue scores 0 , it makes no difference whether the other scores 1 or 100. This manipulation was included to examine whether provision of information about the usefulness of recognition, in particular, affected its use. The validity and discriminabilty information can be seen as an aid to answering the meta-cognitive ques-

\footnotetext{
\({ }^{1}\) This is different from the original German cities task, in which cues had to be retrieved from memory and city names were revealed.
}
tion facing the participant - i.e., how useful is knowing that I recognize an object for drawing an inference?

All cues and their validities and discriminabilities for both environments are shown in Table 1. These cue validity and cue discriminability rates were calculated for the subset of 100 comparisons the participants had to make in the task, rather than for the whole set of possible comparisons. The reason for this was to ensure that participants in the "+info" condition could relate the presented cue validity and cue discriminability rates as close as possible to their actual experience when performing the task. The presented information could be used by participants to base their search order on cue validity, cue discriminability or a combination of the two. After each trial, participants received feedback with respect to the accuracy of their response. The experiment was selfpaced.

Figure 1: Screenshot of a trial of the binary version of the US cities task with cue information present ("+info"). See text for details.

Cues were presented in a circular array on the screen in random order. Participants examined cues by clicking on them. The order in which buttons were clicked was selfcontrolled. Deciding to stop examining additional cues was self-controlled, but conditional on having encountered at least one discriminating cue to dissuade guessing.

\section*{Procedure}

Participants completed the Italian version and the US version of the task in random order. Participants were given instructions that they would have to indicate whether or not they recognized a number of cities, after which they performed stage 1 of the experiment, the recognition phase. Participants were subsequently instructed that they repeatedly had to make a choice between pairs of two alternatives. The concepts cue validity and cue discriminability were explained. Participants then performed the second stage of the experiment. After completing the experiment for the first environment, the second environment was administered.

\section*{Design}

Our experiment consists of eight conditions. The cities environment was a within-subject manipulation with two levels: Italian and US. The recognition mode was a between-subject manipulation with two levels: binary and continuous. Cue information was a between-subject manipulation with two levels: +info (info present on screen) and -info (no info on screen).

\section*{Results}

For all statistical analyses, we report not only conventional \(p-\) values but also Bayes factors (e.g., Jeffreys, 1961). In contrast to \(p\)-values, Bayes factors allow researchers to quantify evidence in favor of the null hypothesis vis-a-vis the alternative hypothesis. For instance, when the Bayes factor \(B F_{01}=10\) the observed data are 10 times more likely to have occurred under \(H_{0}\) than under \(H_{1}\). When \(B F_{01}=1 / 5=0.20\) the observed data are 5 times more likely to have occurred under \(H_{1}\) than under \(H_{0}\). In the following, Bayes factors for analysis of variance are based on the BIC approximation (e.g., Wagenmakers, 2007; Masson, 2011), and Bayes factors for \(t\)-tests are based on the default Bayesian \(t\)-test proposed by Rouder, Speckman, Sun, Morey, and Iverson (2009).

We ran a \(2 \times 2 \times 2\) ANOVA with mode and cue information as between-subject independent variables and environment as a within-subject independent variable. Response accuracy was higher in the Italian environment (73.9\%) than in the US environment ( \(69.2 \% ; F(1,96)=78.5, p<.05, B F_{01}=1.1\). \(10^{-12}\) ). The following subsections report on the recognition proportion, the recognition validity and discriminabillity, and the recognition usage respectively.

\section*{Recognition Proportion}

Figure 2 shows the proportion of cities that were recognized for each environment. As expected, recognition was higher for the US cities environment than for the Italian cities environment, as evidenced by a main effect for environment \(\left(F(1,96)=298.9, p<.05, B F_{01}=2.0 \cdot 10^{-30}\right.\); cf., Goldstein \& Gigerenzer, 2002). Continuous recognition led to some parts of the scale being used besides the two extremes, suggesting that participants did not treat recognition as purely binary. However, the extremes were still the most popular.

\section*{Recognition Validity and Discriminability}

Recall that the validity and discriminability of the recognition cue was calculated for each participant separately based on their answers in stage 1 of the experiment. Based on the recognition proportion for each environment, we expected to find that recognition was more valid, but less discriminating, for the Italian environment than for the US environment (cf., Goldstein \& Gigerenzer, 2002). We were interested to see how cue mode would affect cue validity and discriminability.

Figure 3 shows recognition validity and discriminability for both environments. For recognition validity, there is a main effect for environment \(\left(F(1,96)=4.9, p<.05, B F_{01}=\right.\) 0.82 ; note that the Bayesian test indicates the evidence is

Figure 2: Proportion of cities recognized for the binary environment (top-left panel) and the continuous environment (other panels).
ambiguous); recognition validity may be higher in the Italian environment than in the US environment. There is also a tentative main effect for mode \((F(1,96)=4.6, p<.05\), \(B F_{01}=0.99\); note that the Bayesian test indicates the evidence is ambiguous); validity for binary cues may be higher than for continuous cues.

For recognition discriminability, there is a main effect for environment \(\left(F(1,96)=57.8, p<.05, B F_{01}=5.8 \cdot 10^{-10}\right)\); recognition discriminability is lower in the Italian environment than in the US environment. There is also a main effect for mode \(\left(F(1,96)=70.4, p<.05, B F_{01}=1.1 \cdot 10^{-11}\right)\); continuous cues discriminate better than binary cues.

Figure 3: Recognition validity (top) and discriminability (bottom) for the Italian (left) and US (right) environments.

We have established there are differences in the validity and discriminability of the recognition cue that are a direct consequence of the cue being binary or continuous: recognition discriminates between response alternatives more often, but the extra information is, tentatively, less valid. Do decision makers use the recognition cue differently depending on the mode of the cue?

\section*{Recognition Usage}

The top panels of Figure 4 show the proportion of trials the recognition cue was used for each environment. On average, participants did not use the recognition cue on all trials. On an individual basis, \(9 \%\) of the participants used the recognition cue on all trials in the Italian environment and \(8 \%\) of the participants used the recognition cue on all trials in the US environment.

For recognition use, there was a main effect of mode \(\left(F(1,96)=9.4, p<.05, B F_{01}=0.09\right)\); decision makers use continuous recognition more than binary recognition. There was also a main effect of environment \((F(1,96)=22.8\), \(p<.05, B F_{01}=2.4 \cdot 10^{-4}\) ), decision makers use the recognition cue more in the US environment than in the Italian environment. Interestingly, there was a mode by environment interaction \(\left(F(1,96)=4.0, B F_{01}=1.33\right)\). In the Italian environment, recognition is used more often if it is continuous than if it is binary \(\left(t(98)=-3.65, p<.05, B F_{01}=0.02\right)\). In the US environment, recognition usage does not depend on the mode of the cue \(\left(t(98)=-1.52, p>.05, B F_{01}=2.21\right.\); note that the Bayesian test indicates the evidence is somewhat ambiguous). It is likely then, that the benefits of continuous recognition are highest when only a small portion of items are recognized. Finally, there is little evidence for a main effect of cue information \(\left(F(1,96)=3.3, p>.05, B F_{01}=1.88\right.\); but note that the Bayesian test indicates the evidence is somewhat ambiguous).

The bottom panels of Figure 4 show the average position in which the recognition cue was searched, given that it was examined for each environment. On average, participants did not search the recognition cue first. On an individual basis, for both environments, the lowest mean position of examination for the recognition cue was exactly 2 , suggesting that not a single individual used the recognition heuristic in its most stringent form.

For recognition position, there was a main effect of mode \(\left(F(1,95)=4.5, p<.05, B F_{01}=0.08\right)^{2}\); recognition was used earlier when it was binary than when it was continuous. There was no main effect of environment \((F(1,94)=2.1, p>.05\), \(B F_{01}=3.27\) )

\section*{Conclusion}

The goal of our experiment was to isolate 'pure' recognition and to examine participants' use of recognition information in the absence of concomitant evaluation. We argued that this would give us insight into participants' meta-cognition about the usefulness of recognition in different environments. What have we learned?

First we note that the accuracy of inferences about population size was higher for an environment about which participants, initially, knew less (Italian cities) than for one about

\footnotetext{
\({ }^{2}\) Two participants never used the recognition cue and as such had no recognition position data. Recognition position was divided by the total number of cues for each environment to make both environments compatible.
}

Figure 4: Proportion of trials the recognition cue was used (top) and position in search order (bottom) for the Italian (left) and US (right) environments.
which they knew more (US cities). But was the difference driven by adaptive use of recognition information? Under a strict interpretation, even in our novel task, recognition should be consulted on every trial - unless a participant has reason to believe that it will never discriminate (e.g., if they know they recognized either all or none of the cities in the environment). The results showed that was clearly not the case, with only a small proportion of the participants using the recognition cue on all trials. Moreover, even the participants that did examine recognition on every trial did not exclusively examine this cue first, challenging the idea that recognition information is somehow privileged in inference tasks (e.g., Pachur \& Hertwig, 2006).

Additionally, we examined whether we could increase usage of recognition by measuring recognition on a continuous rather than a binary scale. We concluded that for the Italian environment where only a small proportion of the items were recognized, measuring recognition on a continuous scale led to recognition being used more often, despite the fact that recognition was less valid for the continuous scale than for the binary scale. No such effect was found for the US environment, in which on average about half of the cities were recognized. Though it is possible that the intermediate datapoints on the continuous recognition scale simply reflect perceived task demands by the participants, this alternative explanation does not seem to be in line with the fact that participants subsequently use continuous recognition more.

Our final question was whether participants would use recognition more often when their recognition cue was more valid. Surprisingly, we concluded the opposite: recognition was used more frequently in the US environment than in the Italian environment, despite the fact that recognition was more valid, on average, in the Italian environment. This finding suggests that meta-cognition about the usefulness of recognition is not particularly fine-tuned: adaptive use of recognition would predict greater reliance in environments where it is more useful (Gigerenzer \& Goldstein, 2011).

Thus we conclude that 'pure' recognition can be compensated: knowing that we recognized one object and not another, but not knowing why is not enough for most participants to make a decision. Furthermore, it is not the first piece of information participants search for. In addition, our results show that recognition is more than a binary yes-or-no phenomenon. Allowing participants to indicate their recognition on a continuous scale led to an average increase in usage.

These results provide a novel and intriguing set of empirical regularities concerning the use of pure recognition information in a multi-attribute decision task. The next stage of this project will draw on the considerable advances that have been made in developing computational models of recognition-based judgments (e.g., Marewski \& Mehlhorn, 2011; Marewski \& Schooler, 2011) in an attempt to describe these data more fully. Our starting point will be to compare models that assume recognition information is used as evidence that can be accumulated much like any other cue to aid inference (e.g., van Ravenzwaaij, Moore, Lee, \& Newell, 2013) with those that afford recognition an elevated status.

\title{
The Path Less Taken: When Working Memory Capacity Constrains Insight
}

\begin{abstract}
Higher working memory capacity (WMC) supports performance on a wide variety of complex cognitive and academic activities (Barret, Tugade, \& Engle, 2004). However, a growing body of research demonstrates that higher WMC can have disadvantages-leading individuals to employ complex performance strategies that are less optimal for a given task (cf. DeCaro \& Beilock, 2010). We examine this possibility in the domain of insight problem solving. Participants \((N=84)\) completed Matchstick Arithmetic problems thought to either rely on controlled search and retrieval processes (non-insight problems) or diverging from known mathematical constraints (insight problems). Consistent with a large body of research on WMC, higher WMC was associated with higher non-insight problem accuracy. However, higher WMC led to significantly worse insight problem-solving. Although higher WMC supports complex problem-solving strategies, relying on these may lead individuals to miss associatively-driven solutions that are important for insight.
\end{abstract}

Keywords: Working memory capacity; attention; insight; problem solving.

\section*{Introduction}

A great deal of work has demonstrated that higher working memory capacity (WMC) is advantageous to an array of complex cognitive and academic activities, such as reasoning, comprehension, and problem-solving (see Barrett, Tugade, \& Engle, 2004, for a review). Indeed, WMC-the ability to hold and manipulate information in a temporary active state-has been said to be "so central to human cognition that it is hard to find activities where it is not involved" (Ericsson \& Delaney, 1999, p. 259). However, a growing body of research demonstrates that higher WMC can have disadvantages-leading individuals to employ complex performance strategies that are less optimal for a given task (see DeCaro \& Beilock, 2010, for a review). In the current work, we examine the possibility that higher WMC can hinder creative thinking in the form of insight problem-solving. Specifically, we examine the hypothesis that those who have the ability to implement complex problem-solving strategies may be more likely to miss associatively-driven solutions that are important for insight.

\section*{Working Memory Capacity}

WMC supports the ability to suppress distractors and guide attention toward relevant information in goal-directed tasks (McCabe, Roediger, McDaniel, Balota, \& Hambrick, 2010). The predictive power of WMC as a construct stems from this domain-general capacity for attentional control, and individual differences in WMC emerge primarily when that capacity is challenged (Engle, 2002). So-called "executive attention" is accomplished via controlled processing, which is important in novel or interference-rich situations and when goals come in conflict with prepotent responses (Unsworth \& Engle, 2007).

A large body of research has been built around the wellestablished differences in performance outcomes of individuals who fall toward either extreme of the WMC scale. Kane and Engle (2000) found that individuals with lower WMC demonstrated a greater vulnerability to proactive interference, and were more likely to lose track of task goals than their higher WMC counterparts (Unsworth \& Engle, 2007). Additionally, studies have found that individuals with lower WMC display higher rates of attentional capture (Conway, Cowan, \& Bunting, 2001; Kane, Bleckley, Conway, \& Engle, 2001), and have greater difficulty discriminating relevant and irrelevant information (Unsworth \& Engle, 2007).

It is no surprise that the ability of higher WMC individuals to control attention leads to greater ability to implement more difficult, multi-step problem-solving strategies (Engle, 2002). Indeed, the ability to execute complex strategies may lead individuals to select strategies in line with their ability-even if the task does not call for a controlled processing approach. Beilock and DeCaro (2007) explored this idea by examining the strategy selection of higher and lower WMC individuals completing Luchins’ (1946) water jug task. This task requires individuals to use three depicted water jugs with varying capacities (e.g., Jug A=23, Jug B=96, and Jug C=3) to fill a "goal" jug with a certain capacity (e.g., 67). For example, one might fill Jug \(B\), then pour that amount into Jug \(A\), and then pour the remaining amount into Jug C twice (i.e., B-A-2C). Participants were explicitly instructed to mentally derive the answers (i.e., without the use of paper), and use the simplest strategy possible. The first few problems were solve-able using a single complex formula (B-A-2C). The final few problems could also be solved using this formula (e.g., Jug

A=34, Jug B=72, Jug C=4; Goal=30). However, a much simpler strategy could also be applied (e.g., A-C). On these final problems, individuals with higher WMC were more likely to employ the complex algorithmic strategy (i.e., B-A-2C), even though more efficient strategies were available. Individuals with lower WMC were instead quicker to abandon an algorithmic approach and adopt a lessdemanding shortcut strategy relying on a more diffuse focus of attention.

These findings demonstrate that individuals higher in WMC may tend to use more complex strategies even when simpler ones are more efficient for a given task. Such overreliance on complex strategies can harm performance on some tasks (e.g., Gaissmaier, Schooler, \& Rieskamp, 2006; Wolford, Newman, Miller, \& Wig, 2004). For example, when associative responses guide well-learned skill execution, as with proceduralized tasks, controlled attention can disrupt performance (DeCaro, Thomas, \& Beilock, 2008). Additionally, various situational and taskspecific factors such as performance pressure (Beilock \& DeCaro, 2007; DeCaro, Thomas, Albert, \& Beilock, 2011) and expertise (Ericsson \& Delaney, 1999; Wiley, 1998) have been shown to moderate the role of controlled processing in learning and performance situations. A better understanding of when and why less WMC can prove advantageous is necessary to fully grasp the limitations of this pervasive system of cognitive constraint.

\section*{Insight Problem-Solving}

An area in which this question is being explored with great interest is research in insight problem-solving. The link between WMC and insight is not well understood, and there has been much debate over how best to facilitate the type of creative thinking insight problem-solving requires. One approach looks at the role of attention in problem-solving.

Insight problems require the use of strategies that diverge from obvious approaches, and are supported by a more diffuse focus of attention (Ansburg \& Hill, 2003). Noninsight problems, conversely, are best solved by following a progressive series of analytic steps, which requires controlled processing and relies on WMC. According to Representational Change Theory (Ohlsson, 1992), insight problems generally trigger an inadequate mental representation of the problem situation and solution criteria. Explicit search processes reinforce this faulty representation, and are unlikely to lead to the correct solution path. Instead, unsuccessful solution attempts often result in impasse, a state characterized by an apparent dearth of viable problem operators. It is only through a reappraisal of the initial representation that the correct solution path becomes accessible to the solver, often in a sudden and transparent manner (Kounios et al., 2006; Kounios \& Beeman, 2009; but see also Ash, Cushen, \& Wiley, 2009).

Much of the research on insight problem-solving has focused on questions surrounding the phenomenon of impasse, specifically why impasse occurs and how it is overcome (Ohlsson, 1992; Jones, 2003). One explanation is
that the problem solver unwittingly imposes unnecessary and/or misguided constraints on the problem space (Knoblich, Ohlsson, Haider, \& Rhenius, 1999). Additionally, preoccupation with more familiar problem operators (i.e., ones that have worked in the past) can make it difficult to access more novel operators that are critical for insight (Knoblich, Ohlsson, \& Raney, 2001). To the extent that one continues to implement strategies based on these constraints, one will fail to reach an insight solution (Wiley, 1998).

\section*{Working Memory and Insight Problem-Solving}

Because of their reliance on associatively-driven problemsolving solutions, insight problem-solving may be less benefited by the use of complex, algorithmic problemsolving strategies. Indeed, the use of such strategies can actually hinder the ability to derive a solution (Schooler, Ohlsson, \& Brooks, 1996; Wiley \& Jarosz, 2012). Studies have shown that WMC is related to the ability to solve novel problems and adapt to new situations (Barrett et al., 2004). However, if individuals higher in WMC have a tendency to rely on a more controlled attentional focus and inhibit peripheral information, they may also neglect potentially relevant information held outside of the perceived problem space (cf. Ansburg \& Hill, 2003). Thus, counter-intuitively, one might expect higher WMC individuals to perform worse on insight problem-solving tasks.

Support for this idea comes from a range of studies demonstrating that less focused (i.e., more diffuse) attention benefits insight problem-solving, whereas applying more controlled attention hinders the ability to derive insight solutions. For example, moderate alcohol intoxication both reduces WMC and improves insight problem-solving (Jarosz, Colflesh, \& Wiley, 2012); solving insight problems at one's non-optimal time of day improves performance (Wieth \& Zacks, 2011); and patients with frontal lobe impairment demonstrate better insight-problem accuracy (Reverberi, Toraldo, D'Agostini, \& Skrap, 2005). In contrast, verbalizing the problem steps during solving decreases insight performance, possibly by "overshadowing" insight processes (Schooler et al., 1996).

\section*{Current Study}

The current study examines the role of individual differences in WMC in solving both non-insight and insight problems, using the Matchstick Arithmetic task (Knoblich et al., 1999). Matchstick Arithmetic problems are false arithmetic statements written using matchsticks. The matchsticks represent Roman numerals, arithmetic operators, and equal signs. Each matchstick problem is composed of three roman numerals separated by two arithmetic signs, and has a unique solution consisting of a single move.

Participants were given three types of matchstick arithmetic problems, shown in Figure 1. Standard type (ST) matchstick problems are solved by moving a matchstick
representing a value of 1 from its position in a given roman numeral to a different position in the same or a different numeral on either side of the equal sign. The "I" matchstick is considered a "loose chunk" because it can be removed without invalidating the remaining figure and is easily appended to many others (Knoblich et al., 1999). The simple manipulation of loose chunks in ST problems is consistent with prior knowledge that reordering values in an equation leads to success (Öllinger, Jones, \& Knoblich, 2008). ST problems do not involve impasse (Knoblich et al., 2001), or restructuring (Öllinger et al., 2008), considered defining features of insight problems (Ohlsson, 1992). Consistent with Öllinger et al. (2008), we refer to ST problems as non-insight problems.

Constraint relaxation (CR) matchstick problems require transforming the initial false statement (e.g., III + III = III) into a correct, but tautological, statement by changing the plus sign into an equal sign (III = III = III). Solving CR problems is thought to be achieved by relaxing the constraint that correct arithmetic statements cannot contain more than one equal sign. These are commonly considered insight problems (Knoblich et al., 1999).

Finally, chunk decomposition (CD) problems require the solver to decompose a "tight chunk" in order to identify the decisive move. A tight chunk was defined as a single roman numerical figure composed of two matchsticks that together form a meaningful unit (e.g., V, X). For example, when participants see the incorrect arithmetic statement IV \(=\mathrm{III}+\) VI, they must transpose the V into an X by sliding one matchstick to find the solution IX = III + VI. CD problems are typically considered insight problems. However, findings from these problems do not always correspond to the findings from CR problems, making it difficult to determine if these problems are of the same nature (Knoblich et al., 1999; Knoblich et al., 2001; Öllinger et al., 2008). Thus, although we explored performance on CD problems, we were unable to derive clear hypotheses about the relationship between performance on these problems and WMC.

Figure 1. Example Matchstick Arithmetic Problems

We predicted that higher WMC would be associated with increased non-insight (ST) problem-solving accuracy. However, we predicted the opposite pattern for insight (CR) problems, that higher WMC would lead to lower insight problem-solving accuracy. Such findings would be consistent with a growing body of research demonstrating that more working memory capacity can lead to controlled problem-solving approaches that overshadow more optimal associatively-driven solution paths (Wiley \& Jarosz, 2012).

\section*{Method}

\section*{Participants}

Participants were 84 undergraduate students enrolled in psychology classes (63 female; age \(M=21, S D=4.6\); range 18-46 years). An additional 3 people were excluded from the study because they had been exposed to matchstick arithmetic problems before. One person was excluded for errors on more than 20 percent of the sentence task of the aRspan (Conway et al., 2005). Participants received course credit for participation.

\section*{Materials}

Problem-solving task Participants completed Matchstick Arithmetic problems (Knoblich et al., 1999), consisting of false arithmetic statements written with Roman numerals (I, II, III, etc.), arithmetic operators (,+- ), and equal signs depicted as matchsticks (see Figure 1). Problems were completed on paper. Participants were instructed to transform the initial false arithmetic statement into a true arithmetic statement while adhering to the following rules: (a) only one matchstick can be moved, (b) no matchstick can be discarded, (c) upright sticks and slanted sticks are not interchangeable, and (d) the result must be a correct arithmetic statement. Each matchstick problem was composed of three roman numerals separated by two arithmetic signs, and had a unique solution consisting of a single move. Participants were given eight matchstick arithmetic problems divided across two problem sets containing four problems each. Problems sets were divided into two categories (non-insight; insight) based on the move required for solution: the non-insight problem set consisted of four ST problems, and the insight problem set consisted of 2 CR problems and 2 CD problems. Problem sets were administered in counterbalanced order.

Working memory measure Working memory capacity was measured using the Automated Reading Span task (aRspan; Unsworth, Heitz, Schrock, \& Engle, 2005; Redick et al., 2012). In the aRspan, an attention-demanding processing task is interleaved between items presented for serial recall. Participants are shown a sentence and instructed to judge whether it makes sense or not; then they are shown a letter. After a sequence of sentence-letter strings ranging from 3-7 in length, participants are asked to recall the letters in order. All participants complete a total of 15 sequences of
sentence-letter strings, including 3 of each length, presented in random order. ARspan scores range from \(0-75\), with higher scores denoting greater levels of attentional control (Unsworth \& Engle, 2007). The task takes 15-20 minutes to complete.

\section*{Procedure}

After providing informed consent, participants completed the experimental tasks individually. Participants were first introduced to the problem-solving task, and were given a maximum of 10 minutes to solve each of two sets of problems (i.e., 20 minutes total). After completing both problem sets, participants were given a questionnaire asking about previous experience with the matchstick task. Participants then completed the aRspan on a computer. Finally, participants completed a demographic questionnaire and were debriefed.

\section*{Results}

Preliminary analyses revealed that accuracy on CD problems \((M=.69, S D=.41)\) was positively correlated with accuracy on both non-insight ( \(M=.68, S D=.30\) ), \(r=.32, p\) \(=.003\), and CR type insight problems ( \(M=.13, S D=.34\) ), \(r\) \(=.25, p=.021\). Because the CD problems did not appear discriminatory of either insight or non-insight problem types, they were excluded from further analyses. Accuracy on CR type insight problems was not correlated with accuracy on non-insight problems, \(r=.06, p=.566\), consistent with previous studies using matchstick arithmetic (Knoblich et al., 1999).

Figure 2. Non-insight and insight problem-solving accuracy as a function of working memory capacity. Low and high working memory points are plotted at \(\pm 1\) SD below and above the mean.

We evaluated whether the effect of insight and noninsight problem-solving accuracy depends on WMC using
an ANCOVA, in order to treat WMC as a continuous variable. Problem type (insight versus non-insight) was included as a within-subjects factor. WMC and a WMC \(\times\) problem type interaction term were included in the model as covariates.

A significant main effect of problem type was found, \(F(1\), \(82)=297.39, p<.001, \eta_{\mathrm{p}}^{2}=.78\). There was no main effect of WMC, \(F<1\). The interaction between problem type and WMC was significant, \(F(1,82)=5.65, p=.02, \eta_{\mathrm{p}}^{2}=.06\).

In order to examine the nature of this interaction, followup analyses were conducted using simple regression. As shown in Figure 2, higher WMC was associated with generally better non-insight problem-solving accuracy, although this relationship did not reach significance ( \(B=\) \(.016, S E=.011, p=.153\) ). In contrast, higher WMC was associated with significantly lower CR insight problemsolving accuracy ( \(B=-.013, S E=.006, p=.041\) ).

\section*{Discussion}

The current results support the prediction that less attentional control is better for insight problem-solving. Using the Matchstick Arithmetic task, we found that higher WMC was associated with somewhat better non-insight problem-solving but significantly worse insight problemsolving. The latter finding is counterintuitive in light of a great deal of literature demonstrating that more attentional control contributes to better performance on a range of higher-order cognitive tasks (c.f., Conway et al., 2005). These findings are, however, consistent with a growing body of research finding that lower WMC is advantageous on tasks relying on more associative or procedural processes (DeCaro \& Beilock, 2010).

Although a diffuse focus of attention is important for creative problem-solving processes such as insight (Jarosz \& Wiley, 2012), the relationship between WMC and insight has been inconsistent across studies. For example, Ash and Wiley (2006) found that WMC predicted performance on insight problems when the problems required an extended initial search phase. WMC was not related to performance on insight problems in which the search phase was shorter, presumably leading to impasse and restructuring more quickly (see also Fleck, 2008). These findings lend support to the spontaneous restructuring account of insight, which proposes that a necessary change in an initial problem representation is achieved through automatic processes and therefore does not depend on WMC. This finding converges with other evidence demonstrating that associative and divergent thinking rely on automatic processes that occur outside conscious awareness (Dijksterhuis \& Meurs, 2006).

Spontaneous accounts of insight do not, however, preclude the argument that attentional control may disrupt those processes that are important for restructuring. Associative processes are better for creative problemsolving but, critically, are supported by decreased latentinhibition (Carson, Peterson, \& Higgins, 2003). The abilities that facilitate performance on non-insight problems and are supported by controlled processing may therefore be
inappropriate for solving insight problems, and may harm performance. Too much focus can unnecessarily constrain the problem space, limiting the field of viable operators for solution and hindering the ability to achieve insight. Additionally, an overreliance on complex strategies may contribute to persistence within a faulty problem representation.

Some have proposed alternate routes by which creative solutions are achieved: one that is flexible, associative, and is characterized by lower levels of cognitive control, and another that is persistent, deliberate, and supported by a more focused analytic approach (De Dreu, Nijstad, Baas, Wolsink, \& Roskes, 2012). Which pathway is more readily accessible may depend on interactions between individual difference and task-specific factors. Research in strategy selection suggests that differences in WMC may be an important factor in determining which path an individual is likely to take (e.g., Beilock \& DeCaro, 2007; Gaissmeier et al., 2006). The current results suggest that higher WMC leads individuals to select a more focused analytic approach to insight problem-solving. However, future research is needed to examine the actual problem-solving strategies used by individuals of varying WMC.

Future research should also consider additional factors that may impact success at insight problem-solving, including boundaries to the current results. For example, if it is possible to achieve insight through methodical analytic persistence, then individuals with higher WMC could eventually attain insight-they would just require more time in order to exhaust and reject more obvious solution paths before identifying the correct one. Another factor likely to moderate strategy selection is goal transparency. Insight problems are ambiguous by design, and the challenge of these problems often hinges on this occlusion of decisive task objectives. If individuals with higher WMC know to consider everything as potentially relevant, they may be less likely to filter out important parts of the problem (e.g., Colflesh \& Conway, 2007; Conway, Cowan, \& Bunting, 2001).

Although we demonstrate that higher WMC can lead to lower insight, certain situational factors may therefore improve the ability of higher-capacity individuals to select more appropriate problem-solving strategies. By considering the interaction between individual differences and situational factors on the focus of attention, we may be better able to predict when insightful thinking will be best supported.

\begin{abstract}
Visual information contributes fundamentally to the process of object categorization. The present study investigated whether the degree of activation of visual information in this process is dependent on the situational relevance of this information. We used the Proactive Interference (PI) paradigm. In two experiments, we manipulated the information by which objects could be retrieved from memory: by both semantic and shape information or by shape information only. The pattern of PI-release showed that if objects could be stored and retrieved both by semantic and shape information, then shape information was overruled by semantic information. If, however, semantic information could not be (satisfactorily) used to store and retrieve objects, then objects were stored in memory in terms of their shape.
\end{abstract}

Keywords: Object shape; proactive interference; memory; categorization.

\section*{Introduction}

If we observe a cat-like creature in the zoo, even if it is a type that we have never seen before, we may classify that animal as belonging to the same category as lions, tigers and pumas. Presumably, the reason for doing this is that the observed animal shares some observable properties with those of the other cat-like animals that we remember having seen before. Object categorization is hence a fundamental process in constructing and using our memory, as it helps to organize our knowledge and relate (novel) objects to other objects in order to assign meaning to them.

This process of object categorization is driven by mental representation. When we encounter an object, we create a mental representation based on sensory and semantic information. In order to categorize the object, the mental representation is compared to a mental prototype that represents category members (Rosch \& Mervis, 1975) or to other category exemplars in memory (Nosofsky, 1986). The representations are compared on both sensory and semantic information, however the relative weighting of these two types of information varies across concepts and semantic categories (Humphreys \& Forde, 2001; Warrington \& McCarthy, 1987). For example, the shape of an animal or the color of a fruit might be more important to assign the
object to the correct category than the shape or color of a kettle. In the present study, we investigate the role of sensory features in the categorization of visual objects. We focus on the visual sensory feature shape and investigate whether the relative weighting of shape and semantic information affects the organization of semantic memory.

Barsalou (1999) proposed that sensory information plays a critical role in cognition. According to his Perceptual Symbols theory, perception, action, and cognition share processing mechanisms. He views mental representation as a process of sensory-motor simulation. Central in his theory are perceptual symbols by which a mental representation is defined. A mental representation is constructed of a combination of several perceptual symbols for different components of the concept. This perceptual symbol formation process does not only concern the concept's visual features (e.g., its color, shape, and orientation), but operates as well on other sensory modalities such as audition, haptics, olfaction, and gustation. As such, perceptual symbols are learned through actual experiences with concepts. Modality-specific sensory-motor systems capture such experiences and hierarchical association areas integrate experiences from different modalities. Hence, these association networks represent knowledge of the concept that can be recruited for cognitive processing via the process of simulation (i.e., mental representation).

Evidence supporting the PS theory is provided by work that shows that visual sensory information is indeed activated during language comprehension (e.g., Huettig \& Hartsuiker, 2008; Pecher, Van Dantzig, Zwaan, \& Zeelenberg, 2009; Pecher, Zeelenberg, \& Raaijmakers, 1998; Stanfield \& Zwaan, 2001; Van Dantzig, Pecher, Zeelenberg, \& Barsalou, 2008; Van Weelden, Schilperoord, \& Maes, in press; Zwaan, Stanfield, \& Yaxley, 2002). For example, Huettig and Hartsuiker (2008) showed that naming a category exemplar (e.g., musical instrument - saxophone) elicited eye movements to a picture of a semantically unrelated object that was similar in shape (e.g., ladle). This activation of visual sensory information is context related. Zwaan, Stanfield, and Yaxley (2002) showed, for example, that context can affect the particular shape of the object that
is represented. In their experiment, participants were presented with sentences like 'The ranger saw the eagle in the sky' or 'The ranger saw the eagle in its nest,' which were followed by a line drawing of the object described in the sentence, in this case an eagle with outstretched wings or an eagle with folded wings. Participants recognized the picture faster if the implied shape of the object in the sentence matched the shape of the object in the picture. In the same line, Van Weelden, Schilperoord, and Maes (in press) showed that sentence structure (which can define the relation between multiple objects) influences the shape of the represented object(s) as well. In their experiment, participants were presented with sentences that invited to compare two objects like ' \(A\) spinning top is like a ballerina,' which were followed by two line drawings of the objects described in the sentence. The two drawings either had a similar or dissimilar shape. Participants recognized the pictures faster if they were similarly shaped. Hence, a sentence structure that invites to (conceptually) compare two objects affects the shape of their mental representation.

While language has been shown to elicit perceptual representations, there is also work that shows that the opposite occurs as well, that is, that semantic information is activated during visual object perception. Boucart and Humphreys (1997) suggest that as a result of the strong interplay between sensory and semantic information, people cannot even attend selectively to the global shape of an object without automatically processing its semantic properties. Caramazza, Hillis, Rapp, and Romani (1990) try to explain this interaction with their Organized Unitary Content Hypothesis (OUCH). Their theory is based on the idea that, contrary to a word for a particular concept, the object itself tends not to have an arbitrary relationship to its meaning. Some visual sensory features are directly related to the semantic properties of the object that specify its function (cf. Gibson's affordance theory; 1977, 1979). These features are therefore perceptually salient. As such, shape is very frequently a salient perceptual feature.

Accordingly, visual sensory information contributes fundamentally to the process of object identification and categorization. In the present study, we propose that the degree of activation of visual information in the process of object categorization might depend on the situational relevance of this information (Chaigneau, Barsalou, \& Samani, 2009; Pecher et al., 1998). We define this situational relevance as the result of the visual and semantic relations between the objects. For example, we might predict that when we have to look for an overarching category for a number of presented objects, visual features, such as shape, might play a bigger role if objects belong to different semantic categories as compared to when they stem from the same semantic category. Therefore, in the present study, we investigate whether shape information is encoded differently in our semantic memory for objects from similar and dissimilar semantic categories.

One way to investigate how visual information is encoded, and hence whether the objects are organized in semantic memory by means of their shape, is by looking at the process of retrieval of this particular information. The encoding and retrieval of the encoded information are interdependent; a retrieval cue will be effective if and only if the information in the cue was generated at encoding (Blaxton, 1989; Morris, Bransford, \& Franks, 1977; Tulving \& Thomson, 1973). Hence, by examining whether the shape of objects is used as a retrieval cue when trying to retrieve objects from memory, we can determine whether shape information was encoded in the semantic memory.

To do so, we use the Proactive Interference (PI) paradigm (Wickens, 1970). Proactive interference occurs when previously encountered information interferes with the memorial access of more recently encountered information. The standard procedure to test this interference is to present a triad of items from the same semantic category and, subsequently, have the participant perform a 25 -s rehearsalpreventing task, such as a backward counting task. Then, participants recall the triad. This procedure is repeated for four trials. The idea is that because the items are members of the same semantic category, the meaning of the items is being encoded and so is the meaning of the non-presented category under which they subsume. The PI paradigm results in decreasing performance on the recall task as more triads from the same semantic category are presented. Because participants use the same category cue to recall the items, increasing interference arises. If, however, the semantic category shifts on the fourth (i.e., the critical) trial, the category cue will change as well. Therefore, the discriminability and accessibility of the items will increase, resulting in an increased performance on the recall task. This mechanism is called release from interference.

In previous studies, the PI paradigm has been used to investigate the magnitude of the semantic distance between exemplars from different semantic categories (i.e., shift from fruits to vegetables as compared to shifts from fruits to professions), phonemic categories (i.e., shift from words with 'air' sound to 'eye' sound), and sensory features (i.e., shift from 'round' words to 'white' words) (Wickens, Dalezman, \& Eggemeier, 1976; Zinober, Cermak, Cermak, \& Dickerson, 1975). The main conclusion drawn from these studies is that the degree of release from interference is inversely related to the number of common characteristics. That is, a shift between categories with a high overlap in characteristics (i.e., from fruits to vegetables) obtains a lower release from interference as compared to a shift between categories with no overlapping characteristics (i.e., from fruits to professions).

Marques' (2000) study showed release from interference as a result of a shift from nonliving to living things. Interestingly, Marques tested this living/nonliving distinction for both words and pictures of the objects. The visual stimuli yielded the same types of interference effects
as verbal stimuli. Accordingly, this study shows that the PI paradigm can also be used to investigate which retrieval cues people use to recall visual objects from their memory and, hence, which information was encoded when the visual objects were processed.

The present study employs the PI paradigm with the visual manipulation of object shape. We refer to shape as the outline of the picture of a particular object, rather than its inherent shape. We predict that if depictions of objects are encoded in such a way as to include information about the shape of the objects, then objects with a particular shape should form a different category than objects with another shape. Therefore, interference should build up as objects with similar shapes are presented on successive trials, and a release from interference should occur with a shift of shape. Yet the relative weighting of shape information might differ as a result of the situational relevance of this information. In two experiments, we manipulate the semantic and shape similarity between the objects and, thereby, the situational relevance of shape. In Experiment 1, we combine a shift of shape with a semantic shift. For this type of shift, we expect that a semantic category cue will be sufficient to recall the objects from the critical trial. So, for this situation, the role of shape might be inferior. In Experiment 2, we will only manipulate a shift of shape, keeping the semantic category similar throughout the experiment. For this situation, we expect shape to be a distinguishing factor and to be used as a retrieval cue.

\section*{Experiment 1}

This first experiment evaluated the role of shape in the PIrelease situation with both a shape and semantic categorical shift. The semantic shift comprised a shift between two natural categories, fruits and flowers. We used this type of shift because living things are primarily differentiated on the basis of perceptual features (Humphreys \& Forde, 2001; Warrington \& McCarthy, 1987). That is, most types of natural objects have a high perceptual overlap, and therefore small perceptual differences are highly informative. Hence, it can be expected that visual information will have a relatively high weighting as compared to other types of information in the representation of living things.

Both the participants in the Shift and No-Shift condition received three fruits triads followed by a flower triad. In the No-Shift condition, the shape of the fruits and flowers did not change throughout the experiment. The objects either were round in shape or were shaped irregularly. In the Shift condition, however, the shape of the objects changed on the critical trial. The critical trial established a shift from irregularly shaped objects to round shaped objects or vice versa.

For both the Shift and No-Shift condition, we predicted release from interference to occur as the change from fruits to flowers reduces or eliminates interference. However,
there may be gradual differences in the amount of release, both as a result of the shape shift itself and the type of shape shift. We expected the release to be most prominent for the Shift condition as there is an additional shift of shape. Considering the type of shape shift, we predicted the release to be stronger when triads changed from round shaped objects to irregularly shaped objects than the other way around. If pictures of objects are encoded in such a way as to include information about the shape of the objects, then the buildup of interference is stronger for round objects, which might result in a stronger release effect.

For the No-Shift condition, we predicted the release from interference to be hampered when the triads of the four trials consist of round objects. Although there was a semantic change from fruits to flowers, the objects remained perceptually similar. As a result, the previously seen objects may continue to interfere with the objects presented on the critical trail. When the triads of the four trials consist of irregularly shaped objects, however, this interference effect may be more moderate as the objects are not perceptually similar. The semantic shift would then be sufficient to eliminate such interference effects.

\section*{Method}

Participants Eighty Tilburg University undergraduates (57 women) participated for course credit. The mean age was 21 years, ranging from 18 to 34 .

Materials \({ }^{1}\) The stimulus pictures consisted of 18 pictures of fruits ( 9 round shapes and 9 irregular shapes) and 6 pictures of flowers ( 3 round shape and 3 irregular shapes). The pictures were arranged in triads ( 6 for fruits and 2 for flowers). In arranging these triads, we controlled for various factors. For the fruits triads, we controlled for typicality. In a typicality pretest, ten participants (who did not participate in the future PI experiment) were asked to sort the pictures of the objects from most typical member of the category 'fruits' to the least typical member of this category. Based on this taxonomy, every fruits triad was assigned a low, medium, and high typical member of the category. In addition, every fruits and flowers triad consisted of three differently colored objects. We kept the visual complexity similar across triads in terms of mean JPEG file sizes (Chikhman et al., 2012; Donderi, 2006).

Design The experiment had a \(2 \times 2 \times 4\) design, with Condition (levels: Shift and No-Shift) and Triad Shape (levels: Round shape and Irregular shape) as betweensubjects factors and Trial (levels: 1, 2, 3, and 4) as withinsubjects factor.

\footnotetext{
\({ }^{1}\) See dcilab.uvt.n1/LisanneVanWeelden/materials.pdf for the materials of Experiment 1 and 2.
}

Procedure The participants were informed that the purpose of the experiment was to test their ability on both backward counting and their memory of triads of objects. During each trial, participants first saw a fixation cross in the center of the screen for 2 s . Subsequently, the objects of one triad were presented one-by-one for 2 s each (with no interstimulus interval). Participants were instructed to identify the objects silently, to remember them, and also to remember the order of the objects. They were told that they had to recall the objects in the right order afterwards. A three-digit number was then presented in the middle of the screen for 25 s during which the participant had to count backwards by threes out loud. Participants were instructed to count backwards as fast as possible while still being accurate. After 25 s the question 'Which three objects did you see?' appeared, signaling the beginning of the 12 s recall period. Participants typed the names of the three objects. After 12 s the question was replaced with "Time's up" to indicate the end of the recall period. Participants pressed a button to continue to the next trial. The next trial started again with the fixation cross. Participants trained on both the counting backward and memory task with a four trial training block.

\section*{Results and discussion}

For each participant, the mean recall score was computed for each trial. Following the procedure of Wickens, Dalezman, \& Eggemeier (1976), one point was given for each object recalled correctly and one extra point was assigned when the three objects were recalled in the correct order. So, for each trial, there was a maximum of 4 points. The mean scores per Condition and Trial are presented in Figure 1.

PI-buildup and PI-release effects were analyzed independently. The PI-buildup analysis was performed on the first three trials. The PI-release analyses were performed on (1) the third and fourth trial and (2) on the fourth trial separately. For all three analyses an ANOVA was conducted with Condition (levels: Shift and No-Shift) and Triad Shape (levels: Round shape and Irregular shape) as between-subjects factors. For the PI-buildup analysis the latter factor concerned the Shape of the first three triads, whereas for the PI-release analyses this regarded the Shape of the fourth triad. The PI-buildup analysis also involved the within-subjects factor Trial (levels: 1, 2, and 3).

For PI-release, the analysis on the third and fourth trial revealed a main effect of Trial, \(F(1,152)=31.19, p<.001\), \(\eta_{\mathrm{p}}^{2}=.17\). The mean recall score was higher on the fourth trial \((\mathrm{M}=3.55, \mathrm{SD}=.95)\) than on the third trial \((\mathrm{M}=2.53\), \(\mathrm{SD}=1.31\) ). Participants recalled more items after the semantic shift. There was no effect of Condition, \(F<1\), or Triad Shape, \(F<1\), and there were no two- or three-way interactions between the factors, \(F<1\). The analysis on the fourth trial alone revealed neither a main effect of

Condition, \(F<1\), and Triad Shape, \(F<1\), nor an interaction between the two, \(F(1,76)=1.98, p=.16\). Thus, the semantic shift did result in release from interference, but there were no (gradual) differences in release as a result of the shift in shape on the fourth trial.

For PI-buildup, the analysis showed a main effect of Trial, \(F(2,228)=9.31, p<.001, \eta_{\mathrm{p}}^{2}=.08\). Participants recalled fewer items as the number of trials increased. Post hoc analyses showed that the decrease from trial 1 to trial 2 was significant, \(p<.05\). The decrease from trial 2 to trial 3 did not reach significance, \(p=.22\). There was no effect of Condition, \(F<1\), nor an effect of Triad Shape, \(F<1\). The analysis did not reveal any two- or three-way interactions between the factors.

Figure 1: Mean recall scores on each trial for the Shift and No-Shift condition in Experiment 1.

These results show that shape information was overruled by semantic information. Only semantic information was used as retrieval cue, as indicated by the build-up of interference during the first three trials and the release from interference when the semantic category changed. The change in shape did not affect performance. We expected that the role of shape becomes more prominent if a semantic retrieval cue is not sufficient to recall the objects of the critical trial. This possibility was explored in Experiment 2.

\section*{Experiment 2}

This second experiment evaluated the role of shape in the PI-release situation without a semantic categorical shift. Participants in both the Shift and No-Shift condition received four fruits triads. Identical to Experiment 1, the shape of the fruits was similar throughout the four trials in the No-Shift condition, in the sense that the objects either had a round shape or were shaped irregularly. In the Shift condition, the shape of the objects changed on the critical trial. The change concerned a shift from irregularly shaped objects to round shaped objects or vice versa.

For the Shift condition, we predicted release from interference to occur as a result of the shape shift. Again, we expected the release to be more prominent when triads changed from round shaped objects to irregularly shaped objects than when they shifted in the opposite direction. For the No-Shift condition, we predicted that the buildup of interference would continue throughout the four trials. The decrease in performance was expected to be the strongest for the round shaped objects as compared to the irregularly shaped objects.

\section*{Method}

Participants Eighty Tilburg University undergraduates (57 women) participated for course credit. The mean age was 22 years, ranging from 18 to 33 .

Materials The triads of the first three trials were the same as in Experiment 1. The experimental materials for these triads consisted of consisted of 18 pictures of fruits ( 9 round shapes and 9 irregular shapes). For the present experiment, the triads of the fourth trial consisted of 6 pictures of fruits ( 3 round shapes and 3 irregular shapes). In arranging these triads, we controlled again for typicality, color, and visual complexity.

Design and procedure The design and procedure were the same as in Experiment 1.

\section*{Results and discussion}

For each participant, the mean recall score was computed for each trial. As in Experiment 1, there was a maximum of 4 points. The mean scores per Condition and Trial are presented in Figure 2.

PI-buildup and PI-release effects were analyzed independently in the same manner as Experiment 1. For PIrelease, the analysis on the third and fourth trial revealed a trend of an effect of Condition, \(F(1,152)=2.76, p=.09\). The analysis also showed a trend of an interaction between Condition and Trial, \(F(1,152)=2.89, p=.09\). There was no main effect of Triad Shape, \(F<1\), or Trial, \(F<1\), nor any other two- or three-way interactions. The analysis on the fourth trial alone revealed a main effect of Condition, \(F(1\), \(76)=5.70, p<.05, \eta_{\mathrm{p}}^{2}=.07\). The mean recall score was higher for the Shift condition ( \(\mathrm{M}=2.58, \mathrm{SD}=1.30\) ) than for the No-Shift condition ( \(\mathrm{M}=1.92, \mathrm{SD}=1.05\) ). Participants recalled more items after the shape shift. There was no main effect of Triad Shape, \(F<1\), nor an interaction between Condition and Triad Shape, \(F(1,76)=2.21, p=.14\). So, the shape shift resulted in release from interference, causing an increase of the recall scores on the fourth trial.

For PI-buildup, the analysis showed a main effect of Trial, \(F(2,228)=18.40, p<.001, \eta_{p}^{2}=.14\). Post hoc analyses showed that both the decrease from trial 1 to trial
\(2, p<.01\), and from trial 2 to trial \(3, p<.001\), was significant. There was no effect of Condition, \(F<1\), nor an effect of Triad Shape, \(F<1\). The analysis did not reveal any two- or three-way interactions between the factors.

Figure 2: Mean recall scores on each trial for the Shift and No-Shift condition in Experiment 2.

These results show that if semantic information is insufficient to recall the objects of the critical trial, shape comes into play. The fact that shape is used as a retrieval cue to recall objects from memory suggests that the objects are assigned to a subordinate shape category within the semantic category of 'fruits'.

\section*{General discussion}

The purpose of the present study was to investigate the role of shape in semantic memory organization of visual objects. We predicted that if depictions of objects are encoded in such a way as to include information about the shape of the objects, then objects with a particular shape should form a different category than objects with another shape. We also predicted that the degree of activation of shape information might depend on the situational relevance of this information. Therefore, in two experiments, we investigated semantic memory organization in two different situations using the PI paradigm. We created these different situations by manipulating the objects' shape and semantic nature. The results of the present study suggest that semantic memory organization of objects is indeed dependent on the interaction between semantic and shape information.

Experiment 1 showed that if objects can be categorized both on semantic and shape information, then shape information is overruled by semantic information. Namely, as indicated by the release from interference as a result of the semantic category change, semantic information was used as retrieval cue, which was not affected by the shift in shape. Hence, it seems that object categorization is largely
driven by semantic features, as those features received higher activation than perceptual features.

Experiment 2 showed however that shape does play an important role in object categorization, that is, if semantic information is not a distinguishing factor and therefore does not receive high activation. In this experiment a situation was created in which the semantic information remained unchanged, whereas the shape of the objects did change. The release from interference as a result of the shift in shape showed that object shape was indeed used as retrieval cue. So, in this situation, objects are categorized based on their shape.

To summarize, object categorization is driven by semantic information to a large extent, yet if semantic information cannot be (satisfactorily) used to store and retrieve objects, then shape comes into play.

\begin{abstract}
We report three studies examining mechanism of propertysensitive induction. First, we demonstrate that, contrary to a common assumption, property does not influence retrieval of knowledge about premise categories. Second, we introduce property-driven explanations as a possible source of property effects and provide first evidence for this proposal.
\end{abstract}

Keywords: induction; property effects; retrieval; explanation.
Generating hypotheses about uncertain outcomes from limited evidence - inductive inference - is a pervasive cognitive activity. In order to be successful, inductive inference must be flexible. For example, if you learn that a new influenza virus has been discovered in chickens, you may reasonably get concerned about your own health; but if chickens were announced to carry a certain defective gene, you are much less likely to worry about catching one during your next meal. Indeed, a vast body of empirical evidence demonstrates that people make systematically different inferences when they project different properties (see Coley \& Vasilyeva, 2010, for a review). Heit and Rubinstein (1994) proposed that property affects induction by indicating different subsets of features as relevant for evaluating premise-conclusion similarity. Goodman (1972) provided a logical argument for constrained recruitment of features: since any category has a potentially infinite set of features and can be infinitely similar to any other category, it is a necessary logical requirement for inductive inference to impose some initial constraints to limit a subset of relevant features.

Although it is generally agreed that induction requires constrained recruitment of prior knowledge, and there is evidence that projected property may provide one such constraint (Coley \& Vasilyeva, 2010; Heit \& Rubinstein, 1994), the mechanism of property-based constrained recruitment remains unclear. Existing models of induction either do not specify the psychological mechanism of property effects (McDonald, Samuels, \& Rispoli, 1996; Medin, Coley, Storms, \& Hayes, 2003; Rips, 1975; Osherson, Smith, Wilkie, Lopez, \& Shafir, 1990; Sloman, 1993; Sloutsky \& Fisher, 2004), or acknowledge the computational nature of their account that may not correspond to actual psychological processes involved in inductive inference (e.g. Tenenbaum, Kemp, \& Shafto, 2007; Heit, 1998).

We report three studies that examine two candidate psychological mechanisms of property effects in induction: property-moderated retrieval of relevant knowledge about premise categories from long-term memory, and generating explanations of why premise categories might have the property to begin with. In contrast to the majority of studies
on induction that use argument evaluation task, we employed inference generation task: participants were given an inductive premise and asked to generate their own conclusions. Coley \& Vasilyeva (2010) demonstrated that this task provides a particularly sensitive measure of participants' spontaneous use of different kinds of relevant knowledge, in the context of an ecologically valid inductive problem.

\section*{Property-Moderated Knowledge Retrieval as a Mechanism of Property Effects}

Generation of an inductive hypothesis is inherently knowledge driven; when one learns that A has a novel property X , one uses what they know about A and its relations to other things to form guesses about what else is likely to have X. One source of input to inductive inference is knowledge about premise categories. When such categorical knowledge is accessed, a probabilistically determined subset of features and relations that comprise the representation of that concept becomes available as a raw material for the inference. For example, if A turned out to be a duck, such features as "is a bird", "flies", "lives in ponds", "quacks" and "eaten by foxes" may come to mind. Although there are many different types of knowledge, knowledge about living things is commonly divided into two broad classes: taxonomic knowledge is based on relations of intrinsic similarity between members, whereas contextual, or ecological knowledge, is based on extrinsic relations between members and other entities. For example, ducks belong to the taxonomic category of birds and ecological categories of aquatic animals and fox prey. Each of these types of knowledge can serve as a basis for an inductive projection from ducks - to other birds, or other aquatic animals, or things that eat ducks.

In addition to the premise category, knowledge about the property can also serve as a source of information. If X in the example above is replaced with a more specific property, such as "carries a certain disease" or "has a certain gene", new knowledge is brought to the table: independently of what we know about ducks, we also know something about diseases and genes: what they are, whether they can be transmitted via contact, etc. How can property influence what projections people end up making? One possibility is that property constrains what types of premise knowledge are used to produce an inductive hypothesis.

A premise category label, as any word, is connected to a vast amount of conceptual knowledge; this knowledge is unlikely to be retrieved in its entirety on any given occasion (McElree, Murphy \& Ochoa, 2006). Rather, retrieval of conceptual information from long term memory is selective and depends on context (e.g. Barsalou, 1982; Swinney,
1979). Within an inductive problem, property may serve as context for the premise category(-ies), and it could affect what information about these categories is retrieved. For example, in response to a premise like "ducks have gene X", one may be more likely to retrieve taxonomic knowledge about ducks (bird, have feathers whereas for ("ducks have parasite X "), one may be more likely to retrieve ecological knowledge about ducks (aquatic, prey to foxes). This mechanism is consistent with the flexible similarity proposal by Heit and Rubinstein (1994) and the Bayesian model of induction by Heit (1998). The advantage of this proposal is that it is more specific, it focuses on describing the underlying psychological process rather than on modeling outcomes of such a process, and it can be tested with behavioral data.

To evaluate this proposal, we conducted two studies. Study 1 examined knowledge recruitment: how knowledge about premise categories predicts outcome inferences about different properties. Study 2 examined knowledge retrieval: how knowledge about premise categories is activated in context of different properties during inference generation.

\section*{Study 1: Property-Specific Knowledge Recruitment}

To begin to specify the role of property in inference generation, we examined how it affects recruitment of category knowledge, or the extent to which available knowledge about premise categories ends up being used in the outcome inferences. For example, if among many facts about ducks, one knows that they live in water, and one uses this knowledge to project a property from ducks to other aquatic animals, we can say that the knowledge has been recruited. The question is whether the nature of the property affects the likelihood of recruiting ecological versus taxonomic knowledge about premise categories.

To address this question, we measured available knowledge about a set of animal categories and examined the predictive relationship between this knowledge and inferences generated about the same set of animal categories (i.e. knowledge recruitment). Most critically for evaluating the first proposal, we manipulated the property in the inference generation task between ecologically-biasing, neutral, and taxonomically-biasing. If property moderates recruitment of knowledge about premise categories, the predictive relationship between category knowledge and inferences should vary with the property. Based on Coley \& Vasilyeva (2010), we expected that property could facilitate recruitment of congruent knowledge, and/or inhibit recruitment of incongruent knowledge. For example, taxonomic properties should facilitate recruitment of taxonomic knowledge, and inhibit recruitment of ecological knowledge; ecological properties should show the converse pattern.

\section*{Method}

Feature-Listing Task Twenty nine participants were given a list of \(42^{1}\) animal names and for each animal were asked to write down anything they could think of that was "generally true of that animal".

Inference-Generation Task One hundred participants were given 42 open ended-induction questions about same

\footnotetext{
\({ }^{1}\) Feature-listing data from 1 animal were lost.
}

42 animals; each stated that a property was true of a single animal species, and asked what other species were likely to have the property. For example, "GENE T5 is found in DUCKS. What else is likely to have gene T5? Why?" Property was manipulated within subjects; participants saw two examples of three kinds of properties: ecological (flu, parasite), taxonomic (gene, cell) and neutral (substance, property). \({ }^{2}\) Each participant was presented with seven questions about each property-each with a different animal premise-in random order. The dependent variables were the frequencies of taxonomic and ecological inferences.

\section*{Results}

Data Coding Four or five trained coders coded features and inferences into two broad classes. Taxonomic (Tax) features and inferences invoked category membership, perceptual features, or non-interactive aspects of behaviors and physiology (e.g. Tax-feature: "bird"; Tax-inference: "other birds will have it"). In contrast, ecological (Eco) features and inferences invoked animals' diet, habitat, or other interactions with entities in their environment (e.g. Ecofeature: "lives in water"; Eco-inference: "other animals that live in water"). Each feature and inference was coded as taxonomic, or ecological, or both, or neither \({ }^{3}\). For every animal, the mean counts of features coded as Tax or Eco were taken as the measures of the amount of salient taxonomic and ecological knowledge about that animal. To quantify inferences, relative frequencies of participants making Tax and Eco inferences about that animal were calculated separately for each property type resulting in 6 means per animal.

Property effects Results showed strong property effects. Eco-inferences were generated most frequently when the property was ecological, followed by neutral and taxonomic properties \(\left(F(2,82)=95.05, p<.001, \eta_{\mathrm{p}}^{2}=.70\right)\); this pattern was reversed for Tax-inferences \(\left(F(2,82)=64.64^{4}, p<.001\right.\), \(\eta_{\mathrm{p}}^{2}=.61\); all planned pairwise comparisons \(p\) ' \(\mathrm{s}<.001\) ).

Knowledge recruitment We examined relations between premise category knowledge and property in predicting inferences in 12 simple linear regressions. In one triplet of regressions, ecological premise category knowledge served as a predictor of Eco-inferences, separately for ecological, neutral and taxonomic property. The other triplets covered the three remaining combinations between knowledge type and inference type, broken down by the property. The standardized regression coefficients are shown in Figure 1.

Eco-inferences For Eco-inferences (Fig. 1a) the predictive power of knowledge varied with the property. Eco-knowledge was overall a positive, albeit nonsignificant, predictor of Eco-inferences when participants were reasoning about a neutral ( \(R^{2}=.057, \beta=.239, p=.132\) ) or taxonomic \(\left(R^{2}=.034, \beta=.242, p=.128\right)\) property, but its

\footnotetext{
\({ }^{2}\) The 6 properties were selected from a larger pool of properties based on a norming study measuring participants' beliefs about the distribution of properties across taxonomic and ecological categories.
\({ }^{3}\) Coding categories were not mutually exclusive; a given response could receive multiple codes if it unambiguously invoked multiple codable kinds of relations.
\({ }^{4}\) Data were scored and analyzed by item. All the analyses on proportions reported below were conducted on arcsine-transformed data, while the reported means are non-transformed and presented as percentages.
}
contribution was stronger in the presence of an ecological property ( \(R^{2}=.124, \beta=.352, p=.024\) ). When we examined the contribution of Tax-knowledge to Eco-inferences, overall larger amounts of Tax-knowledge were associated with lower frequency of Eco-inferences (all \(\beta\) 's are negative), and this relationship again varied with property. Taxknowledge inhibited Eco-inferences marginally when the property was neutral ( \(R^{2}=.076, \beta=-.276, p=.08\) ), and reliably so when it was reinforced by a taxonomic property ( \(R^{2}=.12, \beta=-.346, p=.027\) ). Relative to taxonomic and neutral properties, ecological property largely neutralized the inhibitory effect of Tax-knowledge on Eco-inferences ( \(R^{2}=.007, \beta=-.083, p=.605\) ).

Tax-inferences Although, as shown in Fig. 1b, the sign and ordering of predictors generally follow the predicted pattern of strengthening effects of congruent knowledge and weakening effects of incongruent knowledge (with two exceptions), Tax-inferences were not significantly predicted by category knowledge (all \(p\) 's \(>.121\) ).

Figure 1: Eco- and Tax-knowledge about animals predicting relative frequency of Tax- and Eco-inferences about these animals, in the context of ecological, neutral and taxonomic properties. \({ }^{*} p<.05,+p<.1,{ }^{\circ} p<.15\)

\section*{Discussion}

Overall, property had a profound effect on the inferences participants generated, and category knowledge predicted ecological, but not taxonomic inferences. Eco-inferences were facilitated by congruent (ecological) knowledge about premise categories, and inhibited by incongruent (taxonomic) knowledge. Most importantly, the relation between knowledge and Eco-inferences varied with the property: property strengthened effects of congruent knowledge, and weakened effects of incongruent knowledge. The overall pattern of congruent facilitation and incongruent inhibition held for Tax-inferences as well, although it was weaker and did not reach significance. Even though evidence of a relationship between knowledge and inferences was present for Eco-inferences but absent for Tax-inferences, it is sufficient in order to provide an "existence proof" for moderating effect of property on knowledge recruitment. These results are consistent with Heit and Rubinstein's (1994) proposal about a flexible similarity metric, but they go beyond similarity relations and demonstrate flexible recruitment of ecological knowledge about contextual and interaction-based relations among animals.

\section*{Study 2: Property-Specific Knowledge Retrieval}

Even though this demonstration of property effects in knowledge recruitment provides a useful constraint on the general underlying retrieval process, it does not specify it completely. Study 2 directly examines knowledge retrieval by measuring activation of premise category knowledge in real time, as it is accessed during inference generation. We borrowed a cross-modal priming paradigm from Swinney (1979). Participants were auditorily presented with a taxonomic, ecological or neutral property and an animal premise, and were asked to generate possible conclusions. In addition, upon hearing the property and animal, participants were presented with a lexical decision task involving targets related to salient taxonomic or ecological knowledge about the premise animal. For example, a participant might hear a property, gene, followed by the animal, duck, and, after a varying time interval, see on the screen a taxonomic target bird, or an ecological target pond, or an unrelated target sofa, or a non-word soach. The task was to decide whether the letter sequence was a word. The time to respond to the related targets was taken as a measure of activation of Tax- or Eco-knowledge about the premise animal. If knowledge about duck is activated, we expect decisions about related targets (bird and pond) to be faster than about unrelated targets (sofa). If property moderates knowledge retrieval, we would expect decisions about ecologically related targets (pond) to be faster in the presence of an ecological property and/or slower in the presence of a taxonomic property relative to a neutral, or non-biasing property context. Similarly, we would expect decisions about taxonomically related targets (bird) to be faster in the presence of a taxonomic and/or slower in the presence of an ecological property compared to neutral.

\section*{Method}

Materials The stimuli for the induction task were 36 animal premises, each belonging to one salient taxonomic category (mammal, bird, reptile, fish, insect) and one salient habitat-based ecological category (forest, desert, pond, ocean, savannah). Each of the animals was presented in the context of an inductive problem about one of the six properties from Study 1 (flu, gene, etc., presented with unique alphanumeric codes (X5, Z9)). All the animal names and properties were recorded in the voice of a female native speaker of English.

Thirty-six words and 36 pronounceable non-words were used as targets for the lexical decision task. The targets (derived from feature responses in Study 1) were taxonomically related, ecologically related, or unrelated to the animals used as premise categories in the induction task. The strength of association of the taxonomic, ecological, and unrelated targets to the corresponding animals, as well as lack of direct associations between properties and target words, were normed with another group of 18 native speakers of English.

Participants and Procedure One hundred eleven native speakers of English were tested individually, on a MacBook laptop running Superlab 4.0.4 software and set up with headphones and a microphone. The experiment consisted of an open-ended induction task with intervening lexical decision task. Participants were instructed that they would be listening to utterances that would introduce a property, followed by an animal that possesses that property, and their
task was to say out loud (at a cued moment) other species likely to share that property, along with a short justification. Participants were also informed that at "random" moments a sequence of characters would appear on the screen, and their task was to identify it as a word or a non-word as quickly as possible without sacrificing accuracy, using the response buttons. Each trial began with a 2000 msec pause; then a participant heard the property to be projected (e.g., flu M3), followed by a pause of 1000 msec , followed by the name of the premise animal (e.g., bear), followed by a pause and a signal to start speaking. At varying SOAs (stimulus onset asynchrony: 400,900 , or 1650 msec from the onset of the animal name), a target for lexical decision appeared on the screen and stayed there until the participant responded or for 3500 msec , whichever came first. No accuracy feedback was provided. After a 2000 msec pause following the participant's response or the end of lexical decision target presentation, a short beep signaled that the participant could start saying their inference. Participants had 15 seconds to say their response, after which the experiment automatically moved on to the next trial.

Design The main independent variable was property type (taxonomic: gene, cell; ecological: flu, parasite; neutral: substance, property). The second independent variable was the target word type (taxonomic vs. ecological vs. unrelated). Each non-filler animal was yoked to one target word type (taxonomic, ecological, or unrelated). We also varied SOA, but for the sake of brevity, this manipulation will not be discussed here. All the reported analyses were collapsed across SOA.

\section*{Results}

Does property moderate retrieval of knowledge about premise animals? If so, property type should facilitate responses to property-congruent targets and/or interfere with responses for property-incongruent targets.

Accuracy A 3(target type: eco, tax, unrelated) \(x\) 3(property: eco, tax, neutral) repeated measures ANOVA on accuracy in lexical decision task showed no main effect of property \((F(2,220)=.145, p=.865)\). The effect of target type was significant \((F(2,220)=4.33, p=.014)\) : eco- and taxtargets were verified more accurately than unrelated targets \((t(110)=2.63, p=.010 ; t(110)=2.58, p=.011)\); the former two did not differ \((t(110)=.33, p=.744)\). Most importantly, the effect of target type did not interact with property \((F(4,440)=.57, p=.683)\). This suggests that participants were retrieving category-relevant knowledge, but that such retrieval was not moderated by property.

Reaction Time. Reaction time results were consistent with the accuracy analyses. A 3 (target type: eco, tax, unrelated) x 3 (property: eco, tax, neutral) repeated measures ANOVA on RT showed no main effect of property \((F(2,218)=.44, p=.656)\) and a significant effect of target type \((F(2,218)=4.73, p=.010)\) : eco-targets were verified faster than unrelated targets \((t(110)=3.20, p=.002)\); and tax-targets were verified marginally faster than unrelated targets \((t(110)=1.80, p=.074)\); the former two did not differ \((t(110)=1.46, p=.148)\). Again, most importantly, the effect of target type did not interact with the property ( \(F(4,436)=1.24, p=.293)\), suggesting that property does not moderate knowledge retrieval.

Surprisingly, the speed of lexical decisions about filler items (non-words) was affected by the property \((F(2,220)=14.95, p<.001)\) : decisions were slower in the
presence of ecological (1343msec, \(t(110)=4.88, \mathrm{p}<.001)\) and taxonomic ( \(1320 \mathrm{msec}, t(110\) ) \(=3.99, \mathrm{p}<.001\) ) than neutral property \((1253 \mathrm{msec})\); the former two did not differ \((t(110)=1.45, p=.151)\).

Figure 2: Effect of target type and property on lexical decision accuracy and reaction time. Verification of related targets (eco, tax) was more accurate (a) and faster (b) than unrelated targets. This effect did not depend on property (panels c and d). Error bars: 1 SEM.

\section*{Discussion}

Based on the results of Study 1, we expected to find effects of property on knowledge retrieval: specifically, facilitation of property-congruent knowledge and inhibition of property-incongruent knowledge. However, we found no evidence of property moderating knowledge retrieval. Of course, we cannot completely rule out the possibility that the lack of property effects was caused by some procedural flaws of the study. However, because we did see property effects on some lexical decisions about filler words, we know that the method is in principle capable of detecting property effects. And because the premise category did differentially prime related vs. unrelated targets, we know that the method is capable of detecting differential priming. Therefore, it is likely that we failed to see property effects on retrieval because property does not moderate retrieval of knowledge about premise categories from long-term memory.

\section*{Study 3: Property-Moderated Explanation as a Mechanism of Property Effects}

Study 1 demonstrated selective property-moderated recruitment of categorical knowledge to inform inferences. However, Study 2 found no moderating effects of property on knowledge retrieval in real time. If, as we argue, this finding reflects the actual absence of property effects on retrieval rather than an experimental failure, we need to look for another mechanism whereby property can guide selective recruitment of taxonomic and ecological information by inferences. The mechanism that we examine in Study 3 is based on property-moderated explanation of evidence.

As suggested by Sloman's (1994) work, explanation of evidence may affect evaluation of inductive arguments. Even when the similarity between premise and conclusion is held constant, if both can be explained by reference to the
same principle, the perceived strength of an inductive argument can be higher than when premise and conclusion statements require different explanations.

Several features of explanation make it a good candidate mechanism for property effects in induction. For instance, explanation is flexible: there are multiple ways to explain any given observation. A formal explanation refers to categories or inherent properties; a causal explanation refers to the proximal mechanisms of change; and a teleological explanation refers to ends, goals or functions (Lombrozo, 2006). On the subsumption account proposed by Williams \& Lombrozo (2010), explaining an observation involves identifying a larger pattern of which the observation is a part. In this sense, explanation identifies a relevant subset of knowledge about the observation that can serve as a basis for generalizing to other cases - thus satisfying the logical prerequisite for induction stipulated by Goodman (1972).

How might explanation provide a mechanism for property effects in induction? If different properties lend themselves to different explanations, and if explaining consists of identifying an observation as a part of a larger pattern or regularity, then different properties might determine whether a premise of an inductive argument is viewed as a part of one regularity or another (e.g. formal explanations might highlight taxonomic relations, whereas causal explanations might highlight ecological relations). Thus, construction of different explanations could engender differential recruitment of knowledge, and ultimately different hypotheses about how a property might generalize without the necessity of differential retrieval of knowledge.

In Experiment 1, although asked to explain why they generated particular conclusion categories, participants often spontaneously provided explanations for why a premise category exhibited a given property. To evaluate the explanation mechanism, we examined these spontaneous explanations to determine whether different properties were associated with different types of explanations. We expected taxonomic properties to provoke predominantly formal explanations referring to classes of objects (that would eventually translate into category-based, or taxonomic inferences) and ecological properties to lead to predominantly causal explanations, referring to interactions between animals and/or their environment (that would eventually translate into ecological inferences). We had no specific predictions about teleological explanations.

\section*{Method}

Three trained coders independently re-coded all the inferences collected in Study 1 for the presence of formal, causal and teleological explanations. Twelve percent of inferences ( 467 out of 3920 codable responses) contained spontaneous explanations. These explanations were coded as formal (explanations that referred to kind membership, e.g. "mammal gene", or "this is a bird flu"), causal (explanations describing a "story" of interactions between animals and other entities, or a sequence of events resulting in the premise category having the property, e.g. " vultures may get flu E5 from the dead and decaying animals they feed off of" or "[the gene will be found in] fish since pelicans eat them, the pelicans might develop that gene from the fish"), teleological (explanations referring to goals, functions or purposes of properties, e.g. "these cells are to protect them from the cold" or "perhaps B6-cells defend deer from particular viruses that they are exposed to"), or
other (idiosyncratic or vague explanations that could not be assigned to any of the three categories).

\section*{Results}

Scoring. For each animal, we calculated the percentage of subjects who generated each type of explanation out of total number of participants who reasoned about that animal, separately for each property type. This yielded 12 percentages, or relative frequency scores, per animal (3 property types x 4 explanation types), that were arcsinetransformed for the analyses. Uncodable explanations were rare (less than \(2 \%\) of participants per animal) and were excluded from the following analyses.

Analyses To provide support for the proposal that property affects inferences via explanation, we need to show that different properties are associated with different explanations, and that different explanations are associated with different inferences.

Relations between property and explanation. The main question, whether different properties trigger different types of explanations, was addressed by a 3 (property: eco, tax, neutral) x 3 (explanation: formal, causal, teleological) ANOVA on relative frequency of explanations. The overall likelihood of providing an explanation did not vary with the property \((F(2,82)=.044, p=.957)\). However, explanations differed in frequency \(\left(F(2,76)=18.836, p<.001, \eta_{\text {part }}^{2}=.315\right)\) : causal explanations were more frequent (5.3\%) than formal ( \(2.8 \%\), or teleological explanations \((2.4 \%, t(41) \geq 4.59\), \(p<.001, d \geq .71\) ), which did not differ from each other.

Of most theoretical interest was the significant interaction between property and explanation type \((F(4,164)=34.442\), \(p<.001, \eta_{\mathrm{p}}^{2}=.457\), see Fig 3a). Explanations clearly varied with property: for ecological properties, causal explanations were more frequent than formal explanation, which were more frequent than teleological explanations \((t(41) \geq 4.52\), \(p<.001, d \geq 0.70\) ). For neutral properties, causal explanations were also more frequent than formal or teleological explanations, which did not differ from each other \((t(41) \geq 3.00, p \leq .005, d \geq 0.45)\). In contrast, for taxonomic properties, formal and teleological explanations were more frequent than causal explanations \((t(41) \geq 3.42, p \leq .001\), \(d \geq 0.52\) ). These results demonstrate a link between property and explanation type.

Figure 3: a. Percentage of explained inferences involving causal, formal, and teleological explanations for ecological, neutral and taxonomic properties. b. Percentage of Tax- and Eco-inferences for responses with formal, teleological, and causal explanations.

Relations between explanation and inference To examine the link between explanation and inference, we again focused on the subset of responses from Study 1 that included spontaneous explanations. We calculated the percentage of Tax- and Eco-inferences that accompanied
each type of explanation. There was a clear association between explanation type and inference (Fig. 3b): responses that included formal or teleological explanations were much more likely to result in Tax- than Eco-inferences \((t(41) \geq 4.38, p<.001, d \geq 0.68)\). In contrast, responses that included causal explanations were much more likely to include Eco- than Tax-inferences, \(t(41)=8.61, p<.001\), \(d=1.33\) ). This systematic relationship between explanation type and inferences, taken together with the evidence for the relationship between property and explanation type, is consistent with the proposal that explanations mediate the effect of property on inferences.

\section*{Discussion}

To examine whether explanations might moderate property effects in induction, we asked whether different properties were associated with different explanations, and then whether different explanations were associated with different inferences. We have answered both questions in the affirmative. First, different properties triggered different types of explanations. When participants were reasoning about ecological properties, the majority of explanations they provided were causal, referring to a mechanism that could have endowed the animal with the property (e.g., "Owls eat mice and could contract the flu from the mice that it eats"). In contrast, when participants were reasoning about taxonomic properties, they were less likely to use causal explanations, preferring formal explanations ("this cell could be specific to jaguars") or teleological explanations ("T5 is something to keep them warm"). Second, different explanations were associated with different inferences. Causal explanations were more likely to accompany ecological inferences, whereas formal and teleological explanations were more likely to accompany taxonomic inferences.

These findings are consistent with the idea that explanations serve as a mediator between properties and inferences. We acknowledge that these analyses are correlational, and therefore do not provide direct evidence that explanations play a causal role in property-specific inductive inference. Nevertheless, an informal comparison of effect sizes indicates that the mean effect of explanations on inferences ( \(d=1.18\) ) is larger than the mean effect of properties on inferences \((d=0.92)\). This suggests that property-driven explanations are likely to affect inferences directly, rather than being a mere correlate of properties.

\section*{General Discussion}

We provided evidence that property effects do not take place in retrieval. This questions the existing, but not tested, assumption in the field about the mechanism of property effects based on context-dependent retrieval of information from semantic memory (Heit \& Rubinstein, 1994). We also provided some promising evidence that property effects may result from participants generating explanations for the presence of the property in the premise category. If this finding persists, it could strengthen connections between research on explanations and on induction. Most researchers agree that these are related, but very little supporting empirical work exists, although it is increasingly acknowledged that the presence of an available explanation can reduce reliance on overall similarity and override effects of similarity and diversity on induction (see Lombrozo, 2006, for a review). In this project we demonstrated that
explanations do not just "mess up" existing regularities in induction, but may in fact be an important part of the mechanism of one such established regularity - property effects in induction.

To sum up, this project makes a step towards specifying the mechanism of property effects in induction in two ways. First, it suggests that property effects do not work via property-based retrieval of knowledge about premise categories from memory. Second, it introduces propertydriven explanations as a possible source of property effects. Of course, these proposals are not mutually exclusive, and our main suggestion for the further research would be not to abandon studying knowledge retrieval in induction, but to expand research on the mechanism of property effects to include explanations.

\title{
An Information Foraging Model of Interactive Analogical Retrieval
}

\author{
Swaroop S. Vattam \& Ashok K. Goel \\ Design \& Intelligence Laboratory, School of Interactive Computing, Georgia Institute of Technology \\ Atlanta, GA 30332 USA
}

\begin{abstract}
An essential first step in analogy is retrieval of a source analogue appropriate for the target situation. In this paper, we focus on the phenomenon of interactive analogical retrieval (IAR) wherein the source analogues are obtained through interaction with online information environments. We first provide a descriptive account of IAR based on two in situ studies. We then describe an information-processing model (called PRISM) that provides an explanatory account of IAR. We conclude with a discussion of some of the theoretical and technological implications of this work.
\end{abstract}

Keywords: analogy, analogical retrieval, biologically inspired design, design cognition, information foraging.

\section*{Introduction}

Analogy appears to be ubiquitous in human cognition and thus has received much attention in cognitive science (e.g., Burstein 1986; Carbonell 1986; Clement 2008; Gentner 1983; Davies, Goel \& Nersessian 2009; Dunbar 2001; Gentner \& Markman 1997; Hofstadter 1995; Holyoak \& Thagard 1989; Indurkhya 1992; Keane 1988; Kokinov \& Petrov 2001; Kunda, McGreggor \& Goel 2013; Nersessian 2008). An essential first step in analogical reasoning is the retrieval of a source analogue appropriate to the target situation. Here we focus on situated analogy wherein source analogues are obtained through interactions with an external environment rather than being recalled from internal longterm memory. In particular, we focus on the phenomenon of interactive analogical retrieval (IAR) wherein source analogues are accessed from Web-based online information environments.

In this paper, we first present a descriptive account of IAR based on two in situ studies of cross-domain analogies in biologically inspired design. Then, we develop an information-processing model that provides a partial explanation of IAR in terms of its underlying cognitive processes. Our model builds on Pirolli's (2007) information foraging theory of human online information-seeking behavior and Thagard et al.'s (1990) model of analogical retrieval by constraint satisfaction.

\section*{Interactive Analogical Retrieval (IAR)}

We investigate IAR in the domain of biologically inspired design (Benyus, 1997; Vincent \& Mann, 2002), the practice of developing innovative technology using analogies to biological systems. Some well-known examples of products of biologically inspired design include Velcro (inspired by the attachment mechanism of burr seeds), high-performance wind turbines (inspired by the pectoral fins of humpback whales), self-cleaning surface coatings (inspired by the
super-hydrophobic effect of lotus leaves), and fog harvesting devices (inspired by the arrangement of hydrophobic and hydrophilic surfaces on Namibian beetles).

From a cognitive standpoint, biologically inspired design entails cross-domain analogies for solving a target design challenge in, say, engineering, by transferring elements of a source analogue from a different domain (biology). In biologically inspired design, designers (often from engineering) typically are novices in biology: they know of only a small fraction of the vast space of biological systems that comprise the source domain. Thus, in practice the designers often try to access biological analogues from the Web. We call this phenomenon interactive analogical retrieval. (Due to limitations of space, our discussion of the in situ studies below is very brief; Vattam (2012) provides more details.)

\section*{Study Context and Methodology}

We conducted two in situ studies of designers engaged in biologically inspired design in Fall 2006 and Fall 2008 respectively. Both studies were conducted in the context of an interdisciplinary, senior-level, project-based course on biologically inspired design taught at Georgia Tech. The most important element of the course for us was the semester-long design projects. Each design project grouped an interdisciplinary team of 4-6 engineers and biologists based on similar interests. Yen et al. (2011) provide details of the teaching and learning in this course.

As external observers in the Fall 2006 study and participant observers in the Fall 2008 study, we attended almost all the classroom sessions, collected all the course materials, documented lecture content, and observed teacher-designer and designer-designer interactions in the classroom. We documented a total of ten biologically inspired design projects in the two studies. We attended the design meetings of selected teams many times to observe firsthand how the design process unfolded. We took field notes, collected all the design related documentation produced by the teams, and also collected their idea journals. We analyzed the gathered data focusing on the processes and the products of the designers. In terms of the practices, we observed and documented frequently occurring problem-solving and representational activities of designers. In terms of the design products, we observed and documented their "design trajectory" - the evolution of the conceptual designs over time.

\section*{Main Findings}

We found that designers often searched online for biological systems that are analogous to their target design problem. In
fact, this was one of the dominant approaches for finding biological analogues. Designers reported using a range of Web-based information environments, including (1) online libraries of scholarly articles such as the Web of Science, Google Scholar, ScienceDirect, etc., (2) online encyclopedias like Wikipedia, (3) popular life sciences blog sites like Biology Blog, (4) biomimicry databases like AskNature, and (5) general search engines like Google. Online libraries like Web of Science and Google Scholar were the most frequently used websites.

We noted that designers used several heuristics in order to find relevant biology articles, including "biologizing" the problem, problem reformulation, functional decomposition, and using domain-bridging abstractions such as functions, mechanisms, physical principles, etc.

We noted that online information environments on which the designers relied upon did not adequately support the task of finding useful biological analogues. In particular, the designers reported that the online search for analogies was not only time consuming, but often also work intensive, tedious and frustrating.

Our analysis of the designers' online search activity identified three main challenges. The first challenge is findability. The relative frequency of encountering relevant articles containing biological analogues was very low. Designers often went for long periods without finding a single source analogue in a retrieval process that typically extended over several weeks. A rough calculation suggests that designers spent approximately three person-hours of search time on the Web in order to find a relevant article.

The second challenge is recognizability. The designers were prone to making errors in judgment about the true utility of the information resources that they encountered. In almost all online environments, search queries brought back a ranked list of search results. An important aspect of the search process was assessing and selecting promising information resources from this list for further consumption. However, this decision had to be made based on limited information, (e.g., titles, keywords and abstracts of biology articles). In many instances, designers picked up on lowutility articles and spent a lot of time and effort trying to understand its contents, only to realize later that they were not actually very useful (false positives). False positives have both resource and opportunity costs. Conversely, there were situations where designers dismissed a resource that they encountered during the search as having low utility even though it actually contained useful information about a relevant biological analogue (false negatives). The false negatives represent missed opportunities.

The third challenge is understandability. The designers often found it challenging to understand the contents of the biological cases described in the online information resources and develop the knowledge required to transfer to their target problems. This was in part due to the scholarly nature of the biology articles that were encountered and partly because the articles often did not explicitly describe how a biological system worked from a design perspective.

\section*{PRISM: A Model of Interactive Analogical Retrieval}

We now present an information-processing model of IAR. Our goal here is to find explanations for the observed challenges of online analogy seeking, both for (i) understanding cognition in IAR and (ii) developing a technology for supporting online search for cross-domain analogies. Here we focus on the challenges of findability and recognizability; Vattam (2012) addresses the challenge of understandability of biological cases that requires a different kind of explanation.

Our model builds on two existing theories: Analogical Retrieval by Constraint Satisfaction (ARCS) (Thagard et. al. 1990), and Information Foraging Theory (IFT) (Pirolli 2007). IFT is itself a biologically inspired theory of online information seeking behavior. According to IFT, the online information seeking behavior of people is analogous to how animals forage for food in their natural environments. IFT posits that the human information seekers use information scent to navigate from one information region to another in an information environment that is inherently patchy in nature, and from one information patch to another within a region. IFT suggests that the information seekers adapt their behavior to the structure of the information environment in which they operate such that the system as a whole (comprising of the information seeker, the information environment, and the interactions between the two) tries to maximize the ratio of the expected value of the knowledge gained to the total cost of the interaction.

Although several models of analogical retrieval from internal long-term memory informed our work (e.g., Forbus, Gentner, \& Law 1995; Kokinov \& Petrov 1997; Kolodner 1993; Yaner \& Goel 2006), we chose to build specifically on ARCS because it provides a content account of the types of similarity that best explains our observational data. ARCS posits that in order to access sources (represented as schemas in long-term memory) that are analogous to a target (a schema in short-term memory), the access mechanism should simultaneously consider satisfying three kinds of constraints: semantic similarity (the overlap in terms of the number of similar concepts between the target and potential sources), structural similarity (the overlap in terms of the higher-order relationships between the target and potential sources), and pragmatic similarity (the overlap in terms of the pragmatic constraints or goals surrounding the target and potential sources). It is these three pressures acting simultaneously that distinguish analogical retrieval from other kinds of information retrieval.
Thus, on one hand, ARCS explains how source analogues are retrieved from the long-term memory but is silent about analogies situated in external information environments. On the other, IFT explains how people seek information in online information environments in general, but it does not address the pressures of analogical retrieval. Our model specializes IFT to online analogy seeking by introducing the pressures of analogical retrieval from the ARCS model into information foraging. Thus we call our model PRISM (PRessurized Information Scent foraging Model).

Figure 1. PRISM: An information-processing model of interactive analogical retrieval.

Similar to IFT, as Figure 1 illustrates, in PRISM the task of retrieving a source analogue is accomplished by two iterative processes that constitute the general information seeking behavior: between-patch processes (on the left side of the vertical dotted line) and within-patch processes (on the right side). Furthermore, the structure of Web-based information environments has evolved to exhibit certain regularities in the distribution of information resources and the navigation mechanisms that lead to those resources. For instance, when an analogy seeker encounters patches in an online environment, the seeker cannot perceive the contents of those patches all at once. Instead, they are presented with snippets of information, called proximal cues, which the analogy seeker uses to perceive the information scent of the distal information patches. The information scent leads to judgments about the utility of distal information patches and the information seeker can choose to either navigate towards or away from those patches.

\section*{Between-patch foraging}

Between-patch foraging explains the navigation process where the analogy seeker browses the information environment looking for high-utility information patches to consume. In the context of IAR, high-utility information patches correspond to information resources describing sources cases that are analogous to the target. In this process, numerous information patches (e.g., online articles, etc.) compete for the information seeker's attention. These patches may or may not contain information relevant to the goals of the information seeker. Thus, the analogy seeker
expends time and effort navigating from one patch to another until one that can be exploited is found. This is captured by the Formulate Query-Retrieve-Compute Information Scent cycle depicted in Figure 1.

Between-patch foraging using information scent in IAR works as follows. Given a target problem or situation:
1. The analogy seeker probes the environment by formulating and issuing a query. This query is contextdependent and represents the target problem.
2. In response, the environment retrieves and conveys an information region consisting of a set of information patches \(\left\{\left(P_{1},\left\{c_{11}, c_{12}, \ldots\right\}\right),\left(P_{2},\left\{c_{21}, \quad c_{22}, \ldots\right\}\right) \ldots\right\}\), where \(P_{i}\) is an information patch and \(c_{i j}\) 's are the proximal cues associated with the patch \(P_{i}\).
3. The analogy seeker perceives the information scent of the patches based on the proximal cues; the information scent is an estimation of the analogical relevance of different patches to the target: \(\left\{\left(P_{1}, S_{l}\right),\left(P_{2}, S_{2}\right) \ldots\right\}\), where \(P_{i}\) is an information patch and \(S_{i}\) is the information scent that the analogy seeker associates with the patch \(P_{i}\).
4. If the information scent of an information patch exceeds a certain threshold, it is considered relevant (high perceived utility). In this case, the information seeker goes to that patch (by acting on the environment like clicking the associated hyperlink), at which point the environment presents the information patch to the forager. This initiates within-patch foraging.
5. If the scent does not exceed the threshold, it is considered irrelevant (low perceived utility). In this case, one of two things may happen as depicted in Figure 1: (i) the analogy
seeker may stay within the same information region but loop back to Step 3 for processing the next patch in the region, or (ii) the analogy seeker may abandon the current information region and loop back to Step 1 in order to look for more fruitful regions.

\section*{Within-patch foraging}

Once the analogy seeker picks up the scent of a potentially useful information patch, the seeker goes to the patch and starts consuming information in it. In the context of biologically inspired design, this involves comprehending the contents of an article and constructing a mental model of the biological system described in the article. In the withinpatch foraging process, the analogy seeker is also simultaneously evaluating the actual utility of the patch by comparing/aligning/mapping the emerging mental model of the biological system against the target problem. If the evaluation is successful, the agent has obtained a source analogue. If this evaluation fails, then the between-patch foraging process is again initiated, either within the same information region that led to the current patch or with a search for new information regions as depicted in Figure 1.

\section*{Incorporating Pressures of Analogical Retrieval}

There are two potential places in our model where the three pressures of semantic, structural and pragmatic similarity might apply: Retrieve and Compute information scent tasks that are shaded in gray in Figure 1. The Retrieve process may use some notion of similarity to access information patches. But in our model, the Retrieve process is implemented in the environment (e.g., the Google Scholar search mechanism) and thus is black-boxed here. The Compute information scent process computes the perceived utility of an information patch as described below.

\section*{Information Scent Perception in PRISM}

While IFT explains the scent perception for non-analogy information seeking tasks, it has to be adapted to account for the semantic, structural and pragmatic pressures of analogical retrieval. Hence, as part of PRISM, we developed a different model of information scent perception.

Figure 2. Scent perception in PRISM
Our model of scent perception assumes that the analogy seeker has represented the target problem as a target schema as depicted in Figure 2. With a target problem in mind, the analogy seeker forages the information environment for
source analogues. Following the between-patch foraging process described above, the analogist encounters a set of information patches with associated proximal cues. When the analogy seeker encounters proximal cues in the environment, she builds corresponding scent schemas as indicated in Figure 2.

Given the target schema and competing scent schemas, the analogy seeker computes the similarity between the target and scent schemas in four stages similar to ARCS. We illustrate this process with an example. Let us suppose that the conceptual structures representing the dots in Figure 2 consist of predicates. Table 1 illustrates a target schema (P1) consisting of two predicates (P1-1 and P1-2), and two scent schemas (S1 and S2) consisting of two predicates each (S1-1, S1-2, and S2-1 and S2-2, respectively). Let us also suppose that \(A\) and \(M\) are semantically similar concepts, and likewise concepts \(B\) and \(N\) are semantically similar. For example:
A( \(a, b\) ) is Regulate(kidney, potassium_ions); \(M(m, n)\) is Control_Production(pituitary, estrogen); \(B(b, a)\) is Is_Secreted_By(erythropoietin, kidney); and \(N(n, m)\) is \(I_{-}\)Released_By(hypothalmic_hormone, pituitary)
Let us further suppose that \(A(a, b)\) is more important than the other predicates as dictated by the pragmatics of the target situation.

Table 1: Example Target and Scent schemas (adapted from Thagard et al. (1990), pp. 275).
\begin{tabular}{lll}
\hline Target-schema & Scent-schema-1 & Scent-schema 2 \\
\hline P1 & S1 & S2 \\
P1-1: A(a, b) & S1-1: M(m, n) & S2-1: M(n, m) \\
P1-2: B(b, a) & S1-2: N(n, m) & S2-2: R(n, m)
\end{tabular}

Suppose that predicates \(A\) and \(M\) are semantically similar; \(B\) and \(N\) are semantically similar; \(A(a, b)\) is more important (dictated by the pragmatics of the context).

Network Setup: In a manner similar to the original ARCS model, PRISM uses information about the semantic similarity of predicates in the target and scent schemas to create a constraint network. Figure 3 depicts the network corresponding to Table 1: units in the network represent the predicates in the target and scent schemas, and the links between units represent correspondences between the predicates.

The most important units hypothesize that a scent schema is analogous to the target schema. These units have names of the form TARGET=SCENT. ("=" here means "corresponds to," not identity). If the target is P1 and the scent is S 1 , then the \(\mathrm{P} 1=\mathrm{S} 1\) unit represents a correspondence between them. If \(\mathrm{P} 1-1\) is a proposition in P1 that corresponds to proposition S1-1 in scent S1, then the unit \(\mathrm{P} 1-1=\mathrm{S} 1-1\) will have an excitatory link with the unit \(\mathrm{P} 1=\mathrm{S} 1\).

Excitatory links are also set up from a special semantic unit to predicate-predicate units based on the degree of
semantic similarity of the predicates (in Figure 3, there are excitatory links from the semantic unit to \((\mathrm{A}=\mathrm{M})\) and \((\mathrm{B}=\mathrm{N})\) because they are semantically similar according to our assumption). Similarly, excitatory links are also set up from a special pragmatic unit to predicate-predicate units that are considered more important than others (in Figure 3, there are excitatory links from pragmatic unit to \((\mathrm{A}=\mathrm{M})\) because predicate A was assumed to be more important than others). The activation level of the special semantic and pragmatic units is always kept at the maximum value of 1 . Thus, they serve to pump activation to all units that are linked to it.

Inhibitory links are constructed between units representing incompatible hypotheses, for example, between \(\mathrm{P} 1=\mathrm{S} 1\) and \(\mathrm{P} 1=\mathrm{S} 2\). These make utility calculation competitive, in that choosing one scent will tend to suppress choosing of an alternative.

Figure 3. Constraint satisfaction network for computing analogical similarity between target and scent schemas of

Table 1 (following Thagard et al. (1990), pp. 275).
Running the Network: The constraint network is run by setting the activation of all units to a minimal initial (random) level, except for the special semantic and pragmatic units for which activation is clamped at 1 . Then the activation of each unit is updated by considering the activations of those units to which it has links. Cycles of activation adjustment continue until all units have reached asymptotic activation. As in ARCS, the activation of unit \(j\) on cycle \(t+1\) is given by:
\[
a_{j}(t+1)=a_{j}(t)(1-d)+\text { enet }_{j}\left(\max -a_{j}(t)\right)+\text { inet }_{j}\left(a_{j}(t)-\min \right)
\]

Here \(d\) is a decay parameter, enet \(t_{j}\) is the net excitatory input, and inet \(_{j}\) is the net inhibitory input (a negative number), with minimum activation \(\min =-1\) and maximum activation \(\max =1\). Inputs are determined by the equations:
\[
\begin{aligned}
& \text { enet }_{j}=\sum_{i} w_{i j} o_{i}(t) \text { for } w_{i j}>0 ; \text { and } \\
& \text { inet }_{j}=\sum_{i} w_{i j} o_{i}(t) \text { for } w_{i j}<0
\end{aligned}
\]
\(o_{i}(t)\) is the output of unit \(i\) on cycle \(t: o_{i}(t)=\max \left(a_{i}(t), 0\right)\).
Updating the constraint network continues until all units have reached asymptote, that is, a cycle is reached at which the activation change of each unit is less than a specified value, typically a low number (e.g., 0.01). (See Thagard et al. (1990) for more details about setting up the activation network, running such a network, computational complexity, etc.)

Scent of a Patch: When the network settles, the similarity between a target schema, \(P\), and a particular scent schema, \(S_{i}\), is equal to the activation value of the unit \(P=S_{i}\) in the constraint network. Higher the activation accumulated by the unit \(P=S_{i}\) the more analogically similar is the scent schema \(S_{i}\) to the target. The scent of a particular patch, \(I P_{i}\), which is associated with a set of proximal cues, \(\left\{C_{i j}\right\}\), is equal to the similarity between the scent schema, \(S_{i}\), obtained from \(\left\{C_{i j}\right\}\), and the target schema, \(P\).

\section*{Explaining the Challenges of IAR using PRISM}

The findability challenge is attributable to the current keyword-based indexing and access mechanisms in which the Retrieval process in Figure 1 supports access to information based on literal similarity (word-for-word matching) while ignoring semantic, structural and pragmatic similarity. As a result, each attempt at access can contain a large number of superficially similar cases as opposed to cases that are truly analogous, which entails a lower average information yield per region. This yield is inversely proportional to the number of times the Formulate-RetrieveCompute Information Scent loop is executed in the PRISM model depicted in Figure 1: a low yield implies more executions of the cycle. Therefore, between-patch foraging time is higher, the period between successive useful finds is longer, and the frequency of encountering useful information resources is lower.

The recognizability challenge is attributable to the nature of proximal cues that the information seeker encounters in common online environments - specifically, their lack of affordance for accurately perceiving information scent. Perceiving the scent of an information resource in the context of analogical retrieval requires accurately judging the deeper similarity between that target and the source case as represented by their proximal cues. However, the design of proximal cues typically contains small snippets of information, which is insufficient to construct richer schemas. This likely explains why the designers made many recognition errors in our studies.

\section*{Conclusions}

In this paper, we identified interactive analogical retrieval (IAR) as an important phenomenon in the context of biologically inspired design. We provided a descriptive
account of the phenomenon based on our in situ studies of designers engaged in online search for biological analogues to their problems. Our descriptive account identified three main challenges associated with IAR: findability, recognizability, and understandability. Although our in situ studies were conducted in the context of a classroom environment, we posit that these cognitive challenges are quite general: the same challenges are likely to occur in actual practice of biologically inspired design because although practicing designers are experts in their design domain, they are likely to be novices in biology. We posit further that IAR is a general phenomenon: IAR is not limited to biologically inspired design, but occurs whenever people are searching for cross-domain analogies in external online information environments.

We also developed a causal model of IAR called PRISM combining Pirolli's (2007) information foraging theory (IFT) and Thagard et al.'s (1990) ARCS model of analogical retrieval. PRISM extends IFT to account for analogy seeking; it expands ARCS into a model of information scent perception. PRISM provides explanations for the findability and recognizability challenges of IAR we observed in our studies of biologically inspired design.

PRISM could help develop new technology for helping designers find biological analogues more efficiently and easily: the model predicts that the findability and recognizability issues could be addressed, respectively, by changing the indexing and access mechanism and enriching the proximal cues in online environments. Biologue (Vattam \& Goel 2011) is an interactive tool for supporting biologically inspired design based on the PRISM model.

In terms of cognitive theory, we view analogy as situated in external information environments. If we take the boundaries of the cognitive system as including online information environments, as seems to be the case in biologically inspired design, then the phenomenon of IAR becomes an important element of understanding the situatedness of analogical reasoning. By folding in interactions with external information environments, PRISM may provide a starting point to think about a general theory of situated analogy.

\begin{abstract}
This paper presents a hybrid cognitive model engaged in experiments demonstrating a successful mechanism for applying top-down contextual bias to a neural speech recognition system to improve its performance. The hybrid model includes a model of social dialogue moves, which it uses to selectively bias word recognition probabilities at a low level in the neural speech recognition system. The model demonstrates how symbolic and neurologically inspired components can successfully exchange information and mutually influence their processing. Furthermore, the biasing mechanism is grounded in brain mechanisms of perceptual decision making.

\section*{Introduction}

Human cognition comprises high-level knowledge-based processes as well as low-level perceptual and motor processes, both of which are implemented via electro-chemical mechanisms in the brain. High-level cognitive processes are often viewed as symbolic and discrete, while low-level perceptual and motor processes are subsymbolic and continuous. Moreover, high-level processes are taken to operate on structured representations, while low-level processes will usually not be representational at all. Two key challenges in cognitive science are thus to understand (1) how high-level processes are realized in "neural hardware" and (2) how they can interact with low-level processes (e.g., how discrete symbolic knowledge can influence continuous subsymbolic processes and vice versa). We will focus on the second challenge in this paper.

Connectionist computational modeling has made significant progress in addressing (1) over the years, producing more and more refined neurologically plausible models of cognitive functions which are verified physiologically (e.g. (Machens, Romo, \& Brody, 2005)). However, fewer efforts have been made to address (2). Only recently, hierarchical Bayesian models have been proposed as a natural, systematic way to connect higher-level to lower-level processes (Kemp \& Tenenbaum, 2008). Similar to the Bayesian approach, our goal is to understand the interactions between these two types of processes which operate at fundamentally different levels.

Hierarchical Bayesian modeling often focuses on the "computational level" (Marr, 1982), showing how higherlevel processes can influence lower levels (e.g., by showing how distributions of higher-level structures constrain distributions of lower-level items). In contrast, our approach attempts to address all three levels and their mutual interactions. This is because these levels cannot be considered in complete isolation in cases where higher-level processes have to interact with lower-level processes in real-time contexts with realworld inputs. Specifically, we claim that the nature and timecourse of low-level processes imposes significant constraints on the possible ways of exchanging information with higherlevel processes. Low-level processes will limit the types of computations that are allowed in higher-level processes that communicate with them, since they may have stringent timing requirements and will not wait for a computation to finish with a result. Proposals that do not incorporate those constraints might result in models that produce correct results under some empirical regimes, but which are infeasible given implemenation constraints.

For example, a hierarchical Bayesian model of natural language processing might be able to show that high-level knowledge about grammar can successfully bias low-level speech processing, but whether that particular computational way of biasing is actually feasible and realistic in humans can only be determined by taking algorithmic and implementation constraints into account. These constraints include time bounds caused by the incremental nature of the speech processor. In this case the high-level computation can not expect to have access to a whole utterance before it starts biasing, since by that point the speech processor will already have advanced past the point where it is useful. Thus, although there are many ways in which higher levels could influence lower levels at the computational level, most of them are not realized in humans because of implementation or algorithmic constraints.

This paper makes three contributions: first, we will present a general way of integrating high-level processes operating on structured symbolic knowledge with low-level neural pro-
cesses with unstructured signals; second, we will show in the specific context of real-time biologically plausible speech recognition how high-level knowledge about diologues and mental states of interlocutors can be used to dynamically adjust parameters in the neural speech recognizer to improve recognition performance; and third, we will provide results from a real-time evaluation of the implemented model. The model includes a biologically plausible neural speech recognizer, a statistical/symbolic natural language understanding system, and a logic-based model of pragmatical and mental state inference. Previously, we have addressed the bottomup transfer of information, i.e., conversion from the continuous stream of auditory neural firings to symbolic word tokens expected by a natural language processing system (Veale \& Scheutz, 2012b). In this paper we address the reversed direction, the top-down transfer of information and biasing of low-level processes. Specifically, high-level knowledgebased representations of dialogue and interaction context will be used to bias auditory neural activity to improve word recognition performance in spoken language dialogues.

\section*{Background}

In humans and other animals, perceptual decisions are modulated by system state in a top-down manner. Top-down biases have been documented empirically in a variety of contexts such as vision search (Chen \& Zelinsky, 2006), perceptual decision about motion (Hanks, Mazurek, Kiani, Hopp, \& Shadlen, 2011), auditory disambiguation (Hannemann, Obleser, \& Eulitz, 2007)), and others. Furthermore, we are beginning to understand the mechanisms underlying these biases thanks to a combination of neurophysiological studies and behavioral research (e.g. see (Hanks et al., 2011). Perceptual decisions can be well-modelled using parallel diffusion processes (Ratcliff, Gomez, \& McKoon, 2004), and there is evidence that these processes are realized in the brain as neural integrators collecting evidence for each alternate hypothesis independently. Prior probabilities influence the neural integrators based on the past experience of the organism. These influences have been shown to be caused by top-down biases, although some evidence exists that sensory cortex parameters also adapt to match environmental priors (Fiser, Chiu, \& Weliky, 2004), which are outside the scope of this paper (Veale \& Scheutz, 2012a). The shape and parameters of the thresholds and the bias functions responsible for topdown biases on behavior are still under active investigation (Hanks et al., 2011). However, the detailed behavior of these processes is not necessary to implement a working model that takes advantage of the general mechanism of top-down bias to improve perceptual decisions.

In this paper we are specifically interested in top-down biases on auditory word recognition. Contextual biases on word recognition are ubiquitous in the everyday world. For example, visual context and gesturing can be used in noisy situations to produce a sensible hypothesis for what a speaker is saying. This is not a novel observation. Top-down bi-
asing of speech recognition probabilities have been investigated in a traditional speech recognition system (e.g. (Young, Hauptmann, Ward, Smith, \& Werner, 1989)). Our work differs from this previous work in that the speech recognition system is built of biologically-plausible neural circuits modelling the early human auditory system. Although the general concept of using context to bias state in the speech recognizer is similar, the non-symbolic nature of the speech recognizer in our system requires serious reconsideration of how to actually implement the top-down bias. In this paper we adopt a simple approach and bias the temporal integrators representing the competing word categories, which directly influences the symbolic output of the speech recognizer.

The next section presents a short overview of the two most relevant portions of the hybrid model used in this paper. It describes the mechanism for top-down biasing of the neural speech recognizer, and overviews how the system operates.

\section*{Model Overview}

The architecture of the cognitive model used for the experiments in the Experiment Setup Section is summarized in Figure 1. The neural speech recognizer (LSM ASR) is responsible for translating the acoustic signal into text tokens, which are sent to the NLP component. The NLP component parses the text tokens, and performs semantic analysis and utterance type classification. The dialogue system receives semantic information from NLP and updates the agent's beliefs, based on a pragmatic analysis (Briggs \& Scheutz, 2011). The dialogue component also tracks the state of the current dialogue exchange, allowing for predictions about expected upcoming utterance types. Details of how biasing is implemented in the speech recognizer and Dialogue components are presented in the sections below. The model is implemented in the DIARC cognitive architecture (Schermerhorn et al., 2006), whose natural language capabilities have been demonstrated in humanrobot interaction scenarios \({ }^{1}\) (Cantrell, Scheutz, Schermerhorn, \& Wu, 2010; Cantrell, Schermerhorn, \& Scheutz, 2011; Briggs \& Scheutz, 2012).

\section*{The Dialogue Component}

The dialogue component contains knowledge of common dialogue exchange patterns, such as those in Table 1.

Table 1: Dialogue exchange patterns
\begin{tabular}{r|l}
\hline Exchange Pattern & Dialogue Move Sequences \\
\hline Statement-Ack Pair & \(\operatorname{Stmt}(\alpha, \beta) \rightarrow \operatorname{Ack}(\beta, \alpha)\) \\
Yes-No QA-Pair (pos) & \(\operatorname{AskYN(\alpha ,\beta )\rightarrow \operatorname {Reply}Y(\beta ,\alpha )}\) \\
\(\rightarrow \operatorname{Ack}(\beta, \alpha)\) \\
Yes-No QA-Pair (neg) & \(\operatorname{AskYN(\alpha ,\beta )\rightarrow \operatorname {ReplyN}(\beta ,\alpha )}\)\begin{tabular}{r}
\(\rightarrow \operatorname{Ack}(\beta, \alpha)\) \\

}

Figure 1: Information flow through the natural language system. The blue arrow indicates the top-down dialogue context bias on the ASR component introduced in this paper.
\(\operatorname{Stmt}(\alpha, \beta)\) denotes a statement utterance direct from agent \(\alpha\) to agent \(\beta\), while \(\operatorname{Ack}(\beta, \alpha)\) denotes an acknowledgment (e.g. "okay") from \(\beta\) to \(\alpha\). AskYN and AskWH denote a yesno question and general question, respectively.

In this paper we focus on sending bias information to the LSM ASR component in the case of yes-no question-answer (QA) pairs. When the dialogue component detects a yes-no QA-pair has been entered, it sends a list of expected words to the LSM ASR component, specifically "yes" (ReplyY) and "no" (ReplyN). For each expected word \(x_{i}\), a weight value \(0 \leq w_{i} \leq 1\) is also sent to the LSM, denoting how much to weight \(x_{i}\) relative to other biased words (where 0 is equivalent to no bias and 1 indicates maximum bias).

\section*{The Speech Recognizer}

The neural speech recognition system employed in this paper has previously been used to perform speech recognition for real-time human-robot interaction tasks (Veale \& Scheutz, 2012b). The system converts from speech input streams to word tokens that can be used by other components of the cognitive model. The speech recognizer employs the liquid state machine (LSM) computational paradigm (Maass, Natschlager, \& Markram, 2002) to perform recognition on audio input streams. The LSM is implemented using spiking neurons, and readouts are trained via linear regression. Figure 2 presents the main components of the speech recognizer.

Sound is processed into auditory nerve firings corresponding roughly to the strength of frequency channels in auditory input (Figure 2, left). These neurons project to several groups of pre-processing neurons (superior olivary complex) via groups of differently parameterized synapses, resulting in neurons sensitive to the onset/offset/passthrough activity for each cochlear channel. These pre-processing neurons in turn project randomly to the recurrent circuit (liquid), which is a large circuit of randomly connected spiking neurons. "Readouts" (discussed below) are trained via linear regression on a corpus of sound files, with supervisor vectors set to +1 for all instances of the target category and -1 otherwise. Additionally, all readouts are counter-trained against a "noise" corpus in which every readout's supervisor vector is -1 .

Signal-to-Token Conversion Readouts (perceptrons) are trained via linear regression to respond positively to liquid
activity patterns similar to liquid activity patterns evoked by the word examples they were trained on. Readouts are integrated over time with exponential decay (low-pass filtered, time constant 20 ms ), and the value of these are continuously summed into the diffusors (right). In the model, readouts, integrators, and diffusors are only updated every 20 ms . The value of the readout integrator for readout \(r, \sigma_{r}\) is thus defined by the following equation (where \(\tau_{\sigma}\) is the time constant and \(I_{r}\) is the input from the corresponding readout):
\[
\begin{equation*}
\frac{\partial \sigma_{r}}{\partial t}=\frac{-\sigma_{r}}{\tau_{\sigma}}+I_{r} \tag{1}
\end{equation*}
\]

The diffusors compete with one another proportional to how strong their input is. The value of readout \(r\) 's diffusor, \(\Delta_{r}\), is updated according to the following rule:
\[
\begin{equation*}
\Delta_{r}(t)=\left(\Delta_{r}(t-1)+\sigma_{r}\right) \cdot \frac{\sigma_{r}}{\sum_{j}\left(\sigma_{j}\right)} \tag{2}
\end{equation*}
\]

This mechanism prevents the diffusion processes of ambiguous words from reaching threshold simultaneously. Using this system, there must be the equivalent of 100 ms of strong unambiguous evidence for a particular word category before it crosses threshold. This evidence could be provided by longer but weaker evidence, or by top-down bias.

Biasing Mechanism The biasing mechanism functions by injecting energy into the readout integrators, i.e., one level before the diffusion processes. The biaser specifies which categories should be biased, and the relative strengths for those biases. In the current paper, the amount of energy injected with a unit strength of 1.0 is equal to amount that is injected when the corresponding readout is active, thus up to "doubling" the input to the integrator at times when its presynaptic readout is active. Note that this implements the "simplest" diffusion model bias, involving linear bias to the diffusor's input diffusing to a constant threshold.

The result of bias is that biased words have "stronger" responses from their internal integrators, which translates to greater force of growth towards the diffusion threshold. This results in both faster reporting of the word (when the diffusor crosses threshold), and also stronger "confidence" in the word when the words offset is reported at the end of the word.

Figure 2: Visualization the neural model described in this paper. The pictured circuit has only 4 input channels, and a \(3 \times 3 \times 10\) recurrent circuit. The actual circuit has 84 input channels and a \(5 \times 4 \times 20\) recurrent circuit.

The LSM ASR was trained on five spoken instances of eight different words from the same speaker: yes, no, guess, bess, jess, joe, bob and a null response (background noise). The audio files used for testing are the same words spoken by a different speaker of the same gender. The words were chosen because several rhyme or have similar phonetic components to the "target" words "yes" ("guess", "bess", "jess") and "no" ("joe"), or share none ("bob").

The scenario we examine in this study consists of a simple yes-no QA-pair. The system is initiated with an intention to know whether its interlocutor possesses a particular mug in the belief component. The dialogue component, which queries the belief component for intentions to know information, generates the appropriate yes-or-no question:
```

Robot: Do you have the mug?

```

After this NL reuest is generated, a response audio file is presented to the system. These audio files consist of "yes" and "no" responses recorded from a different speaker. Four conditions were examined: (1) "Yes" response, no bias; (2) "Yes" response, with bias; (3) "No" response, no bias; (4) "No" response, with bias. Data from the LSM (integrated readout activity and word recognition score) was recorded at 10 millisecond intervals over the duration of the input.

\section*{Results}

The time course of the diffusors (solid lines) and readout integrators (dashed lines) for every word category are shown in Figures 3a (a "yes" trial) and 3b (a "no"trial). The primary comparison to make is the difference in the trajectories between the biased (each figure, bottom) and unbiased (each figure, top) trials. If the top-down biasing is working correctly, one should see a jump in activity over the unbiased trials for the contextually-appropriate words ("yes" and "no"), and no corresponding jump in any other words. This is precisely what is observed: even accidental weak responses to incorrect words ("bess" - purple in Figure 3b) do not seem to change
significantly between biased and unbiased trials, whereas response to the appropriate word ("no", yellow) does. Similarly for Figure 3a, the activation of the contextually-inappropriate yet similar-sounding word "jess" (teal) does not change significantly between the biased and unbiased cases, yet the activation of the contextually-appropriate yet incorrect word ("no", yellow) is increased. Meanwhile, the activation of the contextually-appropriate and correct word ("yes", red) is stronger in the biased case and quickly advances to threshold.

As a control, a third set of experiments were run in which the responder responded with the similar-sounding but contextually-inappropriate word "joe" (Figure 4). In this case, the trajectories for all words do not differ significantly between the bias and unbiased conditions. However, in the biased condition (Figure 4, bottom), a slight jump in the recognition of the contextually-appropriate word "no"is seen near the end of the utterance. This is expected because the tail end of "no" is similar to "joe", and the additional contextual bias on "no" was sufficient to produce a small amount of drift in the diffusor for the period of similar sounds.

\section*{Experimental Setup}

In terms of quantifying the advantage, one can look at the point at which recognition of the word reaches the confidence threshold (black horizontal bar). The diffusor in the "yes" unbiased condition (Figure 3a, top) crosses the recognition threshold at approximately 540 ms , whereas with bias the diffusor crosses the recognition threshold at approximately 470 ms (bottom), demonstrating a reduced recognition time. Note that the readout values for both "yes" and "no" responses are significantly increased in the biased condition compared to the unbiased condition, as both are anticipated as possible answers (whereas the readouts for the other word nodes remain relatively unchanged in amplitude). In the "no" unbiased condition, the diffusor crosses the recognition threshold at approximately 480 ms (Figure 3b, top), whereas with bias the diffusor crosses the recognition threshold at approximately 360 ms , again demonstrating a a reduced recognition

Figure 3: LSM ASR responses to "yes" and "no" stimuli in no bias condition (top) and bias condition (bottom). The trajectory of activity for the readouts and diffusors for all trained words in response to the injected sound is plotted over time after the question is asked. Dotted lines represent the individual readout integrators for each word, while solid lines represent the diffusors. In both cases, the diffusor for the correct word (red solid line on left, yellow solid line on right) crosses the threshold significantly quicker in the bias condition (bottom). The influence of the top-down bias mechanism can be clearly seen in the increased activity of the readout integrators for "yes" and "no" (red and yellow dotted lines, respectively) in the bias condition.
time. Keep in mind that these are different words that begin at slightly different times and which extend for different amounts of time and have different volumes and distances from the training corpus. Thus it is important to focus on the differences within a word to see the performance increases resulting from top-down biasing.

\section*{Future Work}

Expanding and refining the contexts in which top-down biasing of the speech recognizer will occur will provide ample opportunities for future research. For instance, incremental parse hypotheses in the NLP component could be used to identity likely upcoming words. Certain sentential modifiers (e.g. "I am now at the store" vs. "I am still at the store") can be used in conjunction with belief models and contextual knowledge for prediction purposes. If, for example, common ground in the dialogue exchange was established such that both speaker and listener knew the speaker was at the store previously. The partial sentence, "I am still at-" would be highly indicative of "..at the store". These semantic and belief model implications of these modifiers can be reasoned about in our pragmatics system (Briggs \& Scheutz, 2011). Additionally, some yes-no questions are actually conventionally indirect forms of general questions. For instance, "Do you know who has the mug?" is often an indirect form of, "Who has the mug?" and may elicit a name in response. Our natural
language system has mechanisms of recognizing and reasoning about such indirect speech acts (Briggs \& Scheutz, 2013, forthcoming), and therefore more precise biasing algorithms are ripe for investigation.

A more theoretically interesting extension of the current work will more directly address the theoretical issues from the introduction. In the current paper, only pseudo-symbolic readout neurons were influenced by the top-down bias. This allowed us to explore the time-constraint theme, but not the disconnects in representation between multiple levels. In the future it will be interesting to directly bias the state of the auditory circuit, to further explore how such interactions could take place.

\section*{Conclusion}

This paper introduced a hybrid neural-symbolic model that demonstrates not only the bottom-up communication of cognitive tokens from continuous sensory streams, but also the top-down biasing of neural speech recognition using predictions based on expected dialogue moves. The top-down biasing of the neural speech recognizer results in faster and more confident word recognition for contextually appropriate word categories during dialogue exchanges. The top-down biasing mechanisms are biologically accurate in that the effect of the top-down signal on high-level neurons in the speech recognition circuit parallels that observed in "diffusion" neurons

Figure 4: LSM readout results for "joe" response for no bias condition (top) and bias condition (bottom). Conventions are equivalent to figure 3. The diffusor for the actual uttered word "joe" does not significantly differ between the biased and unbiased conditions, crossing the threshold (black horizontal line) at roughly the same point in both conditions.
recorded from primate association cortex. The hybrid model presented in this paper engages interesting questions regarding interaction between different levels of abstraction. We use this to highlight that implementation-level details can actually constrain the computational level in real-time real-world situations. We believe that it is important to keep this relationship in mind when making claims about human cognition.

\begin{abstract}
Deaf individuals have difficulties in comprehending written text, as well as oral language. As a consequence, learning from text is compromised in deaf individuals. We hypothesized that a transposition of the Italian Sign Language to its written counterpart could enhance signing deaf individuals’ comprehension and learning from text. We confirmed our prediction for comprehension and learning for technical texts in Experiment 1 and for narrative texts in Experiment 2; signing deaf individuals' text comprehension and learning therefore benefit from a written language whose structure reflects the structure of their visual-spatial sign language. We speculate that, for signing deaf individuals, practice in reading written sign language texts might positively affect the ability to comprehend the written oral language texts.
\end{abstract}

Keywords: deaf individuals; text comprehension; learning; Italian Sign Language

\section*{Introduction}

Those who are unfamiliar with deafness may assume that the deaf individuals' auditory deficit can easily be circumvented through the use of written communication: if you have hearing problems, we can easily communicate through written texts. This naïve assumption disregards the nature of profound deafness. The ability to understand written texts presupposes high linguistic competence such as the ability to integrate information from different parts of a text and to derive its inner coherence. Due to their profound hearing loss, prelingually deaf individuals, who have never experienced oral language, have difficulties in comprehending the lexical, morphosyntactic, and pragmatic aspects of written verbal language (Van Hoogmoed et al., 2011). In addition, compared to hearing individuals, deaf individuals are less able to comprehend and remember details from a written text and to reason about the information contained in it (Marschark \& Wauters, 2008). Their specific difficulty in comprehending the holistic meaning of written texts seems to derive from difficulties in connecting different information together and in drawing inferences (Miller, 2002). Indeed, prelingually and profoundly deaf individuals possess adequate single-word
reading ability and vocabulary knowledge (Oakhill \& Cain, 2000). More generally, deaf individuals’ poor linguistic competence must be imputed to their atypical cognitive development (Marschark \& Hauser, 2008). For a start, in hearing individuals, sound plays a role from the earliest months of life in organizing visual attention: when a new event is signaled by sound, visual attention may be shifted appropriately (Smith et al., 1998). Hearing people use audition to monitor both their immediate and distant environment for changing events, while allowing vision to focus narrowly on the task at hand. In deaf individuals, the limited access to auditory information alters the way visual attention skills are deployed: visual attention becomes responsible for both focusing on the task at hand and monitoring events elsewhere in the visual field (Mitchell \& Maslin, 2007). As a consequence, deaf individuals tend to adaptively develop a more spatially distributed visual attention, whereas highly selective visual attention tends to prove difficult (Bavelier, Dye \& Hauser, 2006).
Auditory deprivation also has a direct impact on memory capacity: when hearing individuals are requested to remember simple stimuli such as words, pictures, or numbers, they tend to use a verbal-sequential coding of a phonological or acoustic nature (Marschark \& Mayer, 1998). Deaf individuals appear instead to rely heavily on visuo-spatial coding: their incomplete mastery of language skills detracts from using language as an effective cognitive tool. Consequently, deaf people tend to have a shorter memory span for linguistic materials, compared to hearing people (Logan, Mayberry \& Fletcher, 1996). By contrast, deaf people perform as well as or even better than hearing people on tasks that involve visual or spatial processing (Cattani, Clibbens \& Perfect, 2007).
Furthermore, it has been shown that deaf individuals, in comparison to hearing individuals, have more difficulty with abstract reasoning (Marschark \& Hauser, 2008). In particular, they have difficulties in verbal-analogical reasoning, which requires high-level linguistic skills, and the ability to understand not simple items but complex structures (Edwards et al., 2010). By contrast, deaf people
are not impaired at perceptually based reasoning: they perform as well as hearing people on non-verbal cognitive tasks that do not require the overt use of verbal language, such as figural-geometric analogy tasks, and in visualspatial information processing (Marschark \& Hauser, 2008). However, deaf individuals' moderate skills with abstract reasoning are also due to their broader difficulty with verbal language (Easterbrooks \& Scheetz, 2004).
All this considered, providing deaf individuals with suitable forms of written materials to support their comprehension and learning from texts in educational contexts, is a very important challenge. The focus of our investigation are signing deaf individuals, who are exposed to a natural sign language at birth. Sign languages exhibit grammatical structure at all linguistic levels. However, the acquisition of sign languages features constraints unique to the visual modality (Morgan, Barrett-Jones \& Stoneham, 2007).

\section*{A Written Form of Sign Language}

Sign language is visuo-spatial in nature and has no written counterpart. Some attempt were made to devise appropriate means for representing sign languages: examples are Stokoe-based notations for notating single, decontextualised and standard signs (Pizzuto, Rossini \& Russo, 2006), and Sign Writing, a writing formalism based on transcription of manual and also non-manual elements of non-standard signs and complex units through symbols (Sutton, 1999). These methods require a training to learn to interpret the proposed notations.
Within a less ambitious perspective, we reasoned that some of sign language's features could, however, be reflected in its transposition to a written form. We assumed that such a written sign language might improve signing deaf individuals' comprehension and learning from text by promoting the activation of the visual thought schemata that are activated by the sign language itself (Wilbur, 2000). In particular, our assumption is based on considerations concerning the structural features of written sign language along with the particular cognitive functioning of signing deaf individuals.
First, the written form of sign language offers deaf individuals the possibility to process written linguistic information provided in a syntactic structure that reflects the structure of the corresponding sign language. In sign languages, space has a grammatical function, i.e. it is used to create and maintain cohesion among the different parts of the discourse (Morgan et al., 2008). Thus, for example, sentences in sign languages begin by identifying one or more loci in the spatial mapping, "the process used by the signer to reflect mental representations in physical space for reference and subsequent coreference in discourse as a cohesive device" (Winston, 1995, p.87). Subsequently,
signers point to a precise locus in space in order to evoke to the interlocutors the element that was originally 'placed' there. The particular function of space in sign languages generates a different discourse structure that has no counterpart in oral languages (Pyers et al., 2010).
Second, the text of a phrase in an oral language is longer than the corresponding text in the written sign language version: the written sign language text, like the sign language itself, lacks articles, prepositions, conjunctions, pronouns, and verbal auxiliaries. This claim holds at least for Italian Sign Language (LIS), which makes little use of finger spelling. As signing deaf individuals have a shorter memory span for linguistic material than do hearing individuals, they should benefit from this feature of the written sign language.
Third, signing deaf individuals, as compared to hearing individuals, have a more spatially distributed visual attention; this cognitive peculiarity, along with the consideration that a phrase in written sign language is shorter than the corresponding written phrase from the oral language, leads to the hypothesis that signing deaf individuals can extract in a glance more information from the written sign language text than from the written oral language text.
We tested the prediction derived from our assumptions on Italian signing deaf individuals.

\section*{Experiment 1: Does Written LIS Facilitate Text Comprehension in Signing Deaf Individuals?}

The deaf participants in the experiment were invited to carefully read two texts; they were then invited to recall as much information as they could. Each participant was presented with one text in Italian and another in LIS. We predicted a better recall for the LIS text. Hence, although we did not measure the participants' reading abilities, we made each participant act as his/her own control in the two experimental conditions.

\section*{Method}

Participants Twelve signing deaf adult individuals (5 females and 7 males; mean age: 26 years) with a prelingual and profound hearing deficit (>90 dB hearing loss) and no other disabilities voluntarily took part in the experiment. They were all university students who learned the LIS as their first language from their first year of life.

Materials and Procedures The experimental materials comprised two technical written Italian texts, one concerning the principles of how airplanes fly (Airplane flight, 312 words), and one about the effect on individuals produced by color perception (Responses to color, 315 words) (for excerpt see Appendix 1). For each text, we produced a written LIS version, parallel to the written

Italian version (266 and 243 words for Airplane flight and Responses to color, respectively). To create the written LIS version, a native-speaking signing deaf Italian university student read each Italian text carefully several times and was then video-recorded while translating the text into LIS. She then transcribed the signs produced in the translation into Italian words. The punctuation was introduced for each pause, in order to segment the different phrases, taking into account both manual (signs) and non-manual (facial expressions and body movements) markers occurring simultaneously. Consider, for example, the following excerpt from the Airplane flight written Italian text: "When an aeroplane is in flight, the air divides as it hits the front of the wing. Some of it flows over the upper part of the wing, and the rest over the lower part. The two air flows come together again behind the wing." As an example of the results of the translation, consider the parallel written LIS version of the excerpt above: "Example, plane flies, wing air hits wing in front of, then air divided 2, to go wing over, to go wing under, after air together to go wing behind." Obviously, the English translation of the written LIS texts is not equivalent to the result of transposing the British Sign Language or American Sign Language texts to their written counterparts.

The translations of the two Italian texts to written LIS were evaluated individually by a LIS interpreter and by a LIS deaf teacher to ascertain that the translations as provided by a native signing deaf individual were also acceptable on behalf of them. For the goal of our investigation, it is important to test the beneficial effect of the written sign language when realized by a native signing deaf individual, naïve with respect to trainings and education to become either an interpreter or a deaf teacher. At first, the interpreter and the deaf teacher were invited to watch carefully the two videos, one at a time, and afterwards they considered each single sign produced, taking into account both the manual and the non-manual components. For each semantic unit they were invited to evaluate the appropriateness and comprehensibility of the LIS translation through the following judgments: "Not at all adequate", "Barely adequate", "Adequate on the average", "Adequate". On average, the \(93 \%\) of the semantic units from the Airplane flight text, and the \(96 \%\) of the semantic units from the Responses to color text were judged as at least "adequate on the average"; none of the translations were judged as not adequate at all.
The participants encountered both texts (Airplane flight and Responses to color), one in Italian and the other in LIS. In each group, half of the participants dealt first with the Airplane flight text and the other half with the Responses to color text, so that, overall, the occurrence of each text in the Italian version and the LIS version was counterbalanced. The participants were invited to read each text carefully, one at a time, with no time limits; as soon as they finished reading each text, they were asked to recall as much
information as they could. The recollection was in LIS. All of the participants were video-recorded.
To code the results, each text was divided into 41 semantic units, corresponding to as many main concepts as the hearer could recall. For each text, there is a strict correspondence between the semantic units in the two versions (Italian and written LIS). Two independent judges coded the participants' recollections individually; the judges reached a significant level of agreement on their first judgments for the overall group of participants in the two experimental conditions, calculated using Cohen's K (Cohen's K ranging from .87 to .97 , p always <.001). For the final score, the judges discussed each item on which they disagreed, until they reached full agreement. Each concept (i.e., semantic unit) recalled by the participants was evaluated according to the following coding schema (see also Cutica \& Bucciarelli, 2008; 2011, Vendrame, Cutica \& Bucciarelli, 2010):
Correct recollection: a semantic unit recollected either literally or as a paraphrase;
Discourse-based inference: a recollection in which the participant gives explicit information that was originally implicit in the semantic unit;
Elaborative inference: a semantic unit recollected with the addition of plausible details;
Error: a recollection whose meaning is inconsistent with the semantic unit.
Each participants' recollection was coded as pertaining to just one category. Correct recollections and discourse-based inferences were considered indicators of comprehension and learning from text. Consider, for example, the following semantic units in the Italian color text: "He observed that the function deteriorated in low light but increased in bright light" and the following recollection by a participant: "Example: bright light finger to tap fast; low light finger to tap slow; finger to tap normal normal light". According to the coding schema, we considered the statements "Example: bright light finger to tap fast" and "low light finger to tap slow" as correct recollections, and the statement: "finger to tap normal normal light" as a discourse-based inference.
As a further example, considering the semantic unit in the Written LIS aeroplane text "Wing over this is pressure less", the recollection "the air under pressure to increase, it makes a support, an help" has been coded as a discourse-based inference, whereas the sentence "the pressure to increase wing over" has been coded as an error.

Results and Discussion The two texts were comparable in difficulty; considering each type of recollection separately, we found no differences in performance with the two texts in either the LIS or the Italian versions (unpaired T-test: t (22) comprised between .0 and 1.48 , p comprised between .15 and .1 ). Hence, we pooled together the results for the two Italian versions and those for the two LIS versions.

Table 1 illustrates the mean types of recollection for both the LIS and the Italian versions of the texts. The results show that they produced more correct recollections and fewer errors in the written LIS version than in the written Italian version ( T -test: \(\mathrm{t}(11)=3.43\), tied \(\mathrm{p}=.003\), and \(\mathrm{t}(11)=3.095, \mathrm{p}=.01\), respectively), whereas there was no difference in production of discourse-based (T-test: \(\mathrm{t}(11)=.82\), tied \(\mathrm{p}=.22\) ) and elaborative ( T -test: \(\mathrm{t}(11)=0, \mathrm{p}=1\) ) inferences.

The results of Experiment 1 confirmed our predictions. Signing deaf individuals benefited from the written LIS version of the technical texts. However, maybe because of the considerable technical content of the two texts, we did not observe a benefit from the LIS versions in terms of discourse-based inferences, which denote a deep comprehension of the text (Cutica \& Bucciarelli, 2008). A related, more general question is whether the observed facilitatory effect of the written LIS versions depends on the discourse content, be it technical or narrative in nature. The aim of Experiment 2 was to replicate the findings of Experiment 1 with narrative texts.

\section*{Experiment 2: Does Written LIS Facilitate Comprehension Independently on the Text Content?}

Experiment 2 set out to replicate Experiment 1 with narrative texts.

\section*{Method}

Participants Twelve signing deaf individuals (4 females and 8 males; mean age: 26 years), university students with a prelingual profound hearing deficit ( \(>90 \mathrm{~dB}\) hearing loss), took part in the experiment voluntarily. They had learned LIS as their first language since their first year of life. None of them had other disabilities, nor had they taken part in Experiment 1.

Materials and Procedures The experimental materials comprised two texts, one about the Savannah and one about Mammals (each text contained 346 words) (for excerpts see Appendix 2). For each text, we created a written LIS version
(183 and 204 words for the Savannah and the Mammals texts, respectively), following the same procedures used in Experiment 1.

As for Experiment 1, the translations of the two Italian texts to written LIS were evaluated individually by a Italian LIS interpreter and by a LIS deaf teacher, the same as in Experiment 1. On average, the \(100 \%\) of the semantic units from the Mammals text, and the \(99 \%\) of the semantic units from the Savannah text were judged as at least "adequate on the average"; none of the translations were judged as not adequate at all.

Each participant dealt with both the Savannah and the Mammals text, one in Italian and the other in LIS. Half of the participants dealt first with the Savannah text and the other half with the Mammals text, so that, overall, the occurrence of each text in the Italian and the LIS version was counterbalanced. The participants were invited to read each text carefully, one at a time, with no time limits. As soon as they finished reading each text, they were invited to recall in LIS as much information as they could, during which time they were video-recorded.
To code the results, the two versions of both texts were divided into 38 semantic units, corresponding to as many main concepts as the hearer could recall. As for Experiment 1, for each text (Savannah and Mammals), there is a strict correspondence between the semantic units in the two versions (Italian and Written LIS). Two independent judges coded the participants' recollections individually; the judges reached a significant level of agreement on their first judgments for the overall group of participants with the two versions of the texts, calculated using Cohen's K (Cohen's K ranging from .82 to .89 , p always <.01). For the final score, the judges discussed each item on which they disagreed, until they reached full agreement. Each concept (i.e., semantic unit) recalled by the participants was evaluated according to the same coding schema used in Experiment 1. Consider, for example, the following semantic unit in the written LIS Savannah text: "Food gives animal which? Giraffe"; according to the coding schema, the statement: "Acacia leaves to serve as food giraffe" has been coded as correct recollection, the statement: "Plant acacia serves for improving existence, growth giraffe" as elaborative inference, and the statement: "Animals do not eat acacia" as an erroneous recollection. As a further example, the recollection "Mother pecks egg, exit with help mother" has been coded as a discourse-based inference with respect to the semantic unit in the Italian text "(The shell is to tough) that the mother ostrich sometimes needs to help the chicks to break out".

Results and Discussion The two texts were comparable in difficulty; considering each type of recollection separately, we found no differences in performance with the two texts in either the LIS or the Italian versions (unpaired T-test: \(\mathrm{t}(10)\) ranging from 0 to \(1, \mathrm{p}\) ranging from 1 to .34 ). Hence,
we pooled together the results of the two Italian versions and those of the two LIS versions. Table 2 illustrates the mean types of recollection for each coding category for both versions of the texts.

Table 2: Mean types of recollection (and standard deviation in parenthesis) by the participants in Exp. 2.
\begin{tabular}{|c|c|c|c|c|}
\hline \begin{tabular}{c}

based \\
inferences
\end{tabular} & \begin{tabular}{c} 
Elaborative \\
inferences
\end{tabular} & Errors \\
\hline Written & 11.17 & .58 & .25 & 1.00 \\
LIS & \((5.24)\) & \((.67)\) & \((.45)\) & \((.74)\) \\
\hline Written & 8.50 & .33 & .08 & 1.50 \\
Italian & \((4.36)\) & \((.49)\) & \((.29)\) & \((1.38)\) \\
\hline
\end{tabular}

The results show that signing deaf individuals produced significantly more correct recollections in the LIS than in the Italian version (T-test: tied \(\mathrm{t}(11)=2.13, \mathrm{p}<.03\) ), yet they produced comparable numbers of discourse-based inferences in the two versions (T-test: tied \(\mathrm{t}(11)=1, \mathrm{p}=.17\) ). Furthermore, the differences in production of elaborative inferences and errors in the two versions were not statistically significant (T-test: \(\mathrm{t}(11)=1\) and \(1.15, \mathrm{p}=.34\) to .28, respectively).
The results of Experiment 2 replicated those of Experiment 1: written LIS facilitated deep comprehension and learning from text, in terms of an increase in correct recollections. The conclusion holds independently of the nature of the text, be it technical or narrative. A possible reason why we failed to detect a beneficial effect for written LIS in terms of discourse-based inferences is that deaf individuals have difficulty in drawing inferences (see also Easterbrooks \& Scheetz, 2004).

\section*{General Discussion}

When reading and processing written texts of vocal languages, deaf individuals are more likely to treat written information as unrelated pieces rather than seeking commonality. Crucial features of all sign languages are the spatial arrangement of the signs, the highly characteristic, marked facial expressions or postures, and the gaze direction. Unlike the sequential ordering of the sentence elements in verbal languages, the rich morphosyntactic structure of visual-gestural languages is organized in spatial terms. We assumed that signing deaf individuals' comprehension and learning benefit from a written text that reflects the structure of their sign language, because such written texts might be comprehended using categories that belong to the sign language organization rather than the natural language organization. The results of our experiments on 24 profoundly deaf individuals confirmed the predictions derived from our assumptions. In particular, in both experiments we observed the beneficial effects of the written LIS compared to the written Italian in terms of
an increase in correct recollections by the signing deaf participants.
These results are in line with our assumptions: the written form of sign language offers deaf individuals the possibility to process written linguistic information provided in a syntactic structure that reflects the structure of the corresponding sign language; signing deaf individuals, who have a shorter memory span for linguistic material than do hearing individuals, benefit from the lack of articles, prepositions, conjunctions, pronouns, and verbal auxiliaries in the written sign language; signing deaf individuals, who compared to hearing individuals have a more spatially distributed visual attention, can extract in a glance more information from the written sign language text which is shorter than the written oral language text.
Our finding has strong implications; as deaf people have difficulties in comprehending the written versions of oral languages, their opportunities to learn from written texts and therefore to benefit from school and university education - are heavily restricted. Providing them access to written texts reflecting their sign language would be a step towards an improvement of their ability to comprehend the written versions of oral languages. Consistent, Oakhill and Cain (2000) already hypothesized that for deaf individuals who are fluent in signing, "it would be possible to present written texts via sign language in order to teach skills such as inference making, comprehension monitoring, and the planning and structuring of stories" (ib., p.58). On the basis of the results of our study, we argue that a written version of LIS could be used as an educational tool, in order to approach signing deaf children onto written verbal languages and improve their comprehension skills. Further studies would be useful to investigate in depth the effectiveness of trainings on texts comprehension exploiting written sign language both on adult signing deaf individuals, as well as on signing deaf children.

\begin{abstract}
This article reports on an experiment in which artificial languages with whistle words for novel objects are culturally transmitted in the laboratory. The aim of this study is to investigate the origins and evolution of combinatorial structure in speech. Participants learned the whistled language and reproduced the sounds with the use of a slide whistle. Their reproductions were used as input for the next participant. Cultural transmission caused the whistled systems to become more learnable and more structured. In addition, two conditions were studied: one in which the use of iconic form-meaning mappings was possible and one in which the use of iconic mappings was experimentally made impossible, so that we could investigate the influence of iconicity on the emergence of structure.
\end{abstract}

Keywords: iterated learning; iconicity; combinatorial structure; phonology; cultural evolution; duality of patterning

\section*{Introduction}

Duality of patterning, one of Hockett's (1960) basic design features of language, has recently received increased attention (de Boer, Sandler, \& Kirby, 2012). This feature describes how, in speech, a limited number of meaningless sounds are combined into meaningful words and those meaningful words are combined into larger constructs. How this feature emerged in language is currently still a matter of debate, but it is increasingly being studied with the use of a variety of different techniques such as computer simulations and laboratory experiments. In one of these laboratory experiments, the emergence of combinatorial structure was studied through transmission of artificial whistled languages in the laboratory (Verhoef, Kirby, \& Padden, 2011). For this study the experimental iterated learning paradigm (Kirby, Cornish, \& Smith, 2008) was used. Iterated learning refers to the process of cultural transmission, in which individuals acquire a social behavior by observing the performance of others who also acquired it from observation (Kirby et al., 2008). The results demonstrated that sound systems, when passed on in a transmission chain, adapt to cognitive biases and become easier to learn (Verhoef et al., 2011). Combinatorial structure emerged and the whistled systems became more efficiently coded over generations (Verhoef, 2012). These results demonstrated a possible route towards the emergence of structure in the sounds of speech. The findings challenge
the hypothesis that Hockett (1960) introduced when he linked the emergence of structure to vocabulary expansion and signal dispersal. Even in the case where only a small set of sounds is transmitted and the signal space is not maximally used, combinatorial structure emerges (Verhoef et al., 2011; Verhoef, 2012). In that experiment the influence of semantics was controlled for and the signals did not refer to any concrete meanings. Obviously, in natural human languages meanings are important and the role of semantics in the evolution of linguistic structure should not be ignored (Schouwstra, 2012; Dingemanse, 2012). Would the introduction of semantics influence the emergence of combinatorial structure at the level of phonology? In this article a new experiment is presented in which artificial whistled languages are culturally transmitted and the whistled signals refer to meanings.

\section*{Combinatorial structure versus iconicity}

Arbitrariness was another design feature Hockett (1960) listed for language. This feature refers to the arbitrary mapping between words and their meaning. Hockett uses the words 'whale' and 'microorganism' as an example: 'whale' is a short word for a large animal, while 'microorganism' is the reverse. It has been argued that non-arbitrariness is rare in modern languages and that it is irrelevant for understanding linguistic structure (Newmeyer, 1992). More recently, however, researchers began to realize that non-arbitrary formmeaning mappings may be more widespread than initially thought. When exploring beyond Indo-European languages, non-arbitrariness seems to play a role in many languages (Imai, Kita, Nagumo, \& Okada, 2008; Dingemanse, 2012). This involves classes of words where for instance the shape, complexity, sound or some other characteristic of the meaning expressed is mimicked or iconically represented in the word. Examples have been identified as 'ideophones', 'mimetics' or 'expressives' and the phenomenon is often called sound symbolism.

Sound symbolic mappings in language have been connected to cross-modal mappings in the human brain (Simner, Cuskley, \& Kirby, 2010; Ramachandran \& Hubbard, 2001). There appear to be many cognitive biases in cross-modal perception that are shared by most people. The bouba/kiki ef-
fect is one famous example that shows a strong preference to relate sharp shapes to the name 'kiki' and round shapes to the name 'bouba' (Ramachandran \& Hubbard, 2001). Such shared biases have been argued to play an important role in the evolution of language, by forming a starting point for the initial emergence of grounded speech (Ramachandran \& Hubbard, 2001).

A newly emerging sign language, Al-Sayyid Bedouin Sign Language (ABSL), has recently been described, in which the evolution of duality of patterning can still be observed (Sandler, Aronoff, Meir, \& Padden, 2011). Even though ABSL is a fully functional and expressive sign language, its combinatorial structure appears to be less discrete (Sandler et al., 2011). Could it be the case that this young sign language was able to survive up to now without duality of patterning because the manual modality allows for much iconicity and the language is learnable and transmissible enough without phonological structure? When most mappings are transparent, they may be more intuitive and easier to remember as holistic entities. On the other hand, it has been shown that there is actually an advantage for arbitrary mappings in acquiring word meanings in context (Monaghan, Christiansen, \& Fitneva, 2011). A secondary objective of the experiment described below is to investigate how iconic formmeaning mappings influence the emergence of combinatorial sub-lexical structure. The experiment is similar to the experiment described by Verhoef et al. (2011) and Verhoef (2012), but with meanings attached to the whistled signals. Two conditions were studied: one in which the use of iconic form-meaning mappings is possible and one in which the use of iconic mappings is experimentally made impossible. This was expected to provide insight into the possible role of iconicity in the emergence of duality of patterning since it could reveal whether a situation that allows for more iconicity, can 'survive' without the emergence of combinatorial structure longer.

In summary, the objective of this study is as follows. First and foremost, we investigate whether the addition of meanings leads to a result that is similar to what was found in the whistle experiment without meanings, to see if combinatorial structure also emerges in the presence of semantics. Second, we search for any differences between the two conditions to see whether iconicity could cause a delay in the emergence of structure.

\section*{Method}

In this experiment participants were asked to learn and reproduce whistled signals with a slide whistle (see figure 1) as names for objects they saw on a computer screen. There were twelve whistled signals in the training set in total.

The meanings were unusual objects that look like possible mechanical parts, but they are novel objects for which we do not have words in existing languages. The objects were a subset from those created by Smith, Smith, and Blythe (2011) that were slightly modified. To reduce the structure in

Figure 1: Slide whistle
the meaning space, all objects were transformed to blue tone and could therefore not be grouped by their color. They also did not share shapes or parts and were not structured in any other obvious way. This was needed to limit the emergence of semantics-related compositional structure. A few examples of objects that were used are shown in figure 2 .

Figure 2: Examples of novel objects used in the experiment
Following the paradigm of experimental iterated learning (Kirby et al., 2008), the last whistle sounds that a participant produced for each object were used as the input given to the next participant. However, this is the point where the two conditions differ from each other. In one condition, the 'intact' transmission, the next participant was exposed to the output of the previous participant exactly as it was produced. The mapping from whistled signals to objects was kept intact. In the other condition, the 'scrambled' transmission, the output of the previous participant was altered before it was given to the next person. The produced form-meaning mappings were broken down by scrambling the mappings at each change of generation and by using a different set of objects between consecutive generations. In this way, if there were any iconic relations to emerge in the sets, it would only be helpful for the participants in the first condition and any semantics-related structure is broken down in between the transmission steps. Only the signal sets themselves stay intact.

\section*{Procedure}

During the experiment participants completed three rounds of learning and recall, which were alternated by 'guessing game' rounds. In the learning phase the objects and their corresponding whistle were presented one by one in a random order, and participants recorded an imitation of the whistle. In the recall phase a panel was shown with a button for each object and the participant had to choose each of the objects once to record the right whistle for it from memory. The guessing phases were introduced to encourage people to keep paying attention to the mapping between whistle sounds to objects. In this phase the whistles were played one by one in a random order and for each whistle the participant had to choose
the right object from a panel. This was done with half of the whistle-object pairs after the first learning phase and with the other half after the second. The whistles from the last recall phase were used as training input for the next participant, depending on the condition either with intact or scrambled whistle-object mappings. Transmission was continued from person to person until there were eight generations in each chain and four chains per condition.

\section*{Initial input sets}

Two separate initial whistle sets were constructed. Each set was used as the starting point for half of the chains in each condition. The whistles were taken from a database of whistles that were collected during a pilot study. During this pilot, people were asked to freely record a number of whistles. The two initial sets were constructed so as not to exhibit combinatorial structure. To achieve this, the entropy measure for quantifying combinatorial structure from Verhoef (2012) was used. Sets of twelve whistles were generated randomly from the database until two sets were found with no overlap, that had a comparable and relatively high measured entropy.

\section*{Participants}

In total 64 participants took part in the experiment. They were divided over eight transmission chains, four in each condition. Participants were recruited from the University of Amsterdam community through posters and e-mail invitations. All participants were between the ages of 19 and 41 years old, 43 were female and 21 male. In each chain either two or three men participated. They were compensated for their time with a cash payment of 10 euros.

\section*{Qualitative results}

This section describes qualitative observations as a first impression of the data. The internal structure of the whistle sets is investigated as well as the role of iconicity.

\section*{Internal structure in whistle sets}

On the level of the signals, independent of the objects they refer to, it can be observed that structure develops in a manner that is very similar to what could be observed in the experiment without meanings. Like in that experiment, whistles were introduced that were clearly related in some way to the form of some whistles that already existed in the set. Mirrored versions, combinations of existing whistles, repetitions of the same pattern within a whistle or whistles with similar shapes but different whistle manners for instance appeared. Figure 3 shows an example from one of the chains in the scrambled condition. Here, at generation four, two whistles were in the set that followed approximately the same shape in pitch contour (down and up), but were whistled in a different manner. One of them was whistled in a smooth and unbroken fashion and the other was more staccato-like and broken into pieces. In generation five, one half of each of these whistles is borrowed and reused to form a new whistle. The left part

Figure 3: Development of structure in a chain from the scrambled condition. See main text for an explanation.
of the smooth whistle is also reused and combined with existing whistles. In later generations, these are reproduced and all kinds of other variations on this appear, such as ones that are mirrored again as a whole.

Figure 4: Development of structure in a chain from the intact condition. See main text for an explanation.

Figure 4 shows an example from one of the chains in the intact condition. In this example one whistle from generation three seems to be the inspiration for two new whistles in the next generation: one with one 'bump' and another with two. In generation five the 'two bump' whistle is started to be reused and combined with another pattern and in generation six both the one bump and two bump whistles are being reused, mirrored and recombined more widely. An existing whistle with several up and down movements is even segmented into two parts, where the first part is again the two bump whistle.

To examine the final result of these gradual changes in the chains, we can look at the set of whistles produced by the eighth and last participant in a chain. Figure 5 shows a frag-

\section*{Iconic whistle-object mappings}

When talking about mappings between whistle sounds and objects one may wonder how a whistle sound can iconically depict a visual object. This is difficult to identify as an outside observer, since iconicity is subjective and depends on experience and individual history. However, some examples could be found in the form-meaning pairs in the current data and iconicity could take several different forms in these examples. Most often, the shape of the whistle, or the pitch contour, would mimic certain features in the object. This could for instance be the overall shape of the object, the orientation of the object or the amount of visually distinctive parts on the object. It needs to be noted though that these are subjective observations and that it is not necessarily the case that the participants would be aware of these structural similarities. Judging from the observations, iconic mappings were not found to be widespread throughout the whole experiment. Figure 7 shows a few examples of clearly iconic form-meaning mappings that were encountered.

Figure 7: Examples of iconic whistle-object pairs in the data.
Participants filled out a post-participation questionnaire in which they were asked to describe their specific strategy (if any) for recall and whether they thought the whistles and objects fit well together. Often participants reported strategies in line with the observations described in the previous paragraph. Other strategies that were reported involved: imagining how the object would sound and linking this with the whistle, imagining how the object would move and linking the pitch contour with that, or linking the object with some real object they know and linking the whistle with the sound that object would make. These reports further illustrate the subjectivity of form-meaning resemblance.

In summary, the structures that emerged in the sets of whistled signals resemble the discrete and combinatorial structure that emerged in the experiment without meanings (Verhoef et al., 2011; Verhoef, 2012). Qualitatively, no difference could be observed between the structures in the two conditions and iconicity did not seem to play a large role.

\section*{Quantitative results}

This section describes a quantitative analysis to assess whether the observed patterns are consistent across the data. First, the learnability is investigated by computing how well participants were able to recall the set of whistle-object pairs.

Then, the development of combinatorial structure is measured.

\section*{Recall error}

To find out whether the sets of whistle-object pairs became easier to learn and reproduce, we measured how well participants were able to recall the right whistle for each of the objects. The recall error was measured by comparing each whistle that a participant produced for an object with the whistle linked to that specific object in the input. To determine the distance between two whistles, the same distance measure was used as the one used by Verhoef (2012). This measure compares plunger movement tracks (pitch tracks converted to plunger displacement) with the use of derivative Dynamic Time Warping (Keogh \& Pazzani, 2001).

Figure 8 shows the data for this measure of recall error for the four chains in both conditions, with increasing generations on the horizontal axis. The mean over the four chains for each condition and standard error are plotted.

A linear mixed effects analysis was performed (with lme4 in R) to explore the effect of generation on the recall error, with an intercept for chain as random effect. Likelihood ratio tests of this model against a null model excluding the effect of generation revealed a significant trend affecting error \(\left(\chi^{2}(7)=14.08, p=0.0498\right)\), decreasing it by about \(0.18 \pm 0.056\) (standard errors) from generation to generation for the intact condition, as well as for the scrambled condition \(\left(\chi^{2}(7)=27.25, p=0.0003\right)\) with a decrease of about \(0.1 \pm 0.025\) (standard errors). This suggests that there is an increase in the reproducibility of the form-meaning pairs over generations in both conditions.

Figure 8: Recall error on the whistle-object pairs over generations in both conditions, showing the mean and standard error. Recall error decreases significantly in both conditions.

\section*{Combinatorial structure}

To investigate whether the sets of whistles gradually become more structured over generations, the entropy measure that was used by Verhoef (2012) was applied to the current data. This measure makes use of the notion of entropy from information theory and is based on the idea that a set with more combinatorial structure is composed of less basic building
blocks that are more widely reused and combined. One adjustment had to be made to the measure as it was described in Verhoef (2012). Based on the qualitative observation that there was clearly no one 'right' segmentation that could be used to describe the discretization of the signal space, three different types of segmentation were defined. The whistles were segmented in all three ways and the entropy was computed for each of the three sets of basic building blocks that resulted from the segmentations. The lowest entropy value that was measured was then considered to be the best minimal description length approximation and was used as the measure for (dis)order. The first type of segmentation used silences as segment boundaries. The second type used the minima and maxima in the plunger movement track as segment boundaries and the third used the points of minimal and maximal velocity.

Figure 9 shows the development of entropy for the four chains in both conditions, where 0 refers to the initial whistle set. Again, the mean over the four chains and standard error for each condition is plotted.

A linear mixed effects model was constructed in the same way as for recall error, but with entropy as the test variable. A significant trend \(\left(\chi^{2}(7)=19.73, p=0.006\right)\) of decreasing entropy by about \(0.69 \pm 0.20\) (standard errors) from generation to generation for the intact condition was found, as well as for the scrambled condition \(\left(\chi^{2}(7)=17.22, p=0.016\right)\) with a decrease of about \(0.52 \pm 0.19\) (standard errors). These findings imply that the process of iterated learning in both conditions caused structure to emerge in the sets of whistles that refer to meanings.

Figure 9: Entropy of the whistle sets over generations in both conditions, showing the mean and standard error. Entropy decreases significantly in both conditions.

\section*{Transparency}

Although it is difficult to assess the actual role iconicity played in the two conditions, the results of the guessing game phases could indirectly reveal a potential influence. If the mappings were more transparent in the intact condition, we would expect participants in that condition to score higher on the identification task after only very little exposure to the
data. A linear mixed effects analysis was performed to explore the effect of condition on the scores, with round number (half of the items appeared in a guessing game round after the first exposure to the data and the other half after the second exposure) as fixed effect and intercepts for chain and generation as random effects. Likelihood ratio tests of this model against a null model excluding the effect of condition showed that condition does not affect performance in the guessing game ( \(\chi^{2}(1)=0.210, p=0.647\) ). This could suggest the role of iconicity was minimal in both conditions, or at least did not play a large enough role in the intact condition to boost identification scores. However it needs mentioning that the participants had been exposed to the data before the guessing game phases, which is expected to have influenced the scores.

\section*{Discussion}

The experiment presented in this article shows that cultural evolution in the laboratory causes a system of whistled words for novel objects to become more learnable and more structured over time. This work expands a previous finding that showed the same result for whistled systems without meanings (Verhoef et al., 2011; Verhoef, 2012). For two different situations, one with transmission of intact form-meaning pairs and one with scrambled pairs, we showed that the transmitted whistled systems develop from holistic towards having discrete and combinatorial structure. Sets of building blocks are efficiently reused and combined, similar to the structures of speech. In addition to the data presented by Verhoef et al. (2011), the current data forms another example to show that the emergence of combinatorial structure is not necessarily driven by vocabulary expansion and dispersal as was proposed by Hockett (1960).

As a secondary objective we explored the tension between combinatorial structure and possible iconic mappings. It appeared that the potential for iconic mappings did not prevent the emergence of structure in this experiment. However, when looking at the development of entropy in the two conditions, we can see that the main 'drop' in entropy in the intact condition took place approximately from generation four to eight, while in the scrambled condition, this was sooner, approximately from generation one to five. This could hint at a slight delay in the emergence of combinatorial structure in the intact condition, which would follow the expectation, but the current data from the guessing game phase does not suggest a large influence of iconicity. A more detailed analysis is needed. When we have a better picture of the actual development of iconicity, the development of structure can be linked to it more directly. Finding an objective measure for quantifying iconicity in the data is not trivial however and this will be part of our future continuation of this research.

To conclude, this article provides additional evidence to show that combinatorial structure in language can emerge through cultural evolution. The influence of iconicity in this evolutionary process still needs to be investigated in more depth, but with this study we provide an experimental plat-
form that can be used to tackle this issue. In the future, additional experiments are expected to lead to more insights.

\title{
Inductive Use of Semantic Word-Families to Accelerate Vocabulary Development and Reading Comprehension in Grades 3-4-5
}

\author{

\begin{abstract}
This study explored the acceleration of student vocabulary growth and reading comprehension proficiency through a multi-part instructional strategy for engendering the inductive, semantic word-family-oriented acquisition of vocabulary from context, a difficult task for elementary students. Implemented on a schoolwide basis for an academic year in grades 3-4-5, the intervention was a fourpart enhancement to a traditional basal reading program that constructed and used semantic word families for designated vocabulary words within stories. Results from HLM statistical modeling using student minority status and free/reduced lunch as covariates showed that experimental students in grades 3-4-5 obtained significantly higher achievement on both ITBS Vocabulary and ITBS Reading Comprehension subtests. Implications for research and practice are discussed.
\end{abstract}

Keywords: Inductive reasoning, Vocabulary acquisition, Reading comprehension

A variety of research has pointed to the interdependent linkage among vocabulary knowledge, reading comprehension, and level of literacy (e.g., Baker et al., 1998; Becker, 1977; Biemiller \& Slonim, 2001; Snow, 2002; Wager, 2005). Although substantial vocabulary growth can be attributed to student acquisition of word meaning from reading context (Baker, Simmons, \& Kameenui, 1998), August, Dressler, and Snow (2005) noted that if the proportion of unknown words is too large, then text comprehension which serves as a context for vocabulary development is disrupted (see also Carver, 1994).

Despite technical details in how words (e.g., counting word roots vs. root variants) and word understanding (e.g., recognition vs. in depth understanding) are defined in the literature (e.g., Anglin, 1993; Beck \& McKeown, 1991), research findings agree that children acquire vocabulary at a rate that is too rapid for all the words to be taught directly (see Baker et al., 1998) or learned incidentally through reading (Landauer, 2002; Landauer, \& Dumais, 1996, 1997; Landauer, Foltz, \& Laham, 1998; Landauer, McNamara, Dennis, \& Kintsch, 2007). With this point in mind, the present study addressed the
question of whether student vocabulary acquisition could be accelerated by using a multi-part semantic word-family-oriented learning strategy to inductively broaden vocabulary taught directly. In incorporating criteria suggested by Baker et al. (1998) and Beck and McKeown (1991), the intent of the strategy was (a) to engender an inductive broadening of the vocabulary taught directly and, in doing so, to enhance reading comprehension, and (b) to be feasible for use by classroom teachers within regular classroom settings.

Implemented as a practitioner-oriented model, the instructional intervention reflected several interdisciplinary perspectives: (a) vocabulary research findings with both younger (e.g., Coyne, McCoach, \& Kapp, 2005) and older (e.g., August et al., 2005; Baker et al., 1998; Blachowicz \& Fisher, 2000; Johnson, Gersten, \& Carnine, 1988) students, (b) cognitive science models (e.g., Kintsch, 1994, 1998a, 1998b, 2002, 2004, 2005; Landauer, 2002; Landauer, \& Dumais, 1996, 1997; Landauer et al., 1998, 2007) that emphasize the central role of prior knowledge in comprehension and, (c) our prior research (Vitale \& Romance, 2007) investigating the effect of knowledge-focused reading comprehension strategies on student learning. In the present study, different aspects of these perspectives provided a framework for engendering the semantically-oriented inductive learning of vocabulary.

The design of the present study was a significant enhancement of earlier studies (Romance \& Vitale, 2012; Vitale \& Romance, 2008). First, in this study, the intervention was implemented over an school year in multiple schoolwide sites. Second, teachers were asked to commit to implement the model in eight selected stories in grade 3, 4, and 5. across the school year. And third, the criterion measures (ITBS Vocabulary and Reading Subtests) were administered on a pre-post basis. The specific research questions were:
- Did the instructional intervention which incorporated words taught inferentially accelerate student the vocabulary development as measured by story-specific,
curriculum-based, pre-post tests?
- Did the instructional intervention accelerate student vocabulary development as measured by the nationally-normed ITBS Vocabulary subtest?
- Did the instructional intervention engender a transfer effect to student reading comprehension as measured by the nationally-normed ITBS Reading subtest?

\section*{Perspectives in Vocabulary Instruction}

Although an increasing number of studies have identified factors important in teaching vocabulary in classroom settings (see Baker et al., 1998; Biemiller \& Boote, 2006; Coyne et al., 2005; Nagy \& Scott, 2000), such studies have limitations insofar as providing a comprehensive means for accelerating student vocabulary acquisition. For example, Baker et al. (1998) pointed to the fact that the size and rate of growth of the vocabulary of school age children is far too large to be addressed on a literal word-by-word basis alone, while Anderson \& Nagy (1992) argued that because word meaning is learned primarily in the context of speech or text, direct instruction of vocabulary can address only a small portion of words to be learned.

The approach in the present study was a methodological enhancement of an earlier study (Vitale \& Romance, 2008) that demonstrated significant effects of the inductive model used in the present study on both curriculum-based vocabulary transfer tests and on ITBS Vocabulary. Approaching the question of vocabulary acquisition from a knowledge-based instruction approach (see Bransford, Brown, \& Cocking, 2000), a major tenet of this perspective is that prior knowledge is a major factor in meaningful comprehension, learning, and expert performance. Within this framework, building prior knowledge has been recognized as a major determinant of meaningful learning, general comprehension, and reading comprehension.

In applying a knowledge-based perspective to the classical problem of how persons can know more than experience could have taught (literally) within the context of vocabulary, Landauer (2002) and Landauer and Dumas (1997, 1998) drew on the idea that the underlying semantic dimensions as identified by Latent Semantic Analysis (see Landauer et al. 2007) that represent the relatedness among words, phrases, and prose provide the "learning leverage" through which words are understood. From this view, both the traditional and cognitive science research literatures are consistent in that while vocabulary words can be taught directly, the majority of vocabulary must be gained in a fashion that is inferential. Although some indirect vocabulary acquisition can be explained
through reading, the rate of vocabulary acquisition exhibited by children requires a process that involves the induction of the meaning of new words (since direct teaching and incidental learning from reading contexts are inadequate to explain vocabulary growth).

\section*{Method}

\section*{Participants}

The study was implemented over an 18 week period on a school-wide basis in grades 3-4-5 in a large (185,000 students), highly diverse (African American: 29\%, Hispanic: 19\%, Other: 5\%, Free Lunch: 40\%) school system in southeastern Florida. Using a random selection process with constraints for demographic similarity, three of six schools were assigned the intervention and the other three demographically similar schools served as controls.

\section*{Instrumentation}

Outcome measures consisted of the ITBS Vocabulary and ITBS Reading Comprehension Subtests. These tests were administered by classroom teachers with supervision from the researchers during 2-week periods prior to the beginning of the intervention and after the intervention ended.
The project intervention model also provided teachers with curriculum-based, pre-post lesson tests specific to each story taught. These tests consisted of two components: (a) a word recognition test in which students indicated whether or not they believed they know the meaning of a given word and (b) a sentence writing task in which students used a given word in a sentence. All of the words used in the tests were randomly sampled from the semantic word families associated with key words in specific stories and were not used in instruction. While there was a partial overlap of words used on the pre and post-tests, one-half of the words appearing on the posttest did not appear on the pre-test.

\section*{Experimental Intervention}

Pre-planning identified 4-word semantic word families for each of 3 key vocabulary words in each of 10 regular basal reading stories for use by teachers at each grade level. In Part 1 of the multi-part intervention in each story, teachers pre-taught 3 key vocabulary words in a textbookspecified fashion. Then, as a student reading the story reached a key word, teachers queried students regarding the word meaning in context (e.g., What does the word ___ mean in this sentence? How does this word contribute to the overall meaning of this sentence?).

In Part 2, the same procedure was followed but with pairs of new target words similar in meaning to each of
the pre-taught key words that were pre-taught and then substituted in 3 -sentence blocks from the story that contained the original key words. In Part 2, the teacher query was enhanced with an additional question: How does the use of this new word change the meaning of the sentence or story?

In Part 3, two new target words for each key word were not pre-taught. Rather, they were substituted in the same 3-sentence blocks in Part 2 and, again, students were queried regarding their meaning in context (an inductive process) by adding an additional question to the Part 2 query: How did the meaning of the three sentences from the story suggest what the meaning of the new word should be? Finally, in Part 4, as an expansion task, students presented sentences orally about their own experience using a key or target words.

For use by teachers, story-specific guidelines for each story were computer-generated in an easy-to-follow format in which the words, word definitions, relevant story sentences, and specific questions were inserted for each part of the intervention.

\section*{Design, Analysis, and Procedure}

The instructional intervention was implemented on a school-wide basis in grades 3-4-5 over the school year, with the ITBS Vocabulary and Reading subtests administered during a two-week period prior to the beginning and end of the 18 -week study. Both Experimental and control teachers used the same districtadopted basal reading series and followed the district curriculum plan in selecting stories for instruction. Experimental teachers were asked to commit to teaching 8 stories during the 18 -weeks of the school year in which the inductive vocabulary model would be applied. The study design followed the framework appropriate for a 2Level HLM analysis, with separate HLM analyses conducted for ITBS Vocabulary and ITBS Reading. For the HLM analyses, Level 1 student data consisted of student ITBS Vocabulary or Reading achievement outcomes, with minority (vs. non-minority) status, participation in free/reduced lunch (vs. non-eligible), grade, and the appropriate ITBS Reading or Vocabulary Subtests serving as a covariate. Level 2 classroom/teacher data (with students nested within teachers) consisted of a dummy variable representing treatment ( \(1=\) treatment, 0 \(=\) control) and grade .

\section*{Teacher Professional Development and Implementation Support}

Teacher professional development consisted of 2 days prior the start of the study with two days of "follow-up" during the initial 9 weeks of the intervention. In addition, researcher provided informal support as necessary.

\section*{Monitoring of Intervention Fidelity}

Researchers informally monitored all participating classrooms on a regular/continuing basis through direct observation and through inspection of teaching plans.

\section*{Results}

\section*{Implementation Fidelity}

The intervention involved 22 teachers across grades 3-4-5 and, because some teachers taught multiple sections, a total of 39 classrooms. The average number of stories taught using the vocabulary intervention were \(7.0,6.4\), and 6.2 for grades 3,4 , and 5 , respectively. Observation of classroom implementation by researchers averaging 3.4 visits per teacher found the intervention easy to implement by teachers and the project-developed storyspecific vocabulary guides to be effective. Mean ratings of fidelity of implementation ranged from 82 to 92 expressed on a 100 point scale, in which a rating of 80 percent or more indicated consistent model implementation. Based on the observations in conjunction with teacher planning effectiveness, the model was judged to be implemented with fidelity. Average inter-rater reliability (agreement) on the researcher-developed classroom fidelity observation form ranged from .88 to . 95.

\section*{Pre-Post Story-Based Test Findings}

Figure 1 shows the pre-post lesson achievement gains across the experimental classrooms in terms of mean percent of items correct across students and stories. As Figure 1 shows, students exhibited consistent pre-post achievement growth on the curriculum-based lesson tests.

Figure 1. Mean pre- and post-test scores for Word Meaning and Sentence Writing on the story lessons in grades 3, 4, and 5.

\section*{ITBS Achievement Findings}

One of the three control schools was eliminated from the analysis because of problems with the data resulting from the scanning of their Fall, 2011, prior ITBS response sheets. The results presented here are for the three
experimental and two control schools. Because preliminary HLM analyses found no interactions of treatment with minority status, or free/reduced lunch participation, these interaction components were removed from the final HLM models reported.

The HLM Model analyses with ITBS Vocabulary as the achievement outcome measure found a significant crosslevel interaction between Treatment and Grade, \(t(1348)=\) 1.99, \(p<.04\) ), along with each of the three covariates in the model (White-Asian-Mixed vs. Black-HispanicIndian, Free/Reduced Lunch vs. None, Prior-ITBS Achievement). The Treatment main effect was not significant. However, because of the significant interaction, the General Linear Hypothesis option in HLM was used to test the combined effect of Treatment and the Treatment x Grade interaction model components as a means of interpreting the overall effect of the intervention. The result of this follow-up analysis was significant, Chi-Square ( \(2 d f\) ) \(=11.43, \quad p<.0003\) and confirmed the overall impact of the intervention on student ITBS Vocabulary achievement.

A parallel HLM analysis with ITBS Reading as the achievement outcome measure found both the Treatment main effect, \(t(66)=-2.95, p<.01\), and the cross levellevel interaction between Treatment and Grade, \(t(1431)=\) 2.99, \(p<.003\), significant, along with two of the three

Figure 2. Differences in Estimated ITBS GE achievement between adjusted means of Experimental and Control students by grade. Differences greater than zero show higher achievement for Experimental students. For Reading, Control students outperformed Experimental students in grade 3; however the achievement difference in favor of Experimental students accelerated in grades 4 and 5.
covariates (Free/Reduced Lunch vs. None, Prior-ITBS Achievement). The covariate White-Asian-Mixed vs. Black-Hispanic-Indian was not significant. As in thepreceding analysis, because of the significant interaction, the General Linear Hypothesis option in HLM was used to test the combined effect of Treatment and the Treatment x Grade interaction model components as a means of interpreting the overall effect of the intervention. The result of this follow-up analysis was significant, Chi-Square (2df) \(=11.90, \quad p<.003\), confirming the impact of the Vocabulary Intervention on student ITBS Reading achievement.
In order to further interpret the combined Treatment main effect at Level 2 and the cross-level Treatment x Grade interaction, estimates were computed from the HLM models for ITBS Vocabulary and ITBS Reading of the differences between adjusted means for the Experimental and Control students by grade level for each ITBS achievement outcome. As shown in Figure 2, the intervention resulted in a magnified effect of the favor of Experimental students as grade level increased.

\section*{Discussion and Conclusions}

In conducting studies on vocabulary acquisition, earlier (Romance \& Vitale, 2012; Vitale \& Romance, 2008) investigations of the inductive vocabulary model along with research cited in the literature (e.g., Kintsch, 2012; Landauer, \& Dumais, 1996, 1997; Landauer et al., 1998, 2007) were suggestive that development and inductive use of general semantic (i.e., conceptual) meaning should be considered as an important focus of vocabulary learning rather than simply building understanding of specific words in a literal fashion. This perspective is supported by findings from earlier work (Vitale \& Romance, 2008) which explicitly demonstrated the impact of the model on the inferential performance of students on tasks based on the semantic word families used and by the fact that the impact of the model on the ITBS Vocabulary test served as an achievement transfer measure.
From an applied research perspective, the present study replicated and extended the preceding studies (Romance and Vitale, 2012; Vitale and Romance, 2008) in terms of instructional time (duration of intervention) and increased use of the intervention across grade levels (grades 3-5). Demonstrating the effect of the intervention on reading as well as on vocabulary was an important finding of the present study because engaging students in the inductive vocabulary intervention implicitly required them to focus attention on comprehension of each story. This "sideeffect" of the model serves as a potential explanation of the effect of the vocabulary intervention on reading achievement.

One important goal of future studies would be to
explore the cumulative effect of the present intervention on both the vocabulary development and reading proficiency of low-SES students when implemented on a multi-year basis. For practitioners, the present study is suggestive of how student vocabulary acquisition and reading proficiency can be accelerated through the enhancement of their regular reading programs. Considered together, the present findings are consistent with traditional and cognitive science research in that while recognizing vocabulary words can be taught directly, it is feasible for schools to accelerate student vocabulary growth in an inductive fashion that also improves student reading comprehension.

\begin{abstract}
It has been suggested that a referent's accessibility is affected by the degree to which it is in the speaker's attention. Assuming that less accessible referents are less likely to be pronominalized, this predicts that speakers under cognitive load use more elaborate referring expressions. However, speakers under load may also have difficulty taking into account their addressee's perspective, which may either lead to more use of the speaker's own discourse model or to more economic expressions. To tease these effects apart, we conducted a story completion experiment in which cognitive load was manipulated by the presence or absence of a secondary task for the speaker. In addition, we dissociated the speaker's and the addressee's perspectives. Our results do not provide evidence for the hypothesis that cognitive load reduces the accessibility of referents in the speaker's own discourse model, suggesting that speaker attention does not determine accessibility.
\end{abstract}

Keywords: cognitive load; referring expressions; accessibility; perspective taking

\section*{Introduction}

When speakers refer to something, they have to choose a certain type of referring expression, such as a definite description (e.g. the girl) or a pronoun (e.g. she). Traditionally, the speaker's choice of a referring expression has been assumed to be tailored for the addressee (e.g. Ariel, 1990; Gundel, Hedberg, \& Zacharski, 1993). According to this view, speakers make assumptions about the cognitive status of the referent in the mind of the addressee. An important factor in determining this status is the salience of the referent in the discourse. For example, if the referent was the topic of the preceding sentence, it can be assumed to be highly accessible in the addressee's discourse model, and therefore it does not need an elaborate description to be reactivated. Because the addressee knows that the speaker would have used a more elaborate expression if she had a less activated referent in mind, the use of an attenuated expression, such as a pronoun, aids the addressee's interpretation.

However, studies that have manipulated speakers' attention resources suggest that the activation of mental representations in the speaker's own memory is also important for the choice of referring expression. For example, Arnold and Griffin (2007) and Fukumura, Van Gompel, and Pickering (2010) varied the number of possible
referents in the discourse, and found that speakers used fewer pronouns when a referential competitor was present, even though the referent was salient in the discourse (i.e. topical). In addition, speakers have been found to choose fewer attenuated expressions for salient referents when they are distracted by another task (Rosa \& Arnold, 2011). These findings suggest that the choice of referring expression is affected by the degree to which the referent is in the speaker's attention: referent accessibility, and hence pronoun use, decreases when the speaker has to spread attentional resources over multiple possible referents or multiple tasks.

If restrictions on speakers' attention resources influence the accessibility of referents in their own memory, speakers experiencing an increased cognitive load should be more likely to use elaborate expressions such as full noun phrases. However, increased cognitive load may also affect the degree to which speakers are able to take into account the perspective of the addressee (e.g. Epley, Keysar, Van Boven, \& Gilovich, 2004; Horton \& Keysar, 1996). For example, Horton and Keysar (1996) showed that when under time pressure, speakers were not taking into account the addressee's perspective in choosing whether or not to include an adjective in their referring expressions. Thus, cognitive load may make the choice of referring expression more egocentric. On the one hand, this could mean that this choice is based more on the speaker's own discourse model (e.g. Fukumura \& Van Gompel, 2012). That is, when speakers are under load, they might be less able to calculate whether the referent is accessible for the addressee or not. Because in many cases speaker and addressee have access to the same discourse information, it is generally difficult to distinguish between a referring expression that is tailored for the addressee and a referring expression that is based on the speaker's own model of the discourse when all discourse information is shared. For example, a referent that is highly accessible in the addressee's discourse model is often also highly accessible in the speaker's discourse model. When the speaker's and the addressee's perspectives differ, however, speakers under load might be inclined to use pronouns when the referent is salient in their own discourse model but not salient in the addressee's discourse model. Conversely, they might be inclined to use full noun phrases when the referent is not salient in their own discourse model but salient in the addressee's discourse model.

On the other hand, speakers under load may fail to take into account any information about discourse salience, and resort to using more pronouns in general, because these are short, have little semantic content, and are hence easy to produce (Almor, 1999; Burzio, 1998). For example, studies on children and elderly people have found that having limited working memory capacity increases the use of pronouns in contexts in which the referent is not salient for the addressee (e.g. references following a topic shift; Hendriks, Englert, Wubs, \& Hoeks, 2008; Wubs, Hendriks, Hoeks, \& Koster, 2009; see also Almor et al., 1999).

To tease these possible effects of cognitive load apart, the linguistic salience of the referent should be varied, because the effect of cognitive load might be different for salient and non-salient referents. In addition, to determine whether cognitive load affects the speaker's discourse model or the speaker's assumptions about the addressee's discourse model, the speaker's and addressee's perspectives should be dissociated. Therefore, we conducted a story completion experiment in which we manipulated perspective, referent salience and cognitive load. Perspective was manipulated by presenting one of the sentences of the story only to the speaker, over headphones (cf. Fukumura and Van Gompel, 2012). The referent was considered linguistically salient for the speaker when it was mentioned in this privileged sentence, and not salient when it was only mentioned in the introductory sentence. Since the addressee did not hear the privileged sentence, referent salience was reversed for the addressee. Cognitive load was manipulated by giving the speaker a second, unrelated (but also verbal) task in the first or the second half of the experiment.

We hypothesized that if cognitive load lowers the accessibility of referents in the speaker's discourse model, it should decrease pronoun use, irrespective of the referent's linguistic salience. If, on the other hand, cognitive load makes perspective taking more difficult, there should be a stronger tendency to use the speaker's own discourse model in the dual task condition. That is, speakers should be more likely to use pronouns when the referent is salient in their own discourse model (and not in their addressee's), than when the referent is salient in the addressee's discourse model (and not salient in their own). Alternatively, speakers may tend to use more pronouns in general when under increased cognitive load.

\section*{Methods}

\section*{Participants}

Sixty-four students (47 female; mean age: 20.2 years) from Tilburg University participated in the experiment for course credit. Half of them acted as speakers, the others acted as addressees. All were native speakers of Dutch, the language of the experiment.

\section*{Materials}

The experimental items consisted of 16 pairs of photographs, taken from Vogels, Krahmer, and Maes (in
press), accompanied by two introductory sentences and the onset of a third sentence. The first picture of a pair always showed one male and one female person sitting next to each other. In the second picture, one of these persons performed an action, such as walking away or getting a glass of water. This person will be referred to as the target character, as participants were expected to refer to this character in their continuations. There were two versions of each picture pair; one in which it was the male person and one in which it was the female person that performed the action. An example of a picture pair is shown in Figure 1.

\section*{A: Speaker-salient condition}

\section*{B: Addressee-salient condition}

Figure 1: Example of a stimulus item in two conditions. Sentence 1 was read aloud by the speaker; sentence 2 was presented only to the speaker over headphones. Context sentences are translations of the Dutch originals.

The first sentence introduced both characters with indefinite noun phrases, either een meisje "a girl" and een jongen "a boy" or een vrouw "a woman" and een man "a man". One was mentioned as the subject, and the other in a
prepositional phrase (e.g. Een meisje zat te discussiëren met een jongen "A girl was arguing with a boy"). This sentence was read aloud by the speaker to the addressee. The second sentence described some emotional or physical state of the person mentioned in the prepositional phrase (e.g. De jongen raakte enorm gepikeerd "The boy got really annoyed"). This sentence was prerecorded by a female native speaker of Dutch, and only heard by the speaker over headphones. The onset of the third sentence was always Vervolgens... "Subsequently...", serving as a cue for the speaker to complete the story.

In addition, 20 picture pairs served as fillers. These differed from the experimental items in that some showed either two male or two female characters or only one character. In the accompanying sentences, some characters were given labels such as een verkoopster "a saleswoman" or een Duitser "a German", and sometimes the same character was the subject of both introductory sentences. An additional 4 items were included as practice items.

\section*{Procedure}

The experiment took place in an experimental room. Two participants were randomly assigned to the role of speaker and addressee. The participant taking the role of speaker was seated at one end of a table, behind a laptop connected to a serial response box, and was wearing headphones. The participant taking the role of addressee was seated at the other end of the table, and was given a booklet containing all different picture pairs and an answer sheet. The experiment was run on the laptop using E-Prime 2.0, and was only visible to the speaker. The speaker's task was to complete the stories depicted by the picture pairs for the addressee. In one half of the experiment, the speaker received a secondary task (cognitive load condition), while there was no secondary task in the other half (no cognitive load). In the no cognitive load condition, each trial started with the item number presented on the screen, accompanied by a 500 ms beep, followed by a cross-hair. Then, the first picture of a pair appeared on the left side of the screen. After 3 s the first introductory sentence appeared below the picture in a red font. The speaker read this sentence aloud to the addressee. After 5 s the second sentence was presented to the speaker over the headphones. Next, while the first picture remained visible, the second picture appeared automatically on the right side of the screen, together with the onset of the third sentence, which also appeared below the picture in a red font. The target character in the second picture was either the subject of the first introductory sentence, and therefore linguistically salient for the addressee (addressee-salient condition), or the subject of the second sentence, which was only presented to the speaker (speaker-salient condition). At this time, recording started, and the speaker completed the sentence based on the event shown in the picture, by saying it aloud to the addressee. After 6 s, recording stopped and the pictures and sentences disappeared. The addressee's task was to select the correct picture pair out of three options from the booklet and mark
the correct answer on the sheet. The addressee gave the speaker a hint when the next trial could be started.

In the cognitive load condition, the appearance of the first picture was preceded by the words BAL "ball" or DAL "valley" (Goudbeek \& Krahmer, 2011), which was presented in the middle of the screen for 1 s . The same happened at the end of the trial, followed by the question Was dit woord hetzelfde als het vorige woord? (Ja/Nee) "Was this word the same as the previous word? (Yes/No)". The speaker then pressed either the green/Yes or the red/No button on the response box. They did not receive feedback on their answers.

The participants received instructions both orally and in written form. Speakers were explicitly told that the sentence presented over headphones could not be heard by their addressee, but that they had to pay attention to it nonetheless, since they would be asked about these sentences after the experiment as an attention check (which was indeed the case). They were also encouraged to pay attention to the dual task by way of a prize offer for the participant with the fewest errors. To keep the speaker aware of the addressee's needs, the addressee was allowed to ask the speaker clarification questions if anything remained unclear, but only after the speaker had finished the story.

The experiment was divided into two blocks, of which one contained the dual task and the other did not, counterbalanced for order. Each block was preceded by two practice items. The experimenter was only present during the instructions and the practice trials. The experiment took about 25 minutes.

\section*{Data coding}

From all speakers' continuations of the third sentence, we selected the first subject reference, which was expected to refer to the target character. Any further references (e.g. in another follow-up clause) were ignored. We excluded 33 cases in which the first subject did not refer to the target referent, 7 plural references, 3 indefinite references, 1 case in which the sentence presented over the headphones was repeated literally, and 1 missing case. In addition, there were 2 cases in which the referring expression was repaired. However, because the repair was of the same type in both cases (e.g. 'the man... uh the boy'), we kept these cases. In total, we excluded 45 trials (8.8\%). The remaining 467 subject references were coded for the type of referring expression: either full noun phrase or pronoun.

\section*{Design and statistical analyses}

Crossing the two factors Referent salience and Cognitive load resulted in a 2 (speaker-salient, addressee-salient) x 2 (cognitive load, no cognitive load) within-participants design. Participants were assigned to one of four lists, each of which contained one version of a given item. The items were presented in a pseudo-random order, with at least one filler item between two consecutive experimental items.

We performed a logit mixed model analysis on the log odds for a pronoun (Jaeger, 2008). Referent salience and Cognitive load were included as fixed factors, and participants and items as random factors. The fixed factors were centered to reduce collinearity. Starting with a full random effect structure, we excluded random slopes that did not significantly contribute to the model fit. Only the final model will be reported.

\section*{Results}

Upon inquiry, only 6 participants reported that they found the secondary task difficult. Still, the overall error rate was \(9.7 \%\), suggesting that participants might have been overestimating their performance. Few errors were made in the attention check following the experiment (1.7\%), suggesting that speakers were attending to the sentences presented over the headphones.

Figure 2: Proportion of pronoun references to the target character in the four conditions.

Figure 2 shows the proportion of pronoun references to the target character by referent salience and cognitive load condition. We found a main effect of referent salience: pronouns were more frequent when the referent was salient only for the speaker (23.6\%) than when it was salient only for the addressee (8.3\%), \(\beta=-2.26\); \(\mathrm{SE}=0.85 ; p<.01\). There was also a main effect of cognitive load: more pronouns were used when speakers performed a dual task (17.2\%) than when they did not (15.7\%), \(\beta=1.40\); \(\mathrm{SE}=\) \(0.56 ; p<.05\). These effects were qualified by a significant interaction, \(\beta=2.85\); \(\mathrm{SE}=0.95 ; p<.01\), suggesting that cognitive load only increased pronoun use in the addresseesalient condition. The model included random intercepts for participants \(\left(s^{2}=2.85\right)\) and items \(\left(s^{2}=0.15\right)\), as well as bysubject random slopes for referent salience \(\left(s^{2}=12.06\right)\) and cognitive load ( \(\mathrm{s}^{2}=3.08\) ). This suggests that participants
varied substantively in the way their pronoun use was affected by the context sentences and the dual task. The contribution of the random slope for cognitive load to the model fit was only marginally significant ( \(p=.06\) ). Removing it decreased the effect size of the fixed factors, but the interaction effect remained significant at the \(\alpha=.05\) level.

\section*{Discussion}

Speakers used more pronouns when the referent was salient for them (but not salient for their addressee) than when it was not salient for them (but salient for their addressee). This suggests that speakers chose referring expressions more according to the referent's accessibility in their own discourse model than according to assumptions about the referent's accessibility in their addressee's discourse model. This is in line with Fukumura and Van Gompel (2012), who found that speakers were not taking into account their addressee's perspective in choosing referring expressions when the two perspectives were dissociated.

If cognitive load decreases the accessibility of referents in the speaker's own discourse model, as suggested by Arnold and Griffin (2007), we should have seen fewer pronouns across the board when speakers performed the dual task. This is not what we found. Instead, speakers were somewhat more likely to use pronouns when under load, at least in the addressee-salient condition. This finding is also not in line with the hypothesis that cognitive load makes it harder to calculate the referent's accessibility in the addressee's discourse model. If that were the case, the dual task condition should have increased the tendency to use the speaker's own discourse model. That is, speakers under load should have been more likely to use pronouns in the speaker-salient condition, and less likely to use pronouns in the addressee-salient condition.

Our results seem compatible with the hypothesis that speakers under load are more likely to use less costly expressions, such as pronouns (Almor, 1999; Burzio, 1998). That is, when distracted by a secondary task, speakers have fewer memory resources available that are needed to infer that less salient referents should be referred to with more elaborate expressions. The fact that cognitive load only increased pronoun use in the addressee-salient condition may be due to the preference to use pronouns anyway when the referent is salient for the speaker.

An alternative explanation for the effect of cognitive load is that speakers are less able to keep track of their own discourse model when they are under load. This would cause their use of referring expressions to become less consistent, i.e. the choice of referring expressions becomes less tied to the discourse context (Arnold, 2010). This would explain the finding that the difference between the speakersalient and the addressee-salient condition becomes smaller under load. In addition, this explanation would not be incompatible with the finding by Arnold and Griffin (2007), Fukumura et al. (2010) and Rosa and Arnold (2011) that cognitive load leads to fewer attenuated expressions, since
these studies investigated only contexts in which referents were always linguistically salient. Thus, the present study at least stresses that dissociating the salience of the referent in the speaker's and the addressee's perspective is necessary to tease the possible effects of cognitive load apart, i.e. whether it affects the speaker's representation of the discourse or the speaker's assumptions about the addressee's representation of the discourse.
Although our results suggest that speakers tend to use their own discourse model, replicating Fukumura and Van Gompel's (2012) findings, it is striking that the overall proportion of pronouns is quite low. Even in the no cognitive load, speaker-salient condition, in which one would expect many pronouns if speakers only took into account their own discourse model, the percentage of pronouns out of all referring expressions did not exceed \(30 \%\). This relatively low proportion of pronouns might be due to the manipulation of perspective: Perhaps speakers were taking into account the addressee's informational needs, but not up till the level of calculating the referent's cognitive status for the addressee. This kind of detailed audience design might be cognitively too costly (e.g. Brennan \& Hanna, 2009; Horton \& Gerrig, 2005). Therefore, speakers may just have increased the use of elaborate expressions to be as clear as possible for the addressee, as soon as they were aware of the fact that not all information was shared. Fukumura and Van Gompel (2012) found evidence for such a minimal, one-bit model of audience design (e.g. the addressee has heard this or not; Galati \& Brennan, 2010; see also Epley et al., 2004) by comparing their condition with privileged information for the speaker to a condition in which all information was shared. They found more pronouns in the shared condition, independently of whether the referent was salient or not. This suggests that speakers use more elaborate expressions when there is privileged information, even though they might run the risk of being overly specific.

Still, Fukumura and Van Gompel (2012) found somewhat higher rates of pronoun use in their privileged, referentsalient condition (Experiment 1: 37\%; Experiment 2: 48\%) than we did in our experiment. This difference could be due to differences in the linguistic materials. Firstly, while the referent mentioned in the second context sentence (which was only presented to the speaker) was referred to with a pronoun in Fukumura and Van Gompel's experiments, it was referred to with a full NP in our experiment, in accordance with the preferred way of referring to an entity previously mentioned as a direct object in centering theory (e.g. Brennan, 1995). The tendency to pronominalize the entity on a subsequent reference may however be stronger when the referent had already been pronominalized. Secondly, speakers may be more likely to reuse the most recent referring expression, which could also have led to more pronouns in Fukumura and Van Gompel's experiments than in ours.
Even though employing a one-bit model of audience design is probably less cognitively demanding than
calculating the referent's accessibility for the addressee, using full NPs to aid the addressee when there is privileged information might be more difficult under load. Hence, if speakers in our study were employing such minimal audience design, our finding that they were more likely to use pronouns under load could be due to difficulties in assessing that the addressee might need more specific information. If this is the case, we would predict that in a situation in which all discourse information is shared, cognitive load does not increase pronoun use, since in that case there is no need to be more specific for the addressee.

One reason why speakers did not make the extra effort to calculate the accessibility of the referent in the addressee's discourse model may be that in the current experiment, as well as in Fukumura and Van Gompel's, references were never ambiguous, since the two characters always had a different gender. Therefore, not taking into account the addressee's perspective would probably not result in interpretation errors. However, in case not taking into account the addressee's perspective would lead to interpretation errors, speakers may base their choice of referring expressions on the discourse model of their addressee (e.g. Fukumura \& Van Gompel, 2012; Horton \& Keysar, 1996). In that case, increased cognitive load might make this perspective taking more difficult, and cause speakers to fall back on their own discourse model.
In our filler materials, which contained stories with characters of the same gender, and hence pronouns were ambiguous, we indeed found more pronouns when the referent was salient for the addressee but not for the speaker ( \(33 \% ; \mathrm{n}=51\) ) than when the referent was salient for the speaker but not for the addressee ( \(13 \%\); \(\mathrm{n}=56\) ), suggesting that speakers were taking their addressee's perspective into account. However, cognitive load did not seem to cause speakers to use their own discourse model. Rather, a pattern similar to that in Figure 2 emerged, with more pronouns under load for referents that were not salient for the speaker. This might be an indication that cognitive load as manipulated here is independent of perspective taking.
Our results suggest that there was quite some individual variation as to how speakers' referring expressions were affected by the dual task. One cause of individual differences could be the use of strategies for remembering the words BAL and DAL. Two thirds of all participants reported to have used some kind of mnemonic (e.g. putting up one finger for BAL and two for DAL), although these were not always employed from the beginning. This is a concern that should be taken up by future studies. Nevertheless, the general trend of more pronouns under load in the addressee-salient condition in the present study seems to hold for all participants.

Finally, an important issue is that cognitive load can be manipulated in different ways that may affect the choice of referring expressions differently. For example, it is not clear whether dual tasks, divided attention to multiple referents, and restricted working memory capacity all produce the same kind of cognitive load. In addition, language
production may be affected differently by verbal or visual secondary tasks (Baddeley and Hitch, 1974; Kellogg et al., 2007). In the present experiment, the use of a verbal secondary task may have especially hindered the production of elaborate linguistic forms. Other manipulations, such as adding time pressure, possibly interfere more with activating non-linguistic representations or with perspective taking. This is an issue that needs further research.

In sum, the present study has shown that speakers use more pronouns when they experience increased cognitive load, at least when the referent is not salient for the speaker (but is salient for the addressee). Whether this is due to a general preference to produce economic forms, or to difficulties in keeping track of the accessibility of the referents in the discourse model should be researched further. However, we have not found support for the claim that cognitive load, at least in the form of the dual task used here, decreases the accessibility of referents in the speaker's discourse model. Hence, although accessibility may be related to attention, it probably does not hold generally that less attentive speakers use more elaborate referring expressions.

\begin{abstract}
We investigate the amount of speech and (co-speech) gestures addressed to infants at \(1 ; 1\) years of age in rural and urban Mozambique, and correlate these amounts with vocabulary size measured at \(1 ; 5\) and \(2 ; 1\). We found that urban infants are exposed to more than three times as much speech and cospeech gestures than rural infants. The results show that the amounts of co-speech gestures and speech predict later vocabulary development in the urban community, but not in the rural community. The results further show that rural infants are delayed in their vocabulary development, which may in part be explained by a transition in the socialization style rural infants experience between the age of \(1 ; 1\) and \(1 ; 5\).
\end{abstract}

Keywords: Child language acquisition; child-directed speech; co-speech gestures; vocabulary development; Mozambique.

\section*{Introduction}

When children learn language, they must have exposure to the target language. It is well established that the amount of exposure correlates strongly to vocabulary development (Hart \& Risley, 1995; Pan, Rowe, Singer, \& Snow, 2005). This does not only hold for the amount of speech children are exposed to, but also for the amount of gestures directed at children (Iverson, Capirci, Longobardi, \& Caselli, 1999; Rowe \& Goldin-Meadow, 2009). In this report we investigate how the amounts of speech and gestures addressed to infants vary among rural and urban communities in Mozambique, and show how these amounts correlate with vocabulary sizes during infants' early development.
One obvious predictor of children's vocabulary development is the amount of verbal input addressed to them. Various studies have, indeed, revealed a strong correlation between parental verbal input and vocabulary development (Hart \& Risley, 1995; Pan et al., 2005). It is not just the amount of words a child is exposed to, but also the variety of words that correlates to later vocabulary size (Hart \& Risley, 1995). It has further been found that the amount of parental verbal input addressed to children, as well as the speed of children's vocabulary development, relates to the parents' social economic status (SES) - the higher the parents' SES, the more words they tend to
address to children, and the larger these children's vocabularies become (Hart \& Risley, 1995).
As with speech, the amount of hand gestures addressed to infants, such as pointing, showing, or iconic gestures, are good predictors of vocabulary development (Iverson et al., 1999; Pan et al., 2005). Infants’ gesture use also predicts vocabulary size (Pan et al., 2005), possibly due to a correlation between parental gesture use and infants gesture use (Iverson et al., 1999). As with the amount of speech, SES predicts the amounts of parents' and infants' gesture use, which relates to later vocabulary size (Rowe \& GoldinMeadow, 2009). One explanation for the role that gestures have on vocabulary development is that gestures help to establish and sustain joint attention, which in turn supports vocabulary development (Carpenter, Nagell, Tomasello, Butterworth, \& Moore, 1998).
It is important to realize that most of these studies were carried out in industrialized societies, but socialization towards children can differ greatly across cultures, and many non-industrial cultures have different attitudes towards child rearing (Schieffelin \& Ochs, 1989). For instance, there are cultural differences regarding the amount of socialization a child is involved in - typically there is relatively little speech directed towards infants from nonindustrialized cultures (Lieven, 1994). Moreover, multiparty interactions are more frequent in non-industrialized than in industrialized communities, and infants tend to have multiple caregivers, including siblings (Brown, 2011; Harkness, 1977). Also, the amount of language socialization depends on the developmental status of a country - mothers from countries higher on a developmental scale tend spend more time stimulating their children by reading books, telling stories, naming, counting and other cognitive tasks (Bornstein \& Putnick, 2012).
Within culture differences may exist between urban and rural communities. Keller (2012), for instance, has proposed that, in addition to prototypical Western urban communities, there are prototypical rural and urban communities in nonindustrialized countries. She has described a number of key characteristics in which non-industrialized rural and urban communities differ. The subsistence-based farming lifestyle
in rural communities, for instance, demands from children that they develop motoric skills and knowledge of social rules. Verbal skills are considered less important. Urban societies tend to be higher educated and expect from their children to receive a good education as well. As a result, linguistic interactions tend to become more important (LeVine et al., 1996). However, non-Western urban communities still adhere to many cultural traditions rooted in their rural decent, such as the role of communal responsibilities from the extended family members in child rearing (Keller, 2012).
In sum, these observations predict that infants from nonindustrialized urban communities would be exposed to more child-directed speech than infants from rural communities. Since there is a tight link between speech and gesture (McNeill, 1985), we would expect to find similar differences regarding the use of gestures and co-speech gestures addressed to infants. A previous analysis of the same observations presented in the present paper, however, has revealed no significant differences between a rural and an urban community in Mozambique regarding the amount of social interactions that young infants have with the members of their extended families (Mastin \& Vogt, 2013). These social interactions were based on the infants' attention states (Bakeman \& Adamson, 1984), and include both verbal and non-verbal interactions. This raises the question whether there are actual differences in the amount of speech addressed to the infants.
Based on the above-mentioned studies, which have demonstrated that speech and gestures are sound predictors for vocabulary development, we further expect to find that the amounts of speech, gestures, and co-speech gestures predict later vocabulary. In this paper, we try to confirm these predictions using a longitudinal ethnographic study among infants from rural and urban Mozambique.

\section*{Methods}

\section*{Participants and field sites}

We selected two field sites in Mozambique: one site compiled from two adjacent residential suburbs in the country's capital of Maputo; the other site was made up of three small villages just outside the rural, provincial town of Chokwe in Gaza province, about 200 kilometers away from the capital. From each community we recruited 22-25 families with an infant in the range of \(1 ; 0\) to \(1 ; 2\) years old ( \(1 ; 1\) on average) at the start of our study. Our local research assistants explained the general purpose and procedures of our study to the participating families in their native language, and we obtained a signed informed consent from the infants' mothers. During the course of our longitudinal study, we lost various participants due to illness, mortality or relocation. In addition, we removed two participants from our analysis, because the parental reports on vocabulary development showed a decrease in expressive vocabulary,
which rendered their data unreliable. As a result, we provide results for 14 participants from each field site.
The participants from the rural community were all native Changana speakers (a Southern Bantu language spoken in parts of Mozambique and South Africa); in most cases this was the only language spoken in the household. Only in a few families was another related local language occasionally spoken. In the urban community, most families raise their children bilingually in Mozambique's official language of Portuguese, and Ronga, a language that is mutually intelligible with Changana. Table 1 shows some demographic information concerning our participants.

Table 1: Demographic information. Note: Primary education in Mozambique is organized in two levels of primary school: EP1 for 5 years and EP2 for another 2 years.
\begin{tabular}{lll}
\hline Participant information & \begin{tabular}{l} 
Rural \\
\((n=14)\)
\end{tabular} & \begin{tabular}{l} 
Urban \\
\((n=14)\)
\end{tabular} \\
\hline Males / Females & \(7 / 7\) & \(9 / 5\) \\
Avg age (SD) & \(1 ; 1.8\) & \(1 ; 1.6\) \\
& \((0 ; 0.26)\) & \((0 ; 0.28)\) \\
Education level mothers & & \\
None & 6 & 1 \\
EP1 & 5 & 5 \\
EP2 & 3 & 6 \\
Higher & 0 & 1 \\
\hline
\end{tabular}

There was a fairly balanced split in the number of males and females participating, and the average age was equivalent in both sites. To have an indication of the families SES, we report the mothers' education level. The majority of rural mothers have either completed no education or only the lower levels of education, whereas urban caregivers have all received some education: five mothers have completed the lowest level of education, six have the second level of education, and one has received secondary education. Since the data on education is ordinal, we performed Fisher's exact test to verify whether the education levels of both communities differ significantly and found that it appears not ( \(p=.115\) ). However, when we compared the rural community with the urban community from our (unpublished) norming study using the Chisquared test, we found a significant effect in educational level ( \(\chi^{2}(3)=32.414, \mathrm{p}<.001\) ), while the urban participants' education fits nicely with our norming study \(\left(\chi^{2}(3)=1.318\right.\), \(\mathrm{p}=.725\) ).

\section*{Materials}

We adapted the MacArthur-Bates Communicative Development Inventories (MBCDI) Short Form Vocabulary Checklist (Fenson et al., 2000) into both Portuguese/Ronga and Changana to obtain a parental checklist of words used to measure vocabulary size and development in both Mozambican communities. To do this, we compiled a list
from Fenson et al.'s Level I for infants and extended this with 13 additional items from the Level II checklist to allow the list to be used for children older than 16 months. We then identified vocabulary that was not applicable to the environment, culture or lifestyle of our participants, and replaced these items with appropriate vocabulary that matched the same syntactic or semantic functions as the original English word. The list was further adapted during extensive piloting of the checklist. With the adapted CDIs we conducted a norming study in both communities to obtain expected values of vocabulary development. For details on the adaptation and norming of the MBCDI, consult Mastin and Vogt (2013).

\section*{Data collection}

Data was collected longitudinally at three periods during the course of one year, while the infants were on average \(1 ; 1,1 ; 5\) and \(2 ; 1\) years old. At each time-period, we visited each family twice. At the first visit, we administered a short survey with questions concerning the demographics of our participants. We also videotaped the infants' interactions with their families to allow them to accommodate to our presence. During the second visit, we started with video taping the infants from 45 up to 75 minutes during natural free behavior for data analysis. At both visits, we instructed the families to continue their daily routines and to act as if we were not present. After the video recording was finished, the adapted MBCDI was administered through face-to-face interviews held by a local research assistant to estimate the infants' vocabulary development. In the current study, we report on the video recordings at \(1 ; 1\) and correlate these to the infants' expressive vocabulary at \(1 ; 5\) and \(2 ; 1\) as measured using the MBCDI.

\section*{Coding procedures}

The videos recorded during the second visits were coded for 30 minutes in segments of prolonged duration in which the infant was displaying 'natural' behavior (i.e.: not sleeping, not off camera, not interacting with or disturbed by the experimenters). We also excluded prolonged periods (roughly more than 2 minutes) of breastfeeding, as this might have introduced a bias toward dyadic interactions. For this article, we present results on only child-directed speech and gestures.

Child-directed utterances Two local research assistants, while closely supervised by the authors, transcribed all child-directed speech. All intelligible speech was first transcribed into the local language and subsequently translated into Portuguese. All unintelligible speech were coded as unknown vocalizations, but were included in our current analyses. Because not all speech was intelligible, we measured the number of utterances (i.e. individual speech acts), rather than number of words.

Gestures We coded gestures during episodes of joint engagement (Mastin \& Vogt, 2013), which are activities in which the infants are socially interacting with one or more other individuals. These activities involve dyadic person interactions, as well as different types of triadic joint attention interactions based on those defined by Bakeman and Adamson (1984). Since many interactions observed involved multi-party interactions, we only coded those gestures produced by the communication partner nearest to the child. We adopt a broad definition of gestures as any physical activity with the hand or body that has a clear communicative intent (Zukow-Goldring, 1996). The following gestures were coded:
- Pointing is a gesture where the gesturer extends the arm to indicate an object with the hand or index finger from some distance.
- Showing is a gesture in which an object is indicated using zero proximity, e.g. by tapping on the object or by holding up the object.
- Demonstrating is a gesture where the speaker manipulates an object to show the infant how that object is used, or the type of actions that can be performed upon it.
- Reaching occurs when someone extends his/her arm to obtain or to touch an object, but can (or does) not reach this object. Also requests for objects by extending the hand were included in this category.
- Offering occurs when the speaker offers (or gives) an object or good to the infant.
- Taking occurs when someone takes over possession of an object from someone else.
- Conventional gestures comprises gestures that are symbolic of nature, such as emblematic gestures, but also gestures that bear an iconic relationship with their referent. For example, waving bye-bye, or indicating the size of the target object with the hands.
- Ritualized play accounts for all ritualized interactions or displays that occur between infants and communication partners. For instance, dancing, clapping hands or turntaking games, such as patty-cake.
- Embody occurs when someone directs another by physically "putting them through the motions of some activity" (Zukow-Goldring, 1996, p. 200), provided this has a communicative (or otherwise intentional) function. For example, placing the child on the mother's lap, pushing the infant in a certain direction, or taking someone's hand to demonstrate an action.
- Request for attention comprises any gesture that seeks for the attention of the interaction partner.
For the present study, we collapsed all gesture categories and report on the average number of gesture tokens addressed to the infants.
Both authors coded approximately half of all videos each, after which the coding was assessed and refined using improved coding schemes twice by trained research assistants. Both authors then coded approximately \(20 \%\) of
the video material to calculate inter-rater agreement with the final results. The resulting Cohen's kappa was measured to be 0.67 ( \(84.9 \%\) agreement), which according to Landis and Koch (1977) can be classified as 'substantial'.

Co-speech gestures After coding all gestures, we marked those gestures accompanied by a child-directed utterance as a co-speech gesture. We report the average number of cospeech gestures addressed to infants.

Figure 1: This figure shows the average amounts of childdirected utterances, gestures and co-speech gestures in the rural and urban areas at \(1 ; 1\). Error bars indicate standard deviations. All differences between communities are significant ( \(\mathrm{p}<.001\) ).

\section*{Results}

Figure 1 shows the average number of utterances, gestures and co-speech gestures addressed to the infants from the rural and urban communities. The graph reveals that urban communication partners address substantially more utterances, gestures and co-speech gestures than their rural counterparts. The number of child-directed utterances observed in the urban community is 5.7 times higher than observed in the rural area (according to the Mann-Whitney U test, \(\mathrm{U}=8 ; \mathrm{p}<.001\) ). The number of gestures - both with or without simultaneous speech - is 2.0 times higher in the urban community than in the rural \((\mathrm{U}=29 ; \mathrm{p}=.001)\). The frequency of child directed co-speech gestures occurs 3.2 times more in the urban community \((\mathrm{U}=22, \mathrm{p}<.001)\).

Table 2: Spearman correlations \(r_{s}\) of total amounts of child directed utterances, gestures and co-speech gestures at \(1 ; 1\) with expressive vocabulary development at both \(1 ; 5\) and 2;1. Note: * \(<\mathbf{p} 05\).
\begin{tabular}{lllll} 
& At 1;5 & & At 2;1 & \\
& Rural & Urban & Rural & Urban \\
\hline Utterances & -0.178 & \(0.554^{*}\) & 0.055 & \(0.607^{*}\) \\
\begin{tabular}{llll} 
Gestures
\end{tabular} & -0.270 & 0.482 & 0.256 & 0.508 \\
\begin{tabular}{l} 
Co-speech \\
gestures
\end{tabular} & -0.061 & \(0.667^{*}\) & 0.139 & 0.520 \\
\hline
\end{tabular}

Table 2 shows the Spearman correlations between the amounts of utterances, gestures and co-speech gestures produced at the infants' age of \(1 ; 1\) and expressive vocabulary sizes at infants' ages of \(1 ; 5\) and \(2 ; 1\). The first observation we can make is that urban child-directed utterances and co-speech gestures have significant correlations to expressive vocabulary size at \(1 ; 5\) (utterances: \(\mathrm{r}_{\mathrm{s}}[14]=0.554, \mathrm{p}<.05\); co-speech gestures: \(\mathrm{r}_{\mathrm{s}}[14]=0.667\), \(\mathrm{p}<.05\) ) and at \(2 ; 1\) (utterances: \(\mathrm{r}_{\mathrm{s}}[14]=0.607 ; \mathrm{p}<.05\) ). Note that all other correlations from the urban community approach significance ( \(\mathrm{p}<.10\) ). The second observation is that from the rural community, no significant correlations with vocabulary are revealed.

Given the differences in the amount of cognitive stimulation between both communities, we would expect to also see differences in the language development between the two communities, and we do (Table 3). The urban infants have a substantially larger expressive vocabulary than the rural infants. According to a two-way ANOVA on Age \(x\) Site, we see a main effect for age \((\mathrm{F}(2,78)=79.91\); \(\mathrm{p}<.001\) ) and for site \((\mathrm{F}(1,78)=13.41 ; \mathrm{p}<.001)\), and no interaction ( \(\mathrm{p}=.221\) ). A Tukey post-hoc test confirms the main effect of age ( \(\mathrm{p}<.001\) ).

Table 3: The average scores and standard deviations on expressive vocabulary from the MBCDI at \(1 ; 5\) and \(2 ; 1\) for both field sites. Note: Differences between urban and rural are significant as indicated with \({ }^{*} \mathrm{p}<.05\) and \(* * \mathrm{p}<.01\).
\begin{tabular}{lll}
\hline & At \(1 ; 5\) & At \(2 ; 1\) \\
\hline Rural & \(17.71(12.23)\) & \(50.85(23.59)\) \\
Urban & \(29.00(19.61)^{*}\) & \(72.92(23.18)^{* *}\) \\
\hline
\end{tabular}

\section*{Discussion}

The objective of this paper is to investigate whether infants from rural Mozambique experience less verbal and non-verbal stimulation than infants from urban Mozambique, and to assess how this correlates to later vocabulary development. The results clearly demonstrate that there are substantial differences between the rural and urban communities at all measured levels, i.e. the amounts of speech (as measured in utterances), gestures and cospeech gestures. This confirms Keller's (2012) predictions, but appears in contrast to our earlier findings that the total amounts of social interactions the same infants engage in whether these are verbal or non-verbal - are roughly the same in both communities (Mastin \& Vogt, 2013).

The difference in child-directed stimulation between rural and urban is largest regarding the number of utterances, which is 5.7 times higher in the urban community than in the rural community. This is considerably more than the difference in the amount of gestures ( 2.0 times higher) or the amount of co-speech gestures ( 3.2 times higher). Further analysis of the results from Figure 1 reveals that in both communities people use gestures more often than
utterances. However, this happens more in the rural community than in the urban community ( 3.5 times vs. 1.2 times). Moreover, we can infer that, on average, almost each utterance in the rural community is accompanied by a cospeech gesture, while in the urban community every other utterance is accompanied by a co-speech gesture.

These findings demonstrate that in the rural community relatively many social interactions with infants are nonverbal interactions. For instance, mothers may massage the infant's body, feed the infant or point to an object without talking. However, when the rural infant is addressed verbally, a gesture usually accompanies the speech. Urban infants are talked to much more frequently, but only half of the utterances addressed to them are accompanied by a gesture. In addition, although the link between speech and gesture appears less strong in the urban community, the absolute amount of child-directed gestural input for urban infants is much larger than for rural infants. Thus, the urban community, indeed, provides a richer language environment for the young than the rural communities do (Keller, 2012; LeVine et al., 1996).

The reason for this difference may well be due to the needs that different lifestyles demand of children when they grow older (Keller, 2012). In the rural community there is more need for children to help in the field or in the household, whereas the urban community value educational prospects for their children. However, other factors may contribute to these differences as well. For instance, there is a small difference regarding the educational levels that mothers obtained, so SES is likely to be a factor (Hart \& Risley, 1995; Rowe \& Goldin-Meadow, 2009). Also, due to globalization, the urban community may have adopted a more Western-like child-oriented socialization pattern (Schieffelin \& Ochs, 1989). Furthermore, there is the possibility that mothers in the rural area are less socially attached to their children until a certain age, either because of the high child mortality rates or because of cultural beliefs. Results from interviews we held indicate that in the rural area many mothers do not consider their child part of the community until well past their first birthday, while in the urban area most mothers considered their child a community member at birth or at least before they reach 6months (Mastin \& Vogt, 2013). Of course, additional issues such as health may play a role, and most likely a combination of factors explains why urban infants are exposed to more speech and gestures. Further research is required to understand why there is so much less childdirected speech in the rural community than in the urban.

Although on average the urban community do not gesture with each utterance, the amount of co-speech gestures correlates strongly to vocabulary size at \(1 ; 5\). Moreover, the amount of utterances addressed to infants in the urban community reveals significant correlations to vocabulary both at \(1 ; 5\) and \(2 ; 1\). So, these findings correspond well to results from earlier research in Western cultures (Hart \&

Risley, 1995; Iverson et al., 1999; Rowe \& Goldin-Meadow, 2009). However, the amounts of speech and gesture do not correlate to vocabulary development in the rural area, which contradicts these previous studies and is hard to explain.

One possible explanation is as follows: a yet unpublished analysis of the amount of social interactions infants engage in with different communication partners reveals that the amount of interactions with mothers is stable over time during infants' second year of life in the urban community. In the rural community, however, the amount of motherinfant interactions reduces substantially between \(1 ; 1\) and 1;5, while interactions with siblings increase by approximately the same amount, and which come to equal those of caregivers in frequency by the age of \(2 ; 1\). Thus, rural infants need to adapt more to changing caregiving structures than urban infants do, with the consequence that the rural socialization structure at \(1 ; 1\) is neither the same as the socialization structure at \(1 ; 5\) nor at \(2 ; 1\). The amounts of speech and gestures at \(1 ; 1\) may therefore not be viable predictors for vocabulary development in the rural area. Analysis of speech and gesture use at \(1 ; 5\) and \(2 ; 1\) should shed new light on this issue. If the interpretation provided here is correct, we expect that co-speech gesture use at \(1 ; 5\) in the rural community to be a better predictor for vocabulary size at \(2 ; 1\) than its use at \(1 ; 1\).

The results from the scores on the vocabulary checklist (Table 3) suggest a difference in the development of vocabulary in both communities. Despite the absence of a correlation between input and vocabulary in the rural community, the most likely candidate for this difference is indeed the difference in the amounts of speech, and consequently the amount of co-speech gestures, that infants are exposed to (Hart \& Risley, 1995; Pan et al., 2005). However, Harkness (1977) observed in rural Kenya that children spending more time with adult caregivers tend to talk more and become linguistically more advanced than children who spend more time with sibling caregivers. So, the differences in the socialization structure may be another candidate. A deeper analysis of who infants socialize with more frequently over time and how this relates to vocabulary development should provide new insights into the role of different caregivers on the infants' word learning processes.

The data presented in this paper are being annotated to develop corpora of multimodal interactions between infants and their social environment that can be incorporated in computer models (Matusevych, Alishahi, \& Vogt, 2013; Vogt \& Mastin, 2013). Using these corpora, we aim to mimic the observed interactions between infants and their surroundings as realistically as possible in multi-agent simulations. With such simulations, we plan to investigate various socio-cognitive theories explaining language development using realistic scenarios in which agents interact socially using speech and gestures according to observed frequencies, and measure the vocabulary
development of the simulated children. One possible application of such a simulation could be to analyze the socio-cognitive mechanisms that underlie the findings from this paper. The envisioned approach will thus provide novel avenues to study cultural and social aspects of multimodal interactions in children's language acquisition computationally in a verifiable manner.

To conclude, we have observed that rural infants are much less exposed to child-directed speech and childdirected co-speech gestures than urban infants, which correlates to their vocabulary development over their second year of life. These findings are in line with predictions based on Keller's (2012) distinction between rural and urban communities. These differences seem to affect vocabulary development as well, but while the results from the urban area are consistent with predictions from western studies (Hart \& Risley, 1995; Pan et al., 2005; Rowe \& GoldinMeadow, 2009), those from the rural community are inconsistent. More fine-grained analyses of the data are undertaken to investigate these differences. In addition, we are currently analyzing data collected from middle class urban families in the Netherlands to carry out a comparative study involving all three prototypical communities proposed by Keller (2012).

\section*{Acknowledgements}

This research was supported with a VIDI grant from the Netherlands Organization for Scientific Research (NWO, grant number 276-70-018). Field research would not have been possible without the assistance of Wona Sanana, Associação Communitária Ambiente da Mafalala, and our Mozambican research assistants. Thanks to Ingrid Masson, Mohamad Hafiz and Van Le for their assistance in coding. Finally, we offer a special thanks to our participant families for their kind hospitality and collaboration.

\title{
Logical Patterns in Individual and General Predication Momme von Sydow (momme.von-sydow@psychologie.uni-heidelberg.de \\ University of Heidelberg, Department of Psychology, Hauptstr. 47-51, D-69117 Heidelberg, Germany
}

\begin{abstract}
Probability judgments about logical propositions have raised substantial doubts about human rationality. Here we explore the idea that people's probability judgments often may not refer to the relative frequency of a set, but instead to the probability of an explanatory logical pattern given the data. This idea has been formalized by Bayesian logic (BL), predicting a system of frequency-based logical inclusion fallacies. The studies presented concentrate on comparing probability judgments about sentences logically relating two attributes of a class or an individual (humans, animals, artifacts). Although BL cannot model probabilities of individual predications directly, it can do so if one assumes that inferences are made about unknown individuals based on imagined samples. The results for general as well as individual predication show a high number of systematic inclusion fallacies in line with BL. Nevertheless, some deviations were found. In the General Discussion, a polycausal approach to inclusion fallacies is advocated. In addition, even if pattern probabilities seem to play a major role, it is suggested that extensions of the BL model may be needed to account for further aspects of real-life predication. Overall, however, even the basic BL model was surprisingly successful for predicting probability judgments about general as well as individual predications.
\end{abstract}

Keywords: Probability judgment; bias; conjunction fallacy; inclusion fallacy; inductive logics; predication.

\section*{Narrow Norms of Predication?}

Throughout Western philosophy (Aristotle, the Stoics, Leibniz, cf. even Kant and Hegel), and particularly since logical positivism (Frege, Wittgenstein, Russell, Whitehead), logic has been central (with slightly different understandings) to defining standards of rational thought. Today, standard calculi of logic and probability may appear narrow in comparison to the much broader Greek concept of logos, but they provide a rigidly defined standard of rational thought. And yet there is much evidence that people's actual reasoning seems to violate these basic calculi. Thus psychology is torn between the Scylla of abandoning normative reasoning (e.g., psychologism) and the Charybdis of claiming that people are fundamentally irrational, even with regard to the simplest rules of these calculi. Although there seems to be some truth in Kahneman and Tversky's (1996) warning against "normative agnosticism", the arguments of Gigerenzer and colleagues (e.g., Gigerenzer, 1996) against them seem reasonable as well: that is, that the blind application of the "narrow norms"' of logic and probabilitytheory often seem misguided. In my view, a domain-specific understanding of rationality may allow for a middle course between these positions. Context-sensitive norms of reasoning that account for our goals as well as the precondition of our models may not need to give up the core of the concept of rationality (cf. von Sydow, 2011).

When the calculi of logic and probability are applied in psychology, standard logic is normally used in deductive, and standard probability theory in inductive contexts. Here we consider both in assessing the inductive probability of logical relationships. Propositional logic addresses the combination of atomic propositions (that can either be true or false) with connectives (AND, OR, EITHER OR, NEITHER NOR, etc.). In the tasks we investigate probability judgments involving several alternative logical sentences, with different logical connectives relating two properties. We are either concerned with the properties of an entity or of a class of entities (individual vs. general predication).

The suggested domain-specific approach to rationality should consider the context and the goals implied. The context of our probability-judgment task is the assignment of attributes to a class. What is a reasonable, observationbased norm for predicating specific logical relationships between attributes, and how does this relate to probabilities (von Sydow, 2011)? At first sight, propositional logic seems a plausible candidate. A sentence such as "ravens are black and they can fly" logically seems to predicate the conjunction of attributes \((B \wedge F)\) to the class of ravens \((R)\). From a falsificationist perspective, this predication is valid as long as no single exception defies the rule. Predications about contingencies in the actual world (in contrast to mathematics) would all be rendered false, since one may assume that they are not free of exceptions. For instance, albino ravens exist, as well as other non-black ravens. It therefore seems reasonable to replace a purely logical adequate criterion of predication by a high-probability criterion (cf. Schurz, 2005). In the raven example, correct predication would require that \(P(B \wedge F \mid R)>\psi\), with \(\psi\) being the high-probability criterion. This proposal additionally appears to solve the problem of non-monotonicity, since now an adequate predication may become inadequate (and vice-versa) during further data-sampling. Nonetheless further problems remain.

Here only the problem of set-inclusion is sketched (cf. von Sydow, 2011, von Sydow \& Fiedler, 2012). The frequentist/extensional probability of the predication "ravens are black and they can fly" can never be larger than the probability of the inclusive disjunction \(P\) ("ravens are black or they can fly or both") \((P(B \vee F \mid R)\) ), since the former refers to a subset of the latter. Likewise, the AND sentence cannot have a larger probability than the tautology ( \(P\) (all feature-combinations are possible)). Using an extensional probability-criterion excludes preferring the predication of a more specific hypothesis over a (less informative) more general one. The tautology \((P(B T F \mid R)=\) 1) would always be a rational predication, even independent of data. Therefore, extensional probabilities could not be reasonable evidence-based criteria for adequate predication.

\section*{Probabilities of Noisy-Logical Patterns}

One way to resolve this problem and the problem exceptions together is to assume that people tend to judge the probability of alternative explanatory logical patterns instead of the relative size of particular sets, when concerned with probabilities of alternative logical predications, each meant as an explanation of the whole situation. A first formalization of this idea has been provided by von Sydow (2011, cf. von Sydow \& Fiedler, 2012). Here only the idea of the model, called Bayesian Pattern Logic (Bayesian Logic, or BL), is sketched, without providing a formal model. In the wake of the renaissance of Bayesian models (cf. Chater, Tenenbaum, Yuille, 2006; Kruschke, 2008; Oaksford \& Chater, 2007) it is formulated as a Bayesian approach. It formalizes the idea of explanatory logical patterns (an AND-pattern, an EITHER-OR-pattern, etc.), under absence of further factors. The model provides the measure of fit between a \(2 \times 2\) frequency table input and \(2 \times 2\) probability tables that may hypothetically have produced the data (hypothetical noisy-logical explanations). The probability tables are based on logical truth tables assuming equiprobability of true cases (cf. Johnson-Laird et al., 1999; Tenenbaum \& Griffith, 2001) and a uniform noise function. Based on these basic assumptions, the model first establishes the likelihood that some observed data have been produced by the probability tables, \(P(D \mid P T)\). To obtain the posteriors, the probabilities of these hypothetical noisylogical explanations given the data \((P(P T \mid D)\) ), one uses the Bayes theorem. To obtain the probability of a connective, one sums up the corresponding posteriors over all noise levels (for technical details, see von Sydow, 2011; cf. von Sydow, 2009, von Sydow \& Fiedler, 2012).

In sum, the extensional probability of a set (relative frequency) is here replaced by the second-order probability of noisy-logical patterns of probabilities (all four cells of a PT add up to 1). These patterns serve as hypothetical logical explanations. It is predicted that people use pattern probabilities to explain a whole situation in logical terms (class \(X\) is \(A\) and \(B\) ), instead of judging the size of a set or subset. Accordingly, \(P\) (ravens are black and they can fly) should be high, not because there are few exceptions but because our subjective frequency pattern best fits a noisy AND-pattern. If one is concerned with pattern probabilities, the probability that a data-set may be produced by an ANDpattern may well be higher than that for an OR-pattern: \(P_{P}(B \wedge F \mid R)>P_{P}(B \vee F \mid R)\). By contrast, a narrow application of extensional probability always requires that \(P_{E}(B \wedge F \mid R) \leq\) \(P_{E}(B v F \mid R)\) (cf. von Sydow, 2011).

Previous work in the conjunction-fallacy debate generally concerned a quite different, story-based task, showing that people may judge the conjunction more probable than the conjunct, e.g., \(P(B \& F)>P(B)\) (Tversky \& Kahneman, 1983). In a few cases, CFs were also shown without stories (e.g., Lagnado \& Shanks, 2002). In any case, most authors have assumed that such conjunction-judgments involve a "conjunction fallacy" (CF). Conversely, BL suggests a
rational explanation at least of a particular class of CFs [for convenience they are nonetheless called "fallacies" here].

The application of BL led to several new predictions and corroborative findings-for instance, on double CFs, sample-size effects, and pattern-sensitivity effects (von Sydow, 2011). The concept of CFs has been generalized to apply to system of logical connectives based on summary information (von Sydow, 2009) or sequential input (von Sydow, 2012). Whether or not other theories may account for independent causes of CFs (e.g., Lagnado \& Shanks, 2002; Tentori, Crupi, Russo, 2012), these results could not be explained by any other current theory. It seems plausible, then to conclude the existence of a class of pattern-based CFs. Additional factors-for instance, unclear set-inclusions (Sloman, Over, Slovak, \& Stibel, 2003), illicit implicatures (Hilton, 1995; cf. Hertwig et al. 2008), and probability format (Fielder, 1988)—remain plausible further facilitators for CFs, even if one is concerned with extensional probability judgments. Nevertheless, a high proportion of CFs were found even when simultaneously using clear formulations, clear set-inclusions, rating scales, and frequency information (von Sydow, 2011).

\section*{Individual vs. General Predications Based on Real-Life Frequencies}

The investigations reported here address three issues.
(1) Previous tests of BL used explicit frequency inputs, either in a table format (von Sydow, 2011) or in an experienced sequential learning format (von Sydow \& Fiedler, 2012). Although this allowed for precise tests of plausible models, it may differ from real-life predication where samples often have to be retrieved from memory. Moreover, the explicit frequencies presented in other tasks might have suggested the use of something like BL. We therefore assess here subjective frequencies of real-life predication independently from the task where participants judged probabilities of different logical sentences. Whereas previous tests focused on the variation of frequencies and only used a small number of scenarios, in order to reduce the influence of uncontrolled priors or other disruptive factors, we here used several different scenarios involving people, animals and artifacts.
(2) Despite previous success in modeling frequency-based prediction, it is an open issue whether the pattern idea is applicable to individual predications as well. BL cannot be applied to individual predication without an auxiliary hypothesis. The formal model has a frequency-based in-put-the four cells of a contingency matrix, ( \(f(B \& F)\); \(f(B \& \neg F) ; \mathrm{f}(\neg B \& F)\); \(\mathrm{f}(\neg B \& \neg F))\). Although some frequentists have been skeptical about probability judgments in individual cases, it seems plausible that humans often base their probability estimates, even for individual cases, on imagined subjective frequencies. The explored auxiliary hypothesis is that for individual predications (concerning e.g., a raven), one may - in the absence of further information simply imagine a hypothetical sample of ravens. This may be used as input for BL (suggested by von Sydow, 2011).

\section*{Overview}

In Preliminary Study 1 we first sampled sentences by asking participants for sentences that related two attributes logically. In Preliminary Study 2, participants provided estimates for the frequencies entered in a contingency table relating these attributes. Then in the main study we investigated general vs. individual predication and assessed in 30 scenarios which logical connective relating two attributes was judged to be most probable (an extended CF task with several connectives). We then modelled the predictions of BL based on the subjective frequencies from Preliminary Study 2. Finally, we compared the model predictions with the results for general and individual predication.

\section*{Preliminary Study 1}

Participants (twelve students from the University of Göttingen) had to fill in the blanks for 6 sentences, each concerning a different logical relationship between two attributes. For each sentence one filled in a class and two attributes, such as "Normally [In der Regel] \(\qquad\) are either
\(\qquad\) or \(\qquad\) ". The order of the six connectives was permutated, and an example was provided: "Normally chairs have four legs AND (at the same time) they have a seat." The predications consistently employed either the verb "to be" or "to have".

After obtaining the results, we narrowed down the number of sentences for Study 2. We excluded arbitrary sentences, obviously deterministic sentences, and sentences that seemed to contain an unwanted or over-complex causal background. We aimed to focus on the relation between two attributes of a class whose co-occurrence could be described in simple logical terms (e.g., ravens are black and can fly). In addition, we supplied four more sentences.

\section*{Preliminary Study 2}

Method Participants (23 students from the University of Göttingen, 78 \% female) provided subjective frequency judgments for the co-occurrence of two attributes in a \(2 \times 2\) contingency table for each of the 50 scenarios investigated. For each randomized scenario, participants assigned a sample of 100 hypothetical cases to the four cells of a table ( \(a, b, c, d\); see Figure 1).
Results Figure 2 shows four examples for the 50 resulting

\section*{Professional Basketball Players}

How certain are you that your estimated frequency distribution is roughly valid? \(\begin{array}{ccccccccccc}\mathrm{O}-\mathrm{O}-\mathrm{O}-\mathrm{O}-\mathrm{O} & \mathrm{O}-\mathrm{O}-\mathrm{O}-\mathrm{O}-\mathrm{O}-\mathrm{O}-\mathrm{O}-\mathrm{O}-\mathrm{O}-\mathrm{O}-\mathrm{O}-\mathrm{O}-\mathrm{O}-\mathrm{O}-\mathrm{O} \\ 0 & 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 & 10\end{array}\) Figure 1: Assessment of frequency estimates in Preliminary Study 2.
four-cell frequency distributions. The results were later used as input for BL to predict the probability judgments in the main experiment. Based on this study the scenarios were selected so as to have four scenarios for each of the six focused connectives. Two scenarios predicted the main connective with the highest relative frequency of participants (even if the pattern probability was below 50\%). The professional-basket-ball-player scenario (Fig. 1a) is an example for an AND-connective. \(P\) (tall AND also quick) is expected predominantly to be estimated higher than the probabilities of larger sets (despite exceptions). For two further connectives, the second most frequent hypothesis was predicted almost as often as the first. The application of the schema worked quite well, apart from the OR-class, where all scenarios reflected at best the second noise level. Finally, we investigated six 'noise-scenarios', where the predictions of BL become less clear, favoring even more than two connectives (generally to at least three).

\section*{Main Experiment}

Method The experiment had a 2 (general predication vs. individual predication, between subjects) \(\times 30\) (scenarios, within subjects) design. 20 participants judged for each scenario which of 15 logical sentences connecting two target attributes is most probably valid (extended CF task). The 30 scenarios were presented in random order and concerned people, animals and artifacts.

Figure 2: Boxplots depicting the distribution of the estimated frequencies in the four cells of the contingency matric (and of the confidence ratings) for four example scenarios (Preliminary Study 2; Median; 25\%-75\% boxes)

The instruction for both general and individual predication-conditions followed the same pattern, e.g., "Imagine [hundred / one] professional basketball player[s]. We are concerned with several propositions about [a] professional basketball player[s]. [...] Please tick the proposition that in this situation seems most probable to you." Participants should answer intuitively. In each of the scenarios participants selected the 1 out of 15 that seemed most probable. For the general predication condition, propositions opened with the class (e.g., "Professional basketball players are..."), and in the individual predication condition, with the individual (e.g., "A professional basketball player is..."). The 15 hypotheses always occurred in the same order, referred to all 16 dyadic logical connectives apart from the falsum/contradiction. For instance: A AND B (H1); A AND not-B (H2); NEITHER A NOR B (H4); A (H5); EITHER A OR B (H9); A OR B OR BOTH (H11), and everything is possible (Verum/Tautology, H15).
CFs \((P(A \wedge B)>P(A))\) may be due to reinterpretation of the logical connectives according to standard conversational implicatures (e.g., Hilton, 1995; Hertwig, Benz \& Krauss, 2008). If the affirmation \(A\) is contrasted with " \(A\) AND \(B\) " it may indeed reasonably be represented as " \(A \wedge\) non- \(B\) ". To avoid such misunderstandings, we in all studies used the formulation " \(X\) are \(A\) (and they are \(B\) or not-B)". Likewise, " \(A\) AND \(B\) " in ordinary language may well refer to " \(A\) OR \(B\) (or both)." In this interpretation, \(P(A \vee B)>P(A)\) is not fallacious. We used an OR-hypothesis and the following AND-formulation: " \(X\) are \(A\) (e.g., taller than 1.8 m ) and at the same time \(B\) (e.g., quick)." The verum read: " \(X\) are tall and quick, tall and slow, short and quick, or short and slow (all combinations)."

Forty participants (from the same population) volunteered to take part, receiving either course-credit or a fee.

Modeling For all scenarios we calculated the predictions of the model based on Study 2. For each participant and scenario we used the estimates for the four cells of the contingency table as input for BL, determining which hypothesis this participant would select as most probable. For reasons of simplicity we ignored further rankings. Calculated for all participants, this provided a reasonable prediction for the distribution of selections in the main task.

Results Figure 3 shows the predictions of the model as well as the accumulated results for the six types of scenario (referring to different dominant connective). Each chart represents four scenarios. Although grouped this way by

\[
\begin{gathered}
\text { Hypotheses } \\
\mathrm{r}_{\mathrm{B} 1-\mathrm{B} 2}=.85, \mathrm{r}_{\mathrm{B} 1-\mathrm{M}}=.78, \mathrm{r}_{\mathrm{B} 2-\mathrm{M}}=.78 \quad \mathrm{r}_{\mathrm{B} 1-\mathrm{B} 2}=.71, \mathrm{r}_{\mathrm{B} 1-\mathrm{M}}=.67, \mathrm{r}_{\mathrm{B} 2-\mathrm{M}}=.89
\end{gathered}
\]

\[
r_{\mathrm{B} 1-\mathrm{B} 2}=.90 ; \mathrm{r}_{\mathrm{B} 1-\mathrm{M}}=.26 ; \mathrm{r}_{\mathrm{B} 2-\mathrm{M}}=.30
\]

Figure 3: For all six focused types of connectives, the graphs provide a visualization of the results for general and specific predications (percentage of selections) and of the model-predication (averaged over scenarios). On the ordinate, the proportion of actually selected or predicted hypotheses (H1 to H15) is shown (cf. text for details).
design, based on Study 2, the scenarios should differ somewhat (low noise vs. high noise). Figure 3 therefore provides merely a simplifying visualization. Nonetheless it does depict the main pattern concisely and well.
In the H1 scenarios (involving, e.g., the basketball-players and ravens scenarios) the AND-connective was the most frequently selected. Such judgments involve estimating \(P(A\) AND \(B\) ) to be more probable than \(P(A), P\) (Either both attributes or none), \(P(A\) OR \(B\) or both), and \(P\) (Tautology). Given the presence of exceptions (e.g., Figure 2a), this would traditionally be interpreted to involve several simultaneous logical inclusion fallacies (von Sydow, 2009). Moreover, it appears that on this level the overall distribution of selections reflect the predictions quite closely. The most striking deviation in this and the other scenarios, however, was that H15 (the tautology), the extensionally correct solution, was selected more frequently than predicted (cf. Fig. 2).
In the H2 scenarios, participants predominantly selected the predicted sentences " \(X\) are \(A\) and not \(B\)," likewise involving several inclusion fallacies, as most probable.
The H11 scenarios yielded the strongest deviations from the predictions (to be discussed below).
For the other scenarios (H4, NEITHER NOR; H5, Affirmation A; H6, EITHER OR), the results corroborated both the predicted dominant selections and an overall high correspondence between BL and the data.
Figure 3 additionally provides strong evidence for a high similarity between results in the two conditions, the individual and general prediction tasks.

These overall results need supplementation from further measures, in order to assess results on the level of the single scenarios. Accumulation of the results of four scenarios of a type, such as in Figure 3, increases the \(N\) (reducing chancefindings) and excludes confounding factors specific to single tasks; but such results will tend to yield too positive a picture.

Table 1: Mean correlations between model-predictions and results, as well as between the two kinds of predication (individual and general) for the single scenarios in the six types H 1 to H 9 ) and a further noise class
\begin{tabular}{cccccccc}
\hline & H1 & H2 & H11 & H4 & H5 & H9 & noise \\
\hline \(\mathrm{r}_{\mathrm{B} 1 \mathrm{~B} 2}\) & .85 & .71 & .79 & .89 & .92 & .82 & .75 \\
\(\mathrm{r}_{\mathrm{B} 1 \mathrm{M}}\) & .78 & .67 & .41 & .63 & .80 & .72 & .24 \\
\(\mathrm{r}_{\mathrm{B} 2 \mathrm{M}}\) & .78 & .89 & .43 & .73 & .91 & .83 & .34 \\
\hline
\end{tabular}

Table 1, despite using averages, for this reason focuses on correlations for the single scenarios in a class. Please note, this differs from correlations on the accumulated level (which actually yield correlations .09 higher on average). Table 1 shows correlations between model and results, as well as between individual and general predicationconditions. The average correlations were all positive and generally large (or very large).

Only for H 11 the average correlations with the model were only moderately positive. This was likewise the case for the high-noise scenarios (where predictions did not favor specific connectives). In these two classes, the number of tautology-selections was higher than expected (H15). The two deviations may be explained along the same lines: as mentioned, the OR-scenarios, just as the noise-scenarios, had much less clear predictions than all other scenarioclasses. The second- and thirdmost frequently predicted hypotheses were not much less frequently predicted than the OR hypotheses themselves. Moreover, even for ORpredictions (based on specific participants of Pre-test 2), the second-highest pattern-probability, did not generally differ substantially from the second-highest. Such uncertainties in both may have led to the selections of H15, which suggested that everything is possible.

Even if the 30 scenarios were analysed individually (which cannot be done here) the overall pattern would remain similar. All 90 calculated correlations were positive, and only \(14 \%\) yielded \(r<40\) (particularly in the mentioned classes). The examples from Figure 2 with dominant AND, EITHER OR, A and OR predictions, for instance, corroborated the predicted dominant selections and had a high model-fit. Nonetheless, a low number of correlations did not show the overall positive results (even outside of the two mentioned classes), with values close to 0 and asymmetrical findings for both specific and general predications.

\section*{General Discussion}

The findings corroborate that people do not judge probabilities extensionally, but instead allow for exceptions. Participants systematically committed a large number of
inclusion fallacies (generalizing CFs, cf. von Sydow, 2009; von Sydow \& Fiedler, 2012). Pattern probabilities, as formalized by BL, were shown to be quite successful in modeling the probability judgments in a multitude of scenarios only indirectly based on frequency estimates in Preliminary Study 2. Other models of CF have not yet been explicitly designed to test for these connectives, but it is as yet highly implausible that some adaptation of these models (e.g., confirmation, inverse probability, representativeness, averaging, quantum logic, support theory, rescaling, signed summation, etc.) will easily account for these data equally well without adopting the very idea of pattern probabilities themselves (cf. von Sydow, 2009, 2011, for more details).

Moreover, there was a large similarity between probability judgments about general predication and prediction about singular subjects. Combining BL with the auxiliary hypothesis that people may base judgments about singular nouns on hypothetical sampling led to quite successful predictions. However, it needs to be mentioned that the current finding might be limited to a generic interpretation of the singular subjects (e.g., "a professional basketball player (PBP) is/has"), although the introduction suggested an individual reading ("imagine one PBP"; "propositions about a PBP"). Further research is needed to investigate the role of different formulations in more detail.

Finally, some quantitative deviations from the predictions were found-some in a quite explainable manner regarding two classes of scenarios- but unsystematic deviations for single scenarios were found as well. Although this did not substantially alter the main findings, it may suggest that further factors are at work. To state it more emphatically, in my view, it would be a surprise if there were in fact no additional factors:
(1) Despite favoring BL as important account for CFs, I think there may be several other causes of CFs as well. I have mentioned other theories above. An example is that people in some contexts may reasonably be interested in the increase of probabilities (confirmation) instead of probabilities themselves (e.g., Lagnado \& Shanks, 2002; Tentori, et al., 2012); and there may well be situations where people are interested in a synthesis of confirmation and the pattern idea: the degree of confirmation of different logical patterns.
(2) Even if focusing on pattern probabilities the current formalization of BL may only be one sub-class of modeling pattern probabilities in real-world predications. The current formalization is concerned with dyadic classes and assumes an equally weighted \(2 \times 2\) input. Considerations to be examined include: (a) Although dyadic dichotomous logic as well as human language is often concerned with dichotomous (or dichotomized) categories, the implicit number of relevant categories can vary and may well matter. (b) The dichotomous classes need not refer to categorical classes, but can point to an underlying ordinal, interval, or rational scale. This may require a modified pattern approach that weights extreme cases more heavily. A domain specific approach to rationality that takes preconditions of models seriously should be sensitive to such aspects. (c) The
categories and resulting frequency estimates may be defined in either an absolute (larger than 1.80 ) or a relative way (large). If the latter, BL's input may needs to be modelled depending on the context. (d) Within the present model, different contexts (scenarios) may lead to different noisepriors (reflecting the learned tolerance for exceptions for different scenario types), whereas here always flat noiseprior was used (cf. von Sydow, 2011). (e) People might assign important properties more weight than unimportant properties.
(3) The relationship between individual and general predication is presumably more intricate than assumed in the studies. As we have seen, BL is designed for general predication with a frequency-input based on a \(2 \times 2\) contingency matrix. This assumes that evidence is ordered as cases to be assigned to one of the table's four cells. The results presented here support the idea that one can model individual probabilistic predication along the same lines by imagining 100 individuals and finding the highest pattern probability for statements as "A sophomore either owns a flat or shares a flat" (Fig. 2b). This seems unproblematic, since individual sophomores still fall into one of the four classes. The EITHER-OR here only expresses a lack of knowledge about which of two classes the individual is actually fits. Nevertheless, sentences such as "this ape from species \(X\) is either aggressive ( \(A\) ) or curious ( \(C\) )" need not indicate lack of information, but rather an alternative meaning: that is, the individual ape may have been \(A\) (without being \(C\) ) and at other times the reverse. Notably, the input-assumption would still hold for individual predication on a sub-individual event level, but on the group level this apparently positive extension of BL to individual predication now seems problematic; for, if an individual is "either \(A\) or \(C\) " it no longer fits any of the four classes ( \(A\) \& \(C, A \&\) non- \(C\), non- \(A \& C\), or non-A \& non-C). This problem may be solved by adding \(1 / 2\) to both relevant cells, resulting at least in similar predications for both levels. Nonetheless, the issue remains problematic if we are concerned with heterogeneous groups of individuals, where in most cases \(X\) are either " \(A\) or \(C\) or both" or " \(A\) and \(C\) " (each based on sub-individual frequency information). The inclusive predicate " \(A\) or \(C\) or both" alone may be inappropriate. Participants may be interested in a pattern of patterns ( \(X\) are \((A \wedge C)><(A \vee C))\); and interpreted as pattern, this does not needs to be equivalent to \(A><C\), as actually valid in propositional logic. Such a pattern-of-pattern interpretation would not only be an interesting field of future research, but it might discourage the selection predicated by standard BL which assumes the absence of sub-classes.

In summary, real-life predication as well as probability judgments about these logical predications may plausibly be affected by a variety of additional factors, either external or ones calling for other more context-sensitive formalizations of pattern probabilities. In the light of such suggestions, the basic BL model was shown here to be surprisingly successful in accounting for a great variety of probability judgments about general as well as individual predications.

\section*{Acknowledgments}

Aspects of this research, presented here in written form have previously been introduced in talks. I am grateful for the inspiring discussions at the Universities of Göttingen (M. R. Waldmann group) and Heidelberg (K. Fiedler group). I am also grateful for help from Martha Cunningham, Johanna Frisch and Dennis Hebbelmann and for the feedback of the anonymous reviewers. This work was supported by the grant Sy 111/2-1 from the Deutsche Forschungsgemeinschaft (DFG) as part of the priority program New Frameworks of Rationality (SPP 1516).

\begin{abstract}
The extent to which people learning categories generalize on the basis of observed instances should depend in part on their beliefs about how the instances were sampled from the world. Bayesian models of sampling have been successful in predicting the counter-intuitive finding that under certain situations generalization can decrease as more instances of a category are encountered. This has only been shown in tasks were instances are all from the same category, but contrasts with the predictions from most standard models of categorization (such as the Generalized Context Model) that predict when multiple categories exist, people are more likely to generalize to categories that have more instances when distances between categories is controlled. In this current work we show that in both one- and two-category scenarios, people adjust their generalization behavior based on cover story and number of instances. These patterns of generalization at an individual level for both one- and two-category scenarios were well accounted for by a Bayesian model that relies on a mixture of sampling assumptions.
\end{abstract}

Keywords: sampling assumptions, generalization, category learning

\section*{Introduction}

The ability to generalize beyond existing data is a basic cognitive capacity that underlies a great deal of human learning, categorization and decision-making (e.g. Shepard, 1987; Tenenbaum \& Griffiths, 2001; Nosofsky, 1986). To complete the inductive leap needed for generalization, people must make some kinds of assumptions about how that data was generated or sampled. A learner's sampling assumptions influence the evidentiary value of the data, and thus alters what they should infer based on it.

One natural assumption is that each observed datum has been selected independently and then labeled as a member (or not) of the category or concept to be learned. An example of this is a parent who tries to teach a child what a "ball" is by randomly picking from all of the toys her room then labelling them as balls or not. This possibility, called weak sampling, implies that all observations \(x\) are equally likely, regardless of what hypothesis \(h\) the learner has about the category. Mathematically, this corresponds to the notion that \(P(x \mid h) \propto 1\).

A different type of data generation, known as strong sampling, presumes that the data has been selected as a random positive example directly from the category to be learned
(Tenenbaum \& Griffiths, 2001). A parent who teaches the word "ball" by showing the child many different kinds of balls (but not other toys) is strongly sampling from the category of BALL. The key consequence of strong sampling is that it licenses tighter generalizations with increasing data. This is because each datapoint is more informative about the boundaries of the category. Mathematically, for a hypothesis \(h\) that consists of \(|h|\) possible category members, the strong sampling model implies that \(P(x \mid h)=1 /|h|\) if the observation \(x\) falls within the category, and 0 if it does not.

There is evidence that people are sensitive to sampling assumptions, making tighter generalizations when the data appear to have been strongly sampled (e.g. Xu \& Tenenbaum, 2007). However, a number of questions remain unresolved, two of which we address in this paper.

The first, more minor, issue relates to the influence of the cover story. As mentioned, work by Xu and Tenenbaum (2007) suggests that both adults and children change their generalization patterns in response to differences in sampling. This appears to contrast with other work by Navarro, Dry, and Lee (2012), which found that although sampling assumptions varied between individual participants (with some assuming strong sampling and others weak), people did not change their behavior according to the cover story they were presented with. One way to resolve the discrepancy between these two studies is to conclude that the data generation process was much more obvious in Xu and Tenenbaum (2007). In that study, participants actually saw instances selected in front of them, whereas in Navarro et al. (2012) participants simply read different cover stories. Here we explore whether it is necessary for people to see data being generated in order to change their sampling assumptions, or whether a more salient cover story manipulation would be sufficient.

The second issue we investigate is a more important and more puzzling one. It is generally acknowledged that inductive generalization is very closely linked to categorization. For instance, exemplar models of categorization (e.g., Nosofsky, 1986) are constructed by assuming that the learner uses a simple probabilistic model to generalize from each stored exemplar to a target item. The "narrowness" of the generalizations is a fixed parameter (referred to as the specificity)

Figure 1: Different predictions made by a standard categorization model (the GCM) and a Bayesian model that incorporates a strong sampling assumption. The GCM, on the left panel, predicts that as the number of instances in a category increases (shown in the figure by the additional points in the bottom row), generalizations should loosen slightly: the solid line corresponding to generalizations based on later additional instances in Category A extends further from Category A. By contrast, the model incorporating strong sampling predicts that generalization based on additional instances will tighten: the solid line in the right panel is much closer to Category A than the dotted line corresponding to earlier, fewer instances.
and does not change as the sample size increases. This is effectively a weak sampling assumption, and it is assumed by both the basic Generalized Context Model (Nosofsky, 1986) and by models such as ALCOVE (Kruschke, 1992) that extend it. These models have proven highly successful at describing human classification behavior, apparently with little need to adapt them to incorporate some version of the strong sampling assumption. If human learners are as sensitive to sampling assumptions as papers such as Xu and Tenenbaum (2007) imply, why has it not been necessary to incorporate such assumptions into existing categorization models?

We can think of at least two possible (not mutually exclusive) explanations for this. The first one is that sampling effects have not been found simply because few studies have gone looking for them. Standard supervised classification designs do not manipulate the sampling assumptions, and it could be argued that the instructions and design of such experiments often imply weak sampling. As such, it is natural to expect that the theories used to explain these experiments would implicitly rely on weak sampling assumptions. A similar suggestion is made by Hsu and Griffiths (2010).

An alternate possibility is that these divergent results arise because of a genuine difference in the nature of the experiments: the number of categories involved. Typical categorization experiments generally involve two categories, with stimuli needing to be classified as belonging to one or the other (Nosofsky, 1986). In contrast, researchers testing sampling assumptions have tended to use tasks in which participants are asked to draw inferences about only a single target category (Xu \& Tenenbaum, 2007; Navarro et al., 2012).

In this paper we test the latter possibility by making use of the fact that strong sampling models make a different prediction from standard categorization models in certain situations. A multiple-category version of a Bayesian generalization model with strong sampling \({ }^{1}\) predicts that if we increase the number of instances in Category A without changing the number of exemplars in the other category, items that lie in between the two categories should decrease in their probability of being classified as members of Category A. This is because strong sampling leads to tighter generalization of Category A with more instances, (right panel of Figure 1). Note further that this is the opposite of what one would expect from a standard exemplar model: adding more exemplars to Category A but not to the other category can only increase the summed similarity between Category A exemplars and a target item. As a consequence, items that lie between the two categories should increase in their probability of being classified as members of Category A (left panel of Figure 1).

These distinct predictions motivate our experiment: we present learners with either one-category or two-category generalization problems, presented either in the context of a strong or weak sampling cover story. We predict that when in the context of strong sampling, people will modulate

\footnotetext{
\({ }^{1}\) The two-category Bayesian strong sampling model is a minor modification of the one-category strong sampling model described by Tenenbaum and Griffiths (2001). The only difference between that model and the current one lies in how the hypotheses about the extension of a category (the"consequential regions") are defined. In the two-category model the stimulus space is divided into two mutually exclusive regions, one for each category. As per the original model, category items are assumed to be sampled uniformly at random from the region of that category.
}

Figure 2: The experimental design. The top panel refers to the three sets of stimuli used across each block in the one-category task. The bottom three panels refer to the three possible sets of stimuli used in the different base rate conditions for the twocategory task (results from the bottom two sets are collapsed into one UNEQUAL BASE RATE condition for the purposes of analysis). All participants performed the one-category task as well as one of the three two-category tasks. The ticks at the bottom of each panel show the location of each of the test points for each condition.
their generalization based on cover stories such that they will tighten their generalization of a category label in response to observing additional exemplars in that category that do not extend the category boundary.

\section*{Method}

Participants Data was collected from 318 participants from Amazon Mechanical Turk. No demographic information was collected so participants remained anonymous. Participants were paid \(\$ 0.50 \mathrm{USD}\) for their participation to complete the task which lasted approximately 15 minutes.
Procedure Each participant performed a one-category and a two-category generalization task in random order following a scenario adapted from Navarro et al. (2012). In the onecategory task, participants observed instances of temperatures at which one type of bacteria was found alive in food. They were then asked to estimate the probability that the same bacteria would be found alive in the food at other temperatures. In the two-category task, participants observed instances of
temperatures where two types of bacteria were found alive in food. They were also told that the two types of bacteria competed for resources, so only one type of bacteria could be found alive in the food at any given temperature. As in the one-category task, participants were asked to estimate the probability that one of the two types of bacteria would be found alive in the food at other temperatures.

The experiment also contained two between-subjects manipulations. The first was a sampling assumption manipulation in which participants were presented with different cover stories in order to influence their beliefs about the sampling process. In the STRONG SAMPLING condition, participants were told that the instances were selected by scientists who had identified a number of temperatures where bacteria were found alive in food. This cover story suggested to the participant that the scientists were only selecting positive examples from the category, consistent with strong sampling. Conversely, in the WEAK SAMPLING condition, participants were told that the instances were the result of an automated pro-

Figure 3: Mean generalization probabilities in the onecategory task across sampling condition and block. Generalization is tighter in the STRONG SAMPLING conditions but does not differ by block.
cess that tested the bacteria at different temperatures. This suggested to the participant that the presented instances were chosen at random from the range of all possible temperatures, consistent with weak sampling. People who were in a given sampling condition received the same (strong or weak) sampling cover story for both the one- and two-category tasks.

The other between-subject experimental manipulation varied the base rate in the two-category generalization task. In the EQUAL BASE RATE condition, the number of instances observed in both categories was the same. There were also two conditions in which one category contained more instances: one in which the left category had more and one in which the right category had more. Because there were no differences between these two conditions, all analyses collapsed them into one UNEQUAL BASE RATE condition. The different conditions are illustrated in Figure 2.

In both the one-category and two-category tasks, the instances were presented across three blocks. In the onecategory task, participants initially saw three green dots representing temperatures where bacteria was found alive in the food. They were then asked to estimate (using a slider) the probability that the bacteria would be found alive at each of 22 temperatures in sequence. As a measure of whether participants were performing the task correctly, two of the 22 test trials were located inside the range of observed instances. After making the 22 judgments, participants were then presented with two more instances and asked to make the same judgments again. In the final block, they were presented with one more instance before repeating the 22 estimates again. Overall, each participant made 66 judgments ( 3 blocks \(\times 22\) queries) in the one-category task.

The procedure in the two-category task was very similar, except that participants were presented with instances representing the temperatures where bacteria from both the left and right categories were found alive (shown as blue and red dots respectively of Figure 2). Participants were asked to estimate the probability that the blue bacteria (the left category) would be found alive in the food at each of 11 temperatures. All

Figure 4: Mean generalization probabilities in the twocategory task across sampling condition, base rate condition, and block. Generalization is tighter in the STRONG SAMPLING condition regardless of category base rate.
of the test points in the two-category task were between the two categories, except for one within the range of instances for each of the categories. As in the one-category case, participants were given additional instances at the beginning of each block and then asked to make judgments at each of the test points. This resulted in a total of 33 judgments ( 3 blocks \(\times 11\) queries).

\section*{Results}

Participants who failed to understand the task (based on their performance on the within-category test points) were excluded from the analyses. We reasoned that people who correctly understood the experimental task would have assigned probabilities close to \(100 \%\) for the test points within the categories. Therefore, participants who assigned a probability of less than \(90 \%\) on all six test points were removed from that condition. This left 203 participants in the one-category task and 165 participants in the two-category task.

Our first question was whether different cover stories about sampling had an effect on generalization. We examined this by first looking at the raw generalization probability estimates provided by participants. Figures 3 and 4 show the mean generalization probabilities across each condition by block. Consistent with our predictions, in both tasks the mean generalization probability was lower (i.e., participants tightened their generalizations more) in the STRONG SAMPLING condition relative to the WEAK SAMPLING condition \((t(201)=\) \(-.290, p<.05\) for the one-category task and \(t(163)=-3.07\), \(p<.05\) for the two-category task).

Another way to determine whether the sampling cover story had an effect is to fit individual data using the mixed sampling model from Navarro et al. (2012). This model interpolates between weak and strong sampling assumptions, assuming that an observation is strongly sampled with probability \(\theta\) and weakly sampled with probability \(1-\theta\). We can use this to calculate a best-fit \(\theta\) value for each person, reflecting the extent to which their generalizations were consistent with strong sampling ( \(\theta\) close to 1 ), weak sampling ( \(\theta\) close to 0 ), or something in between. Because the mixed sampling

Figure 5: Generalization by block in an additional experiment in which participants were given many more instances in blocks 2 and 3. Generalization probabilities tightened with additional instances, suggesting that earlier lack of tightening was due to conservative updating rather than rejection of the implications of a strong sampling model.
model was originally developed to model generalization responses from a single category, we captured participant responses from the two-category case by treating the left category as the single category whose consequential region is bounded by the leftmost point in the right category. Overall, the model was able to provide a good account for individual responses in both tasks, with a median correlation between the model predictions and participant responses of 0.92 in the one-category task and 0.96 in the two-category task.

As expected, there were significant individual differences in inferred \(\theta\) values as a function of cover story. Calculating separate beta regressions over condition for each task (which we did because the distribution of \(\theta\) values deviated from normality) shows that type of sampling condition was a significant predictor of the estimated \(\theta\) value in both the one-category \((z(3)=-4.23, p<.001)\), and the two-category task \((z(3)=-4.38, p<.001)\). Overall, these results suggest that people did change their generalizations in response to the cover story, and that the \(\theta\) parameter in the mixed sampling model is sensitive to that change.

A related prediction was that increasing the number of instances should result in tighter generalization in the STRONG SAMPLING condition. We tested this prediction by comparing generalization probabilities in the first and last (third) block of test trials (shown in Figures 3 and 4). Although there was a significant difference between generalization probability in the first and last blocks in the two-category EQUAL BASE RATES condition (paired-samples t -test, \(t(29)=2.16, p=\) \(0.019)\), the differences in the one-category task \((t(116)=\) \(1.08, p=0.142\) ) and the two-category UNEQUAL BASE RATES condition \((t(65)=1.50, p=0.069)\) did not reach sig-
nificance. \({ }^{2}\) Is this because people do not, as predicted by the strong sampling model, tighten their generalizations with additional instances? Or is it simply that people are conservative, tightening their generalizations less than such a model would predict?

To investigate this question, we ran an additional experiment involving generalization with 47 participants in the onecategory task and 44 participants in the two-category task. The experiment was identical to the STRONG SAMPLING condition of the previous one except that participants were shown many more instances in blocks two and three. As Figure 5 illustrates, when presented with these large amounts of additional instances people in all conditions and tasks tightened their generalizations considerably. Each person's mean generalization probability in the last block was significantly less than their generalization in the first block in both the onecategory \((t(46)=4.53, p<.001)\) and the two-category task \((t(43)=4.07, p<.001)\). Within the two-category task, generalizations tightened significantly in both the EQUAL BASE RATES \((t(14)=2.31, p=0.018)\) and UNEQUAL BASE RATES \((t(28)=3.27, p=0.014)\) condition. \({ }^{3}\) This pattern of tightening with more instances is more consistent with a Bayesian model that includes some proportion of strong sampling than a standard categorization model like the GCM.

\footnotetext{
\({ }^{2}\) As expected, all differences in the WEAK SAMPLING conditions were not significant, with \(p\) values ranging from 0.317 to 0.458 .
\({ }^{3}\) Recall that this condition incorporated the LOWER BASE RATE and HIGHER BASE RATE conditions into one analysis in which both the high-base-rate and low-base-rate left-hand category were combined. Both show significant tightening when analyzed separately as well.
}

\section*{Discussion}

This current work clarifies perhaps the most troublesome aspect from Navarro et al. (2012): that large individual differences in proportion of strong and weak sampling assumptions were observed but people did not seem to be sensitive to the sampling type suggested by the cover story. By directly referencing in the cover story how samples were being generated: either by direct selection for strong sampling or random occurrence for weak sampling, we find reliable differences in generalization between the two cover stories in the onecategory condition. This pattern of results is accounted for naturally by a Bayesian model using a mixture of strong and weak sampling assumptions (Navarro et al., 2012) and is consistent with standard categorization models such as the GCM (Nosofsky, 1986) that rely on differences in the specificity parameter between cover story conditions. We believe the sampling assumption model account is slightly more parsimonious because it a priori predicts that the weak sampling condition will show wider generalization gradients than the strong sampling condition, rather than relying on a freely varying model parameter.

Interestingly, the difference between strong and weak cover stories is found not only in the one-category but also the two-category scenario. That this pattern exists not only when only positive examples of a single category are observed but also when more than one category is observed, suggests that beliefs about sampling processes influence behavior even in situations more traditionally thought of as category learning. As in the one-category scenario, a model Navarro et al. (2012) without category learning processes and relying only on different mixtures of sampling assumptions is able to account for the behavioral results with a high degree of accuracy.

The presence of significant gradient tightening only at large changes in the number of instances suggests some additional process is mediating the effect of gradient tightening predicted by the Bayesian model that incorporates a mixture of strong and weak sampling. One possibility for such a mediating process would be conservatism (Phillips \& Edwards, 1966), some reluctance to update beliefs about the boundary of each category as much as is suggested by a rational model that includes strong sampling. This conservatism may be due to assumptions that learners might be making about other possible sampling processes including noisy instance generation, noisy labelling, or could be the result of cognitive processes that do not weigh each instance equally as the Bayesian model does (Navon, 1978).

In summary, in both the one- and two-category scenarios, people had different patterns of generalization from known instances to new instances based on a cover story that suggested strong or weak sampling was generating the instances they saw. Additionally, the degree of generalization decreased as many more instances were shown from the target category, more than predicted by standard models of categorization like the GCM but less than predicted by a Bayesian model that mixed strong and weak sampling. Patterns of
generalization at an individual level for both one- and twocategory scenarios were well accounted for by this Bayesian model, suggesting people are sensitive to the sampling assumptions that are generating the instances they see during categorization.

\title{
Help-Seeking As A Cause of Young Children's Collaboration
}

\begin{abstract}
Young children's collaboration is a topic of great interest, yet what causes children to initiate collaboration in some circumstances but not others is unclear. In this research, we analyzed preschoolers' collaboration as an information gathering activity in a toy assembly activity. We independently assessed children's competency at a similar building task and, using a separate group of children, the difficulty of each step of the activity. We hypothesized that children would request collaborative assistance when they needed assistance (that is, when they were less competent and/or the task was more difficult), but act independently when capable. The results confirmed that preschoolers were more likely to request collaborative assistance as the difficulty of the activity increased and more so if they were initially less competent. The results suggest that preschoolers' collaboration may be profitably viewed as an information gathering activity.
\end{abstract}

Keywords: Collaboration; help-seeking; social learning; preschool children; play.

\section*{Introduction}

Recently, there has been considerable interest in children's early-emerging social learning abilities, including their reliance on social information (Koenig \& Harris, 2005) and their propensity to learn through collaboration (Duran \& Gauvain, 1993; Foley, Ratner, \& House, 2002; Paradise \& Rogoff, 2009; Sommerville \& Hammond, 2007). Indeed, it has even been argued that these social learning abilities, in particular collaboration and the psychological motivations underlying collaboration, are what distinguish humans from nonhuman primates (Tomasello, Call, Behne, \& Moll, 2005).

Recent research on children's collaboration has emphasized the importance of children's tendency to appreciate joint goals and commitment to collaborators. This research has demonstrated that children collaborate even when doing so does not gain them any explicit benefits (Warneken, Gräfenhain, \& Tomasello, 2012). Nonetheless, what causes children to initiate collaboration is still widely debated. Researchers have proposed a range of factors that highlight complementary processes that are generally consistent with one another (Tomasello et al 2005). The range of suggested factors includes a general motivation to share cognitive states with others, a "curiosity" to understand psychological and physical causes, and a social game theoretic distinctively rewarding to humans
(Tomasello et al, 2005). These possible causes are clearly not mutually exclusive. Moreover, many of them make a similar prediction: when children are offered the opportunity to involve others in tasks, they will do so regardless of whether they need help at all.

Intriguingly, research on people's help-seeking could shed light on why children collaborate in some circumstances, but not all. Specifically, help-seeking involves a help seeker signaling to a helper a desire for them to assist in attaining a goal. Help-seeking often occurs when an individual is not confident in their ability to independently complete the task (Nelson-Le Gall et al, 1990). Interestingly, requests for assistance can result in a range of collaborative exchanges of information and action. For instance, responses can vary from indirect verbal hints that facilitate the help seeker to direct coordination of actions between the help seeker and helper. Indeed, help seekers often prefer to avoid receiving too much help, so as to remain actively involved (Nelson-Le Gall, 1986). Thus, help-seeking generally occurs in relation to uncertainty about independently carrying out the task, and can lead to a variety of collaborative exchanges of information and action.

In this research, we examined children's helpseeking as a proximate cause of collaboration that may contribute to children's learning. From this perspective, children face information gathering trade-offs in acting alone versus collaborating. Relatedly, empirical studies show that children often prefer to play on their own, and indeed there are learning benefits to such autonomous exploration (Schulz \& Bonawitz, 2007). Children at times learn more from acting than from watching someone else perform an action (Berry, 1991; Sommerville, Hildebrand \& Crane, 2008; Kushnir, Wellman, \& Gelman, 2009). However, when a child is cognitively or motorically unable to perform an activity, they gain little or no information by acting. Therefore, in this case the child may seek assistance instead of struggling alone. We hypothesized that, rather than always involving others in their play, children will be more likely to request collaborative assistance only when they need assistance. More specifically, we ask whether the difficulty of the activity and the competence of the individual child will predict changes in the frequency and nature of their collaborative interactions.

The empirical investigation of our hypotheses required permitting children to choose to act independently
or request collaborative assistance. In permitting children to act spontaneously, we needed to form and apply definitions of collaboration in our coding scheme. To do this, we referenced past research on children's collaboration to attempt to remain consistent in the definition of the phenomenon. In past research, collaboration has been defined as actively coordinating actions, verbally planning towards a goal, and taking turns with another person (Foley, Ratner, \& House, 2002; Warneken, Chen, \& Tomasello, 2012). As is described below, we adopted the standard that in order for an event to be described as collaborative, the child needed to coordinate actions and/or verbally plan with the collaborator. Furthermore, to account for and analyze the varied involvement of the child and collaborator in their spontaneous interactions, we ranked each interaction using defined levels of collaboration, as described below.

Our empirical investigation also required an activity which had multiple parts, each with different degrees of difficulty, and measured children's ability to independently complete the activity. To this end, we designed a toy assembly task in which children built toys by following sequences of instructive pictures. To assess children's initial competency children completed an Assessment Toy that provided an estimate of their ability to independently construct the toys, termed the Competency Score. To assess the difficulty of the stimuli, a group of children constructed all of the toys independently without help, and were scored on their ability to complete each step. In this way, we measured the two factors we hypothesized to contribute to children's initiation of collaboration.

\section*{Method}

Participants. Participants were forty preschoolers ( \(\mathrm{M}=52.44\) months, \(\mathrm{SD}=9.7\) months; twenty-one females). Children were recruited from preschools and from a database of research participants whose parents expressed interest in participating in research. The children were all from the surrounding region of a rural university town and were predominantly Caucasian and middle class. Three additional children were excluded from the final sample; one due to experimenter error, one due to uncooperativeness, and one due to teacher interruption.

Stimuli. The stimuli were Edushape Interstar rings. In the current experiment, numerous rings were connected with one another so as to resemble larger objects. Children were shown laminated instructive pictures depicting each step of construction for four different toys.

Apparatus. Testing sessions occurred at a childsized table in a quiet room in the laboratory or in a quiet room in the child's preschool. The interactions were recorded with two Sony DCR-SR68 digital cameras.

\section*{Procedure}

Warm-up Toy. The Warm-up Toy, termed the Key, was completed to teach children how to manipulate the toy pieces and make them look like the instructive pictures. The experimenter told the child that they had some toys and
some pictures, and they could make the toys look like the pictures. The experimenter told the child to watch him/her as they completed the first step. After completing the first step, the experimenter asked the child, "Does that look like the picture?" If the child said no, the experimenter explained that the color, position, and number of pieces all made it look like the picture. The child and experimenter then took turns making the Key. Corrective feedback was given for mistakes.

Assessment Toy. Next the child completed an Assessment Toy, termed the Boat, which provided a graded assessment of the child's competence in independently constructing the toys as shown in the instructive pictures. The experimenter asked the child to do the Boat independently, saying, "You can do this one by yourself by making it look like the picture. Start with the first picture. Each time you need a new picture, just move the picture. Now go ahead and make it look like the picture." As the child completed the Boat, the experimenter quietly watched the child and did not provide assistance or corrective feedback. The child had up to five minutes to complete the Boat.

Test Toys. The child then completed the two Test Toys, Sally and Sally's House. Twenty-two of the children were randomly sorted into the Collaboration Group and eighteen into the Non-collaboration Group. In both conditions, half of the children did Sally first and half did Sally's House first. Children had as long as needed to finish the Test Toys.

In the Collaboration Group, the experimenter looked at the child and said, "Now I can help you make Sally, so just let me know when you want me to do some, OK? So if you want help, I'm right here." The experimenter sat and watched, and did not intervene or provide any sort of verbal feedback unless the child initiated collaboration (see "Collaborative Responses" below for details on how the experimenter responded to bids).

In the Non-collaboration Group, the experimenter said, "You can do this one by yourself by making it look like the picture. Now go ahead and make it look like the picture." The experimenter sat quietly and watched the child complete the toy. The experimenter did not intervene or provide any sort of verbal feedback, and responded to requests for assistance as in the Assessment Toy.

Bids for Collaboration. Based on prior work and our own pilot observations in preschools, children initiate collaboration by establishing eye contact, remarking that the activity is difficult, and directly asking for assistance. We therefore accepted these as bids for collaboration. The experimenter responded to 2 seconds of eye contact and remarks of difficulty by asking, "Do you want me to help?" If the child declined assistance, no collaboration occurred. If the child assented, the experimenter collaborated. The experimenter responded to direct requests for assistance by collaborating with the child without further questioning.

Limits of Collaboration. The experimenter always provided helpful, unhesitating, and accurate
assistance. The experimenter collaborated for a single step at a time, unless the child asked for further assistance on the following step. If the child asked the experimenter not to intervene further, the experimenter stopped collaborating. If the child had made mistakes in steps prior to the one at which they asked for assistance, the experimenter aided in correcting the past mistakes. In this way, the experimenter did not condone errors, functioned as an ecologically valid adult collaborator, and avoided the potential complication of inconsistent experimenter responses across children to vague requests for assistance.

Collaborative Responses. If the child structured the experimenter's response by specifying a particular motoric or cognitive difficulty, the experimenter addressed the particular problem. For example, if the child was struggling to fit two pieces together and commented that it was difficult to put them together, the experimenter assisted the child in pushing them together. In this case, both the child and experimenter would be involved in physically fitting them together. If the child simply asked if one piece went on top of the other, the collaborator provided the information and permitted the child to physically carry out the actions. In response to vague requests for collaboration without child action, for instance looking at the step and stating "This is too hard," the experimenter gathered the correct pieces, carried out the step, and provided an explanation. Likewise, if the child simply asked for verbal clarification, the experimenter's response was limited to verbal clarification. In this way, the experimenter's collaboration was contingent upon the extent to which the child structured it.

\section*{Coding}

Children's Competency- Assessment Toy (Boat). We assessed children's competency in constructing the Assessment Toy. Five parameters assessed for each step of the toys whether children: (1) added the correct number of pieces, (2) made the correct number of connections with those pieces, (3) made the correct type of connection(s), (4) added pieces of the correct color(s), and (5) connected the pieces to the correct part of the existing structure. For each step, children earned from 0-5 points; each parameter was worth a minimum of 0 and a maximum of 1 point. Partial credit (e.g. \(1 / 2\) points) was given for partial completion. Children's performance score on each step of the Assessment Toy therefore had a minimum of 0 and a maximum of 5 multiplied by the toy's number of steps ( 8 steps; range 0-40).

Children's performance on the Test Toys (Sally and Sally's House) during collaboration. The same coding as above was used to assess children in the Collaboration Group as they completed the Test Toys. Once again, children's performance score for each Test Toy had a minimum of 0 and a maximum of 5 multiplied by the toy's number of steps (10 steps each; range 0-50).

Step difficulty of the Test Toys (Sally and Sally's House). The Non-Collaboration Group's
competency on each step of the test toy construction was used as a means of computing the difficulty of the Test Toys' steps in the absence of collaboration. The scoring was the same 0 to 5 scale that was used to measure children's competency during assessment. But, this time we did not sum across steps; instead we used the average competency of the Non-Collaboration group at each step as an index of step difficulty in our analysis (below). .

Collaboration initiated?: A binary response code for each step on which children in the Collaboration Group initiated any collaboration. Reliability coding performed on \(55 \%\) of the sample produced \(100 \%\) concordance.

Level of collaboration: For the Collaboration Group, collaborative interactions at each step were rankordered in five categories from lowest to highest levels of collaborative assistance: (0) no collaboration, (1) the child performed the action and the experimenter provided verbal feedback about the child's action, (2) the child provided information about how the pieces assemble and the experimenter performed the action, (3) both the child and the experimenter provided information about how the pieces are assembled and both were involved in assembling them, and (4) the experimenter performed the actions and provided the information about how the pieces are assembled. If multiple levels of collaboration were present during one step, the step was coded by the highest level present. Reliability coding performed on \(55 \%\) of the sample produced \(92 \%\) concordance, indicating high reliability.

\section*{Results}

Children's Competency. Overall, on the Assessment Toy children averaged a Competency Score of 29.83 out of 40 with a standard deviation of 10.49 . There were no systematic differences at assessment between children in each group (Collaboration: \(M=30.17\), Noncollaboration: \(M=29.84, t(38)=.591, p=n s)\). Thus, our entire sample of children displayed sufficient variation in competency to further investigate our hypotheses.

Collaboration Initiated. Our hypothesis predicted that children would collaborate when they were unable to perform the activity independently, and conversely that they would not collaborate when they could construct the toys independently. Our principal analysis therefore assessed whether the difficulty of the Test Toy steps, as measured by the Non-collaboration Group's average performance, and children's competence, as measured by children's Competency Scores, predicted children's choices to collaborate. There were no order effects (Sally first vs. Sally's House first) in either the Collaboration or Noncollaboration Group, so results were collapsed across order for further analysis.

In assessing our predictions of children's collaboration, we needed to properly account for the dependence amongst children's repeated measurements at each step. We therefore employed a General Estimating Equation (GEE), which is a common form of logistic regression analysis, with children as the repeated effect.

Our first dependent variable was the binary variable: whether children selected to collaborate on each step ( \(1=\) yes, \(0=\) no). We first performed an analysis with step difficulty, children's Competency Scores, age, and toy type (Sally \(=0\), Sally's house \(=1\) ) as the predictors. We included children's gender as a factor (female \(=0\), male \(=1\) ). According to the model, the log of the odds of a child collaborating was significantly positively related to step difficulty ( \(p=.000\) ) and significantly negatively related to children's competence ( \(p=.001\) ). As depicted in Table 1, neither age, gender, nor the particular toy related to children's collaboration. This indicates that when the step was more difficult and the child less competent, children were significantly more likely to collaborate than act independently. Similarly, when the steps were simple and the child competent, children were more likely to act independently.

However, it was possible that children selected to collaborate more as they became tired of the activity as opposed to the difficulty of the steps. We performed a second GEE analysis with toy step and step difficulty as the predictors, and collaboration as the dependent variable. Step difficulty was a statistically significant predictor of collaboration, but toy step was not (Step difficulty: \(\beta=.717\), Wald's \(\chi 2=20.345, p=.000\); Step: \(\beta=-.003\), Wald's \(\chi 2=\) \(.017, p=.896\) ). This result helped to specify that step difficulty, as opposed to the order of the toy steps and/or ordering of the toys, related to children's collaboration.

\hline
\end{tabular}

Table 1: Table 1 shows the results of the parameter estimates for a logistic regression analysis performed with a General Estimating Equation. The model assesses which variables relate to children's choice to collaborate or act independently. Toy (Sally \(=0\), Sally's House \(=1\) ) and gender \((\) female \(=0\), male \(=1)\) were entered as factors. Step difficulty, competency, and children's age were entered as covariates. Degrees of freedom \(=1\).
*** Indicates statistically significant at the . 001 level.
While these logistic regression results were encouraging, we desired a direct assessment of how the two factors in our conceptual model of collaboration compared with children's observed behavior. To do so, we divided the children into three categories of competency and the steps into three categories of difficulty. The majority of children had a Competency Score in the range of 35-40 out of a maximum of 40 , with only one child scoring below 10 . We therefore developed the following categories of Competency Scores: Less Competent (0-20), More Competent (21-35), and Very Competent (36-40). As for step difficulty, the lowest step score was 1.87 and the majority of step scores were above 3.5. To account for the lack of difficult steps, we defined the following three categories of step difficulty: Simple (0-1.0), Somewhat Difficult (1.1-2.0), and More Difficult (2.1-5).

Based on the categories defined above, we calculated the observed probability of children collaborating for each category of competency and difficulty. The observed probabilities are displayed in the line graph in Figure 1a. As shown, collaboration was more likely as the step difficulty increased and children's competency decreased. This result was consistent with our hypotheses.

Figure la: Children were categorized into three competency categories and the toy steps into three difficulty categories. The graph shows children's observed probability of collaboration for each category of children and steps. Standard error bars are displayed.

We were unable to assess a GEE model based on categorical variables representing the categories because some of the cells would contain 0 (the less competent group's children collaborated on all of the more difficult steps). Instead, we assessed how our statistical logistic GEE model's predictions, based on the continuous values of competency and step difficulty, compared with the observed probabilities. Critically, this provides evidence as to how well the occurrence of children's collaboration coheres with the two factors in our conceptual model: step difficulty (represented by "D" below) and competency (represented by
"C" below). Computing the probabilities from the logistic GEE model consisted of applying the following equation:
\[
P=e^{\text {Constant }+. \mathrm{D}^{*} \mathrm{M}_{\mathrm{D}}+\mathrm{C}^{*} \mathrm{M}_{\mathrm{C}}} /\left(1+e^{\text {Constant }+. \mathrm{D}^{*} \mathrm{M}_{\mathrm{D}}+\mathrm{C}^{*} \mathrm{M}_{\mathrm{C}}}\right)
\]

We selected the means (represented by "M" above) of the observed values of each category to be the representative covariate values. We then computed the probability of collaboration using the parameter estimates provided by the logistic GEE model. The results are displayed in Figure 1b.

Figure 1b: As outlined in the text, three categories of child competency and step difficulty were defined. The probability of collaborating was then computed from our logistic GEE model consisting of step difficulty and competency. Standard error bars are displayed.

Figures 1a and 1b, that is, the observed and computed probabilities of children collaborating on a given step, are remarkably similar. The congruence of the cell values and direction of change augment the logistical regression analyses by providing a direct demonstration that children's behavior was consistent with our predictions. Most importantly, this analysis suggests a large portion of children's decisions to collaborate may be a function of two factors: children's competency and the difficulty of the activity.

Levels of Collaboration. We also investigated whether the character, or magnitude, of the collaborative interactions differed as a matter of step difficulty and children's competency. We performed a multinomial distribution GEE in which the dependent variable was the level of collaboration, with no collaboration being level 0 . The specific toy (Sally \(=0\), Sally's House \(=1\) ) and children's gender (female \(=0\), male \(=1\) ) were the factors. The three predictors were step difficulty, children's competency, and age. The resulting analysis indicated that the log of the odds of raising the level of children's collaboration was significantly positively related to step difficulty ( \(p=.000\) ) and significantly negatively related to children's competency ( \(p=.000\); Table 2). This indicates that the collaborative interactions tended to involve more
action and information sharing from the adult collaborator as the difficulty of the steps rose and children's Competency Scores decreased. Neither age nor any of the factors related to the character of children's collaboration. This model furthers our understanding by suggesting that not simply the occurrence of collaboration, but also the character of the collaborative interactions relate to the difficulty of the activity and children's ability to independently execute the activity.

Table 2: Cumulative Logistic Regression Analysis of Children's Level of Collaboration
\begin{tabular}{|c|c|c|c|c|c|}
\hline Predictor & \(\boldsymbol{\beta}\) & \(\boldsymbol{S E} \boldsymbol{\beta}\) & \begin{tabular}{c}

\end{tabular} & -.79 & 2.27 & .12 & .73 & .46 \\
\hline \begin{tabular}{c} 
Toy
\end{tabular} & -.15 & .39 & .15 & .70 & .86 \\
\hline Gender & -.06 & .66 & .01 & .92 & .94 \\
\hline \begin{tabular}{c} 
Step \\
Difficulty
\end{tabular} & .94 & .15 & 37.04 & \(.00^{* * *}\) & 2.56 \\
\hline \begin{tabular}{c} 
Competen \\
-cy
\end{tabular} & -.11 & .02 & 45.81 & \(.00^{* * *}\) & .90 \\
\hline Age & -.41 & .49 & .72 & .40 & .66 \\
\hline
\end{tabular}

Table 2: Table 2 shows the results of the parameter estimates for a cumulative logistic regression analysis performed with a General Estimating Equation. The model assesses which variables are predictive of the character of children's collaboration. Toy (Sally = 0, Sally's House = 1) and gender (female \(=0\), male \(=1\) ) were entered as factors. Step difficulty, competency, and age were entered as covariates. The levels of collaboration, described above, refer to different categories and magnitudes of collaborative interactions. Degrees of freedom \(=1\).
*** Indicates statistically significant at the . 001 level.
Again, it was possible that children involved the collaborator more because of fatigue of the activity as opposed to step difficulty. We therefore performed another analysis to evaluate whether differences in the character of children's collaboration resulted from the order of the steps as opposed to step difficulty. The regression indicated that step difficulty, not the order of steps, related to the character of children's collaboration (Step difficulty: \(\beta=.744\), Wald's \(\chi 2=20.989, p=.000\); Step: \(\beta=.015\), Wald's \(\chi 2=.228, p=\) .633). This provided further evidence that the difficulty of the activity, as opposed to some other aspect inherent in the order of steps, related to the manner in which children collaborated.

\section*{Discussion}

The results show that the probability of a child requesting collaborative assistance on a given step was
predicted both by the child's initial competency in constructing similar toys and the difficulty of constructing the same toys without adult assistance. Indeed, a statistical model consisting of those two predictors alone provided a comparable match to children's observed probability of collaborating (Figures 1a and 1b). Second, the character of children's collaborative interactions, that is, the extent to which children were involved, was predicted by children's competency and step difficulty. This indicates that these two factors are not only related to the occurrence, but also to the substance of collaborative interactions.

These results support an "information gathering" perspective of children's collaboration related to their helpseeking. This can be best appreciated by understanding the link between the difficulty of the activity and the information to be gained by independent versus collaborative behavior. Indeed, children are implicitly motivated to seek more information through active search when evidence is ambiguous or complex (Schulz \& Bonawitz, 2007). Initiating collaboration may have a similar motivation. Indeed, seeking collaborative assistance may be the optimal strategy in circumstances in which independent exploration is not providing the necessary information to overcome difficulty.

Of course, this by no means precludes the importance of other factors, such as a species-wide prosocial disposition (Tomasello et al, 2005). Indeed, it is certain that other factors contribute to young children's collaboration. However, our results suggest that, in the motivation to accomplish a goal (complete a task, learn a new skill, etc.), aspects of the environment - including the type of goal or task, the competency, skill or knowledge of any individual child - may serve as powerful influences on whether collaboration is initiated, if at all. Future work is needed to examine how the various "proximate causes" of collaboration interact in children's everyday behavior and in different contexts, such as peer collaboration.

Our results also suggest a way in which social learning and learning through exploratory play may be fully integrated. That is, children are neither "stubborn autodidacts" (Harris, 2002) when they learn nor are they passive recipients of social information. Rather, through their own activity, children trade between exploring by themselves and exploiting the knowledge of others. By addressing both the nature and the immediate causes of collaborative vs. non-collaborative behavior, future work may shed light on the many ways in which they relate, and how collaboration contributes to children's impressive early learning abilities.

\title{
When words get physical: evidence for proficiency-modulated somatotopic motor interference during second language comprehension
}

\begin{abstract}
New theories of cognition posit an intimate link between higher cognitive processes and the sensorimotor areas of the brain. In a reaction time-based translation task, second language (L2) speakers responded to action verbs using a microphone or a response pad. A significant interaction among Response Modality, Verb Type, and Proficiency indicated that more proficient L2 speakers took significantly longer to respond with their hands to previously seen handrelated verbs, but not mouth-related ones. Conversely, responding using a microphone led to slower latencies in the case of mouth-verbs, but not hand-verbs. Amidst virtually exclusively monolingual research on embodied cognition, the current study provides evidence that reading L2 action verbs selectively interferes with subsequently performed manual or verbal responses, suggesting that semantic representations of these verbs are distributed over neural substrates underlying action execution. The role of proficiency and experience in language comprehension is discussed.

Keywords: embodied cognition, second language, semantics

\section*{Introduction}

Ever since the cognitive turn in psychology, the human mind has been likened to a computer, and the essence of our mental life envisaged as the outcome of complex calculation over abstract symbolic elements. In this traditional framework, human cognition is defined as modular, with distinct components operating on information independently and autonomously (Fodor 1998). In contrast to this perspective, recent years have witnessed the strengthening of theoretical paradigms which posit thought as being grounded in experience and sensation. These have become known as Embodied Cognition theories. According to Embodied Cognition, human concepts are not amodal transductions of sensory data, but are instead grounded in sensory-motor processing itself. Much evidence for embodied cognition comes from studies of language processing. Within this new framework, language comprehension is thought of as grounded in, and intimately linked to, neural resources used in action, perception, and emotion (Barsalou 2008).

By now there exists a wealth of behavioural research which supports the claim that language comprehension and action execution are subserved by common neural resources. For example, Glenberg and Kaschak (2002) demonstrated an Action-Sentence Compatibility effect, where judging the sensibility of sentences which implied a movement towards or away from the body (You gave Andy the pizza vs. Andy gave you the pizza) facilitated congruent arm movements. In a similar sentence sensibility judgement task, Zwaan and Taylor (2006) found that participants were
significantly faster to perform manual rotation of a response knob when the rotation (clockwise or anti-clockwise) was congruent with the meaning of previously presented sentential material (turn the volume up/down). Bergen et al. (2003) asked participants to manually verify names of pictures representing actions, and found that response times were slower when they had to reject actions performed with the same (vs. different) effector. In a different study, Buccino et al. (2005) had participants listen to and judge the concreteness of sentences using hand or feet responses. They observed interference effects pointing toward the conclusion that verbally presented action sentences activate the motor system. These studies suggest that language and action are highly interconnected and that processing action language functionally involves activation of motor representations in the brain. Moreover, this interaction is differentially articulated as facilitation or inhibition, based on the temporal relationship between stimulus and response (Boulenger et al. 2006).

The findings from behavioural studies outlined above find additional support in the neurosciences, where experiments have shown interdependence between cognition and simulation of motor and perceptual states. There have by now been numerous studies which demonstrate that semantic processing of a word activates distributed and diverse networks of sensory and motor information (Farah, McClelland, 1991; Damasio 1990; Caramazza et al., 1990). For example, processing the name of an action engages the motor area which is active during performing that same action (Martin et al., 1995 p. 649-652.). Hearing a word activates auditory associations (Pulvermuller et al 2006), and action-related words elicit cortical activation in the motor areas of the brain, even when the participants are not aware of hearing the word (Pulvermüller et al. 2005). Intriguingly, comprehension of action words does not only reliably activate the motor cortex, but does so in an effectorspecific i.e. somatotopic manner: face, arm, or leg words activate the corresponding parts of the motor system in the central and precentral cortex which control face, arm, or leg movements (Buccino et al 2005, Hauk et al 2004).

Taken together, behavioural and neuroimaging data strongly support predictions and claims of embodied approaches to language and cognition. Semantic representations of words are not amodal or entirely symbolic, but seem to utilise the same neural resources involved in action execution, and it is these strong links which are made apparent in the interactions outlined in the studies above.

Some proponents of disembodied and symbolic approaches to cognition, however, have raised concerns
about the functional relevance of sensorimotor processes in language comprehension (Hickok, 2010; Mahon and Caramazza, 2008). For example, Mahon and Caramazza (2008) have argued that semantic motor activation, as it is described above, could also be incorporated into traditional theories. On this view, the motor cortex becomes activated as an epiphenomenon of, and not part of, semantic retrieval. In other words, semantic motor activation is a result of induced imagery of action, and is as such a downstream consequence of comprehension. However, a number of recent studies presented evidence for automaticity and causality of sensorimotor processes in language comprehension. For example, Pulvermuller et al. (2005) have demonstrated activity in the motor cortex as early as \(100-200 \mathrm{~ms}\) following word recognition - speeds consistent with the idea that these processes are crucial to semantic retrieval (see also Shtyrov et al., 2004). Similarly, Liuzzi et al. (2010) present compelling evidence that the motor cortex is causally involved in learning and processing action words. In their study, transcranial direct current stimulation (tDCS) was used to temporarily disturb the functioning of the motor cortex, which in turn led participants to perform significantly worse in an action word acquisition task, compared to controls. The study indicates that the motor cortex is vital, and even necessary, for word processing, as is also suggested by other TMS, electrical stimulation, and behavioural experiments (Pulvermuller 2005; Fischer and Zwaan, 2008; Glenberg et al., 2008). Results to date thus favour embodied approaches to language comprehension, and make symbolic interpretations of motor semantics rather difficult to maintain.

\section*{The Current Study}

Motor and language processes in the brain seem to form a dynamic and highly interconnected system, with interactions appearing at very early stages. However, a major shortcoming of investigations performed so far is the fact that they are virtually exclusively based on monolingual data, and data obtained from native speakers of a language. Surely, however, any theory that seeks to explain linguistic processes cannot call itself complete without at the same time accounting for how these operate in the majority of the world's population (i.e. bilinguals: Gordon, 2005). With the realisation that over half of the world's population speaks more than one language, this study aims to test the predictions of embodied cognition on people other than monolinguals. The primary question in the experiment reported here is whether in second-language (L2) speakers action-word semantics are distributed over neural substrates involved in action execution. Will L2 speakers, just like native ones, exhibit sensorimotor effects in lexical processing? Do we, in other words, see evidence for interaction between motor and linguistic processes or, alternatively, is there evidence that in their case linguistic processes operate completely independently of sensorimotor ones? How are these affected by proficiency and
experience? Clearly, the extensive work in embodied language processing is in need of specification in terms of how and when grounding takes place in the course of language development.

The current study employed a reaction time-based translation task, which methodologically synthesizes experimental and analytical tools drawn from second language (Altarriba and Mathis 1997, Duyck and Brysbaert 2004) and embodied cognition research (Shebani \& Pulvermüller 2012, Bergen et al 2003, Marino BFM et al 2011). In every trial, participants were presented with a mouth, arm, or leg related verb in their native language (Serbo-Croatian), after which they would see a verb in English. The task was to quickly indicate whether the second verb was a good translation of the first verb, using a button box in one, and a microphone in the other half of the experiment. In half of the trials the English verb was a translation of the Serbo-Croatian one, and in the other half it was not. The critical trials in this experiment were those where the verbs were translations, and were split into two conditions: in one case, the English verbs denoted actions performed with the same body part or effector as the one used for the experimental response (mouth or hand, depending on which experimental response was required), whereas in the other case the verbs indicated actions performed with a different effector.

If we assume a neurobiological model of language in which lexicosemantic circuits are embodied (Pulvermuller, 1999), then verbs describing actions should be realised not only in perisylvian cortical regions traditionally associated with language, but also as circuits in the motor cortex, which is used for executing the actions themselves. If it is true that understanding an action verb produces motor activation, then introducing a concurrent task (the user response) which makes use of that same part of the brain should produce interference, reflected in slower reaction times. In addition, the semantic somatotopy model (Pulvermüller, 1999; 2001) predicts that this interference should be highly specific: processing mouth-related verbs should most strongly interfere with concurrent verbal responses, but not manual ones. Similarly, processing a hand-related verb should lead to much slower latencies when responding with the hand, but not with the mouth.

In the current context of second language speakers, we could expect several possible outcomes: 1. It might be that non-native speakers process language in a completely different way to that of their native counterparts. In other words, their semantic representations might not be distributed across sensorimotor neural substrates - a distribution that might, therefore, be a distinctive hallmark of native speakers. 2. It could be the case that L2 speakers show identical patterns to those of native speakers. 3. Finally, it is possible that L2 speakers show differing amounts of sensorimotor embodiment, as modulated by proficiency and experience.

\section*{Experiment}

\section*{Participants}

Twenty-four right-handed native speakers of Serbo-Croatian (13 female; mean age \(=25.63\) years, \(\mathrm{SD}=3.54\) ) studying at the University of Cambridge took part in the experiment. All participants had normal or corrected-to-normal vision and reported no history of neurological, psychiatric, or language disorders. Participants varied in terms of L2 proficiency, as revealed by the language background questionnaire (see below). All gave their informed consent prior to participation. No participants were aware of the purpose of the experiment.

\section*{Stimuli}

A total of 72 lexical stimuli were used in the experiment: 36 Serbo-Croatian (SC) verbs, and 36 English ones. For each language there were 12 mouth-related (e.g., bite, kiss, sing), 12 hand-related (e.g., peel, take, write), and 12 legrelated (e.g. dance, jump, walk) action verbs. In addition, 18 verb pairs were constructed for the practice trials: 9 practice trials per response modality (mouth/microphone vs. hand/button box). All critical lexical stimuli were matched for psycholinguistic variables such as number of letters, number of phonemes, lexical frequency, and letter bigram frequency. All SC verbs appeared inflected for first person singular present as, for example, in the verb pišem (write), where the suffix \(-m\) attaches to the base form piše-.

\section*{Procedure}

The experiment took place in a sound-attenuated and dimly lit room. Participants sat comfortably in front of a computer screen at a distance of about 60 cm . Stimuli were presented centrally on the screen in lowercase Arial font (size \(=20\) ). Each trial started with a fixation cross presented in the centre of the screen for 1000 ms , followed by a SC verb displayed for another 1000 ms . After a 500 ms interstimulus interval (ISI), an English verb appeared and stayed on the screen until a response was given. Participants were instructed to respond, as quickly and as accurately as possible, whether the English verb was a translation of the previously seen SC verb. They did so by pressing "yes" or
"no" on a button box, in one half of the experiment, and by saying "yes" or "no" into a microphone, in the other half (the order of "mouth response" and "hand response" blocks was counterbalanced across participants). After they gave a response (correct or incorrect), a blank screen was shown for 500 ms , after which a new trial started. Accuracy feedback was displayed only during the practice block. Stimulus presentation and response time collection were performed using the SuperLab Version 4.5 software package (Cedrus Corporation). The experiment consisted of a practice block, and two experimental blocks: one requiring hand, and the other mouth responses. Participants therefore saw each target verb twice, once in each half of the experiment. Each target verb would appear in both the matching and mismatching condition (actions conveyed by L2 verbs shared/did not share the effector with the experimental response). Items were rotated around two presentation lists. If an English target verb was in the sameeffector condition on one list it was in the different-effector condition on the other list, and vice versa. There were equal numbers of same- and different-effector pairs on each list, and equal numbers of participants were tested on each list.

\section*{Language Background Questionnaire}

All participants completed a language background questionnaire. The sample was homogeneous, with all participants being native speakers of Serbo-Croatian, raised in the ex-Yugoslavia territory, and having started learning their L2 at approximately the same time (Mean AoA: 7.86 years, \(\mathrm{SD}=2.4\) ). Overall, participants rated their proficiency in English relatively high, though there were still differences, with some participants having just arrived to England for their undergraduate and graduate courses, and others having been in the country for longer as part of their PhD or postdoctoral research. A simple median split was performed on the proficiency scores, thus creating two groups, the lower and the higher proficiency group, with 12 people in each. The difference in L2 proficiency ratings between these two groups was statistically reliable, \(t(22)=-\) \(7.30, p=.001\). These and other proficiency measures from the language background questionnaire which, importantly, were found to correlate with participants' self-ratings, are summarized in Table 1.

\({ }^{\text {b }}\) Since the majority of scores were IELTS scores, TOEFL and Cambridge Exam scores were also converted to the IELTS scale using the standard Equivalency Table

Figure 1. Mean reaction times for both participant groups in all conditions (H=hand; M=mouth; \(L=l e g\) ). Significant differences in response latencies ( \(\mathbf{p}<.05\) ) are marked with an asterisk.

\section*{Results}

First, trials with erroneous responses were removed. Given that errors were very rare ( \(0.02 \%\) of total trials), they were not analysed separately. No participant performed at less than \(90 \%\) accuracy. Response latencies for correct trials larger than 2SD \(\pm\) mean RT were excluded from statistical analysis as outliers. In total, no more than \(0.5 \%\) of data was lost (Ulrich and Miller 1994).

For the remaining trials, mean RT values for each participant in each condition and block were calculated (see overall means in Figure 1) and entered into a repeatedmeasures analysis of variance (ANOVA) with two withinsubject variables: Response Modality (microphone vs. button box), Verb Type (mouth vs. hand vs. leg), and Proficiency (lower vs. higher) as a between-subject variable. Response latencies were longer when using the microphone than with the button box, and correspondingly the ANOVA revealed a main effect of Response Modality, \(\mathrm{F}(1,22)=\) 44.27, \(p=.001\); partial \(\eta 2=.668\). No other main effect was significant ( \(\gg .05\) ). A two-way significant interaction among Response Modality and Verb Type was found: \(\mathrm{F}(1\), 22) \(=12.58, \mathrm{p}=.002\); partial \(\eta^{2}=.364\). In addition, there was a three-way significant interaction among Response Modality, Verb Type, and Proficiency: \(F(1,22)=15.22, p=\) .001; partial \(\eta^{2}=.409\).
Most importantly, the significant three-way interaction directly addresses the main questions which motivate this study. The interaction indicates that second language speakers of different proficiencies differentially exhibit somatotopic interference on action execution during verb processing. The group of lower proficient speakers showed no significant differences in response times in any of the blocks and conditions. However, more proficient L2 speakers responding with the microphone were slower on mouth verbs than on hand verbs (1394 and 1206 ms respectively, \(\mathrm{t}(11)=3.096, \mathrm{p}=.010\) ). Conversely, their hand responses were slower when processing hand, but not mouth verbs (678 and 620 ms , respectively, \(\mathrm{t}(11)=2.80, \mathrm{p}\)
\(=.017\) ). Responses to leg verbs always patterned with other non-response modality verbs.

Overall then, for the more proficient L2 speakers in the sample, the results reveal a double-dissociation pattern of response interference.

\section*{Discussion}

This study reveals differential interference for mouth and hand responses, brought about as a consequence of processing lexical semantics of action verbs involving different parts of the body, namely the mouth and the hands. Interestingly, this selective effect was modulated by speaker L2 proficiency. In both participant groups, response latencies given with the microphone were longer than those given with the button box. However, our finding that verbal responses are slower than manual ones in L2 speakers is quite in line with results and latencies obtained in previous second language studies (see, for example Kroll et al., 2002). Apart from this main effect, participants in the lower proficiency group demonstrated no significant differences in response times across blocks and conditions. Interestingly, slower responses with hands were observed when higher proficiency participants processed hand verbs, but not mouth or leg verbs. The reverse effect, slower responses during mouth (but not hand or leg) verb processing, was seen when participants used a microphone to respond. These results follow a double dissociation pattern (Shallice 1988; Jones 1983), which allows for much more reliable inferences about the causal and interactive status of the systems and processes involved than was possible in some previous, conceptually similar studies, which only used a single response modality, or used pictorial stimuli where priming from visual features could not be reliably dissociated from true motor interference (see for example Bergen et al 2003; Marino BFM et al 2011). Specifically, this study demonstrates that in more proficient participants processing resources located in specific parts of the motor cortex are shared between action execution and lexicosemantic representations of related verbs. These data, although behavioural in nature, directly bear upon and
support predictions made by psychological and neural models of embodied language processing. Apart from providing novel and strong evidence for embodied semantics, the present study is the first to demonstrate double dissociated and effector specific shared neural resources between action execution and language in nonnative speakers. In addition, it has implications for theories of how grounding takes place, as it suggests that speakers increasingly come to activate non-linguistic systems during word processing as a function of proficiency and experience.

The findings in this study can be interpreted with regard to neurobiological models of language learning and processing. These do not view lexicosemantic representations as static, but adopt an approach in which variation primarily comes not from the strength of formmeaning connections, but the distribution of semantic representations themselves. In other words, it might be the case that there is less meaning associated with L2 lexical forms (for similar proposals see Williams \& Cheung 2011, and Duyck and de Houwer 2008). This explanation makes intuitive sense if we think about the amount of real-life experience with L2 words. For example, L2 words are associated with a much smaller range of senses than L1 words (Finkbeiner and Nicol 2003), and are in the majority of cases learned in artificial classroom environments, often through the use of crude lexical translation. This account is consistent with the literature on cortical learning, where words can be thought of as functional cell assemblies in the brain, formed through Hebbian processes (Pulvermuller 1999). Hebbian learing ("what fires together, wires together") would thus predict that cortical distributions of L2 word semantics are much more restrictive than those of L1 words, due to different (and fewer) learning and usage experiences. If this is the case, then L2 words, learned through translation and with no or limited real-life usage, would be strongly left lateralized and distributed mainly over perisylvian cortices. We should, therefore, as was the case presently, find little activation outside of primary linguistic brain areas. However, if speakers start using L2 words in real-life embodied contexts, such as when studying in a foreign country, then these words would increasingly come to be co-activated with extra-linguistic neural substrates (including the motor cortex), and would "wire together" into a new assembly. The present results are therefore consistent with the idea that the amount of experience and real-life usage leads to changes in the way we semantically represent words. Crucially, there were differences in the amount of time both groups of speakers spent in an English-speaking country (see Table 1), and this difference was statistically reliable \((\mathrm{t}(12)=-2.60, \mathrm{p}=.023)\). In fact, there is evidence for this conclusion from studies testing the linguistic performance of L2 students learning their second language in a classroom vs. an immersed, study abroad setting. Using experimental paradigms similar to the one employed presently, Linck et al. (2009) and Talamas et al (1999) demonstrate that as their proficiency increases, L2
speakers move from exhibiting primarily form-level effects, to showing increased semantic access. This could explain why in the results reported here the participants who spent less time in the UK showed no motor semantic interference during lexical processing, whereas the other group with a significantly longer residence in the country showed reliable double-dissociated interference when processing action verbs. However, while this proposal seems plausible and consistent with neurobiological models of language, it must presently remain at the level of speculation. More work is thus needed to further clarify the questions of how and when grounding takes place in the context of second language acquisition and learning.

\section*{Conclusion}

It has been suggested that embodied sensorimotor systems are an integral part of language comprehension. The current study, for the first time in second language speakers, demonstrates that they increasingly come to incorporate into their action-word semantics the same processing resources used for effector-specific action execution. The resulting somatotopic interference effects observed in proficient L2 speakers present evidence in favour of embodied approaches to language.

\begin{abstract}
When estimating the number of dots in a set, adults show bias and variability that scale with numerosity. Increasing variance in estimation is thought to reflect constant Weber noise on perceptual magnitude representations, while the increasing bias reflects miscalibrated mappings of number words onto magnitudes. Here we argue that response variability in numerical estimation increases with numerosity in part due to uncertainty and slow drift in the mapping of numbers onto magnitudes. We show that individuals' number-to-magnitude mapping functions drift slowly over the course of the experiment, with a shared-variance half-life of over 100 trials ( \(\sim 10 \mathrm{~min}\) ). We thus propose a model that treats the word-to-magnitude mapping function as a major source of estimation variability, and that accounts for cross-subject differences in estimation bias and variability, as well as changes to estimation performance within a given subject over time. In doing so, we reconcile the existing literature on the sources of estimation variability, and provide evidence that uncertainty in the word-tomagnitude mapping function is a key limiting factor in estimation performance.
\end{abstract}

Keywords: Approximate number, number words, numerical estimation

\section*{Introduction}

Human adults have access to at least two systems for representing numerical quantity. The first is a noisy and evolutionarily ancient nonverbal number system, called the Approximate Number System (ANS; see Dehaene, 1997; Feigenson, Dehaene, \& Spelke, 2004 for review). The second is the verbal number word system (e.g., one, two, three, etc.). This system unique to humans allows for the precise representation and manipulation of numerical content. When making estimates, adults draw on both of these systems: they use the ANS to represent the magnitude of the stimulus being estimated, and they use the verbal number system to attach a linguistic label to this magnitude.

The interface between these two systems has been an area of recent interest because it is crucial to characterizing how people can provide explicit verbal estimates of numerosity, and more generally how language relates to perception (e.g., Carey, 2009; Izard \& Dehaene, 2008; Thompson \& Opfer, 2011; Sullivan \& Barner, 2012; Sullivan, Juhasz, Slattery, \& Barth, 2011). The question is important for at least two reasons. First, estimation performance has been shown via intervention studies to be causally related to academic success, raising the question of why, and which aspects of training are most important to educational outcomes (Ramani \& Siegler, 2011; Siegler \& Ramani, 2009). Second, estimation tasks are often argued to elucidate properties of the ANS or their comprehension of number word meanings. In the present study, we tested what contribution - if any - this mapping function makes to estimation error. Specifically, we asked two questions about the nature of the number-to-magnitude mapping
function. First, are the mappings between verbal and nonverbal numerical representations stable across individuals? Second, within individuals, are these mapping stable across time? As argued below, the answer to these questions suggests a novel model of numerical estimation, which explains significant aspects of error by appealing to a dynamically changing mapping function, rather than to the ANS.

Figure 1: (Top) Our account of the bias and variability in human numerical estimation assumes two transformations between the physical stimulus and a verbal numerical response (following Izard \& Dehaene, 2008). First, the approximate number system maps the physical stimulus onto a logarithmic magnitude estimate with constant Weber noise. Second, the magnitude estimates are mapped onto the verbal number; we approximate this mapping as bilinear in \(\log -\log\) space with a variable slope. (Bottom) Two novel features of this account are necessary to capture the patterns of errors in human estimation data (one representative subject shown): (1) the mapping function must be non-linear in log-log space, otherwise the pattern of veridical calibration for small numbers, and systematic mis-estimation for large numbers will not hold, (2) the slope of the high end of the mapping function must be variable to capture the increasing variability of estimation for larger numbers.

In the absence of training or feedback, adults are notoriously inaccurate estimators (Kaufman, Lord, Reese, \& Volkmann, 1949; Izard \& Dehaene, 2008; Minturn \& Reese,
1951). For the purposes of the present project, we are interested in two attributes of this inaccuracy: variability and bias.

First, consider the variability of estimates. The degree of variability in estimates typically increases in proportion to the magnitude of the stimulus being estimated, such that the coefficient of variation (the ratio of the standard deviation of estimates for a given magnitude to the mean estimate of that magnitude) remains constant as magnitude increases (e.g., Whalen et al., 1999). Because variability in estimation behavior scales up with magnitude, estimates are typically said to demonstrate the property of scalar variability.

Scalar variability is thought to arise from Weber noise in the ANS: ANS representations are ratio-dependent, and therefore error in its representation of number also scales with number. For example, it is as easy to tell the difference between 5 dots and 10 dots as it is to tell the difference between 500 dots and 1000 dots using the ANS. Because both nonverbal ANS tasks and verbal estimation tasks exhibit scalar variability, many have concluded that scalar variability in estimation arises because the underlying (ANS) perceptual representations of the magnitudes being estimated exhibits weber noise (Dehaene \& Marques, 2002; Izard \& Dehaene, 2008; Le Corre \& Carey, 2007; Negen \& Sarnecka, 2010; Siegler \& Opfer, 2003) and relatively uncontroversial.

It is clear from the past literature that much of the variability found in estimation arises from variability in the ANS representations that support estimates. However, in the present paper, we ask whether all of the variability in estimation performance is explained by Weber noise, or, alternatively, whether the mapping function that connects the verbal and nonverbal number system also contributes variability to estimation performance. One reason to believe that variability and bias may arise in part from the mapping function between number language and the ANS is that feedback (e.g., showing a participant an example) reduces estimation variability in both children and adults (Barth, Starr, \& Sullivan, 2009; Krueger, 1984; Izard \& Dehaene, 2008; Lipton \& Spelke, 2005) a finding that one might not expect if variability arose entirely from the ANS. A second reason to believe that estimation variability stems entirely from the ANS is that sometimes - as in the data set we present in this paper - the coefficient of variation \((\mathrm{CoV})\) does not remain constant across all estimates. However, the degree to which estimation variability stems from the word-to-number mapping function remains untested.

Next, consider estimation bias. One frequent finding in the estimation literature is that estimates tend to be biased (e.g., systematically too high or too low). Also, bias in estimation performance tends to increase over the course of an experiment. For example, adults often underestimate magnitudes from the very first trial of an estimation experiment. When they do, this underestimation bias persists and is amplified over the course of the experiment (Krueger, 1982). In fact, even when the degree and direction of estimation error made
early in an experiment is experimentally manipulated, bias introduced in the first few trials endures throughout the duration of the entire estimation experiment (Barth et al., 2009; Izard \& Dehaene, 2008; Krueger, 1984; Lipton \& Spelke, 2005; Shuman, unpublished thesis; Sullivan \& Barner, 2012; Sullivan, Juhasz, Slattery, \& Barth, 2011). This influence of miscalibration is often described as stemming from changes to the number-to-magnitude mapping function. However, the nature of this change in the mapping function is still poorly understood. Specifically, it remains unknown how and why the degree of estimation bias increases as more estimates are made.

In the present study, we probed the factors that influence errors in estimation performance, with a special focus on the variability and bias found in individual participants estimates.

Figure 2: (Top) Participants saw 300 trials in which an array of \(n\) dots were briefly presented with the number of dots chosen according to a geometric distribution. Then participants made a guess as to the number of dots presented. (Bottom) A representative subject's data over all 300 trials with number presented (log scale) on the \(x\) axis and number reported ( \(\log\) scale) on the \(y\)-axis. We investigate the sources of bias and variability evident in these patterns of misestimation.

\section*{How do people estimate a quantity of dots?}

As already noted, patterns of bias and variability in estimation arise from both numerical perception and the mapping of these magnitude representations to language (see Figure 1). Our proposal is an amendment of Izard \& Dehaene's (2008) int that we argue that (1) the slope of the higher portion of this mapping function is variable over time, and (2) uncertainty in this mapping causes it to vary across time, thus introducing
additional variability in estimation tasks that increases with numerosity.

Figure 3: Individual subject estimation data (red points) along with best fitting linear (blue) and bilinear (green) mapping functions. Some of our conclusions may be seen in the raw data alone: (1) Variability in log-log space increases with numerosity. (2) Systematic mis-estimation occurs for larger, but not smaller, numbers. (3) Individual subjects have relatively stable idiosyncratic mis-estimation biases.

For our analyses, we consider this mapping to be bilinear in \(\log -\log\) space: it is veridical (falling on the identity line) for relatively small quantities (e.g., those smaller than 10; Sullivan \& Barner, 2012), but then tends towards underestimation for higher numbers. It is not central to our proposal that individuals actually use a strictly bilinear mapping function rather than a more complex mapping - however, our data do not offer the resolution necessary to assess whether a more sophisticated mapping function is used. For our purposes, approximating this function as bilinear makes our results and analyses simpler to describe.

This account offers a means to reconcile previous disagreements in the literature on the approximate number system and numerical estimation. First, while the coefficient of variation ( CoV , Weber fraction) is constant for the approximate num-
ber system, it is not known to be constant in verbal estimation tasks. For example, in previous work on word-to-magnitude estimation tasks, CoV has typically been analyzed only for a subset of the number-line (Izard \& Dehaehe, 2007; Le Corre \& Carey, 2007), or is found to increase with numerical magnitude (Siegler \& Opfer, 2003), or is not reported at all. In the present paper, we present a dataset in which the coefficient of variation in estimates increases with numerosity, suggesting a non-constant Weber fraction. Our account helps to reconcile a constant CoV in the approximate number system with an apparent increase in CoV in estimation, by showing that the coefficient of variation in estimation tasks is driven by variability in the mapping function over time (note that because discrimination tasks don't require verbal responses, they circumvent this mapping and its associated variability). Second, there is some disagreement as to whether there is a stable (consistent across the numerosity scale) mapping of magnitudes on to verbal numbers (Izard \& Dehaene, 2008; Lipton \& Spelke, 2005; Sullivan \& Barner, 2012). Our proposal suggests that, while the mapping of magnitudes to numbers may be consistent across a range of magnitudes at any one point in time, this mapping is not stable over time, yielding inconsistent behavior over trials.

Figure 1 provides an illustration of our model, and shows predictions from reduced classes of this model as compared to one (representative) subject's data. With only constant Weber noise and a stable linear mapping of magnitudes to numbers, we would erroneously predict overestimation and excessive variability for small numbers. Even with a bilinear mapping, constant Weber noise would predict less variability for large numbers and more for small numbers. Only with a variable slope in a bilinear mapping function can we account for the pattern of miscalibration and increasing variability for large, but not small, numbers. In the subsequent section we describe analyses that explicitly test these claims.

\section*{Experiment Methods}

Twenty-four subjects recruited from the UC San Diego psychology department pool participated in an hour-long experiment in which they had to guess the number of dots presented onscreen on each trial (see Figure 2). The number of dots shown was sampled on each trial from a geometric distribution with a mean of 50 , truncated at the low end so that displays had at least two dots. All the dots in an array were the same size (radius of 10 pixels), presented in red on a white background. The configuration of dots was randomly generated by drawing locations from a uniform distribution over the full display area ( \(1024 \times 768\) pixels) with the constraint that the dots did not overlap. On each trial the array of dots was presented for 250 msec , and then subjects were prompted to type in their guess as to how many dots were in the array. Subjects were then asked to type in a second guess about the number of dots in the array. (Our analyses throughout the paper focus on the first of the two guesses, but our conclusions hold if we consider the second guess alone, or the average
of the two). Figure 2 also shows one representative subject's data from all 300 trials.

\section*{Results}

The responses of all 24 participants for all 300 trials in our experiment are shown in Figure 3 on log-log coordinates. Several features of the data immediately jump out. First, estimate variability goes up as a function of number. Since this is an increase in variability in log-log space, it is not consistent with a constant coefficient of variation (a constant Weber fraction) which predicts that variability would be constant in \(\log -\log\) space. Second, while subjects are well calibrated for small numbers, there is a tendency to underestimate for large numbers: most subjects underestimated, but some subjects showed fairly reliable overestimation or veridical average calibration. Third, individual differences in under- or over- estimation appear to be quite reliable. These features are consistent with our account of a variable mapping function, which we elucidate in further analyses below.

\section*{Is magnitude-to-number mapping bilinear?}

We propose that the mapping function is not linear in loglog space, but bends such that small magnitudes are mapped more or less veridically onto number words, but large numbers show a systematic deviation from the identity line. While we do not believe that the true mapping function that people entertain is strictly bilinear, we do believe that it is not simply linear in \(\log -\log\) space. We can show that a bilinear function that is veridical (falls on the identity line) up to some critical number ( \(c\) ), and then deviates from the identity line with some log-log slope of \(s\) can account for data of individual subjects much better than a simple line with an intercept (a) and a slope ( \(b\) ). Since these models both have two parameters, we can simply compare the \(R^{2}\) values of individual subjects. Although the average \(R^{2}\) values are similar ( 0.79 , vs 0.81 ), bilinear fits better describe the data for 20 of 24 subjects (binomial test: \(p=0.0015\) ), see Figure 3.

This piecewise-linear mapping function could indicate a number of possible processes. Perhaps small numbers (less than about 10 - the average point of departure from veridical mapping across subjects) are not part of the mapping between the approximate number system and words, and instead gain their content from estimates made via subitization (e.g., in the company of chunking). Another possibility is that the mapping function is constrained by previous data which clearly disambiguate the numerosity/numbers correspondence, and that lower numbers have more data, and thus fall on the identity line, while higher numbers are constrained only by a requirement for smoothness and monotonicity. A final possibility is that the nature of the mapping function between the ANS and the verbal number system is qualitatively different for relatively small numbers and relatively larger numbers for example, participants might rely more strongly on itembased associative mappings for numbers smaller than 10, but more on a structural mapping between magnitudes and the count list for larger numbers (Sullivan \& Barner, 2012). We

Figure 4: We assess whether variability arises from a slow drift in the mapping function over time by estimating the slope of a bilinear mapping function for different subsets of the 300 trials for each subject. For instance, if we split the 300 trials into thirds (left half), then each third contains 100 trials, if we split into thirtieths (right half) then each thirtieth contains 10 trials. A blocked split (top half) corresponds to taking consecutive portions of the 300 trials: e.g., the first 3rd contains trials 1 through 100, the second 3rd contains trials 101 through 200, the third 3rd contains trials 201 through 300. A modular split (bottom half), corresponds to taking every \(n\)th trial, such that the full range of the experimental session is represented in each subset: e.g., the first 3 rd contains trials \(1,4,7,10, \ldots 298\), the second 3rd contains trials \(2,5,8,11, \ldots, 299\), and the third 3rd contains trials \(3,6,9,12, \ldots, 300\). We compute the across-subject correlation of slope estimates taken from each subset of trials. Darker colors indicate lower correlations, brighter colors indicate larger correlations. Several observations in these heat maps are indicative of a gradual drift in slopes over time within a given subject. (1) Modular splits yield higher across-subject correlations than blocked splits, suggesting that the blocked splits are subject to additional variability due to a gradual change that modular splits avoid. (2) Blocked splits show decreasing correlations as a function of distance: correlations further from the diagonal are lower - the correlation between the first and second third is higher than the correlation between the 1st and 3rd third - indicating that the correlations are slopes are changing slowly over time.
slightly disfavor the first alternative, because the cut-off point between accurate and miscalibrated mapping does not seem to correspond to other cut-offs previously postulated to distinguish between qualitatively different numerosity processes (such as subtilizing and approximate magnitude - Feigenson et al., 2004).

\section*{How reliable is the across-subject variation in the shape of the mapping function?}

We assess the across-subject reliability in shape of the bilinear mapping function via a split-half analysis: we estimate the mapping function (particularly the slope of the higher bilinear portion) in individual subjects in \(50 \%\) of the trials and assess the across-subject correlation across those pairs of estimates, to see whether variation of mapping functions is reliable.

First we assess Blocked split-half reliability: we divide the 300 trials into the first half (trials 1-150) and the second half (151-300). The Blocked split-half across-subject reliability of the estimate of the slope of the erroneous part of the mapping
function that does not fall on the identity line was highly significant ( \(r=0.83 ; t(22)=6.98, p<0.001\) ), indicating that people are very consistent in their idiosyncratic magnitude-to-number mapping errors.

We next assessed Modular split-half reliability: Modular split-half divides the 300 trials into odd trials (1, 3, 5, ..., 299), and even trials ( \(2,4,6, \ldots, 300\) ). In contrast to Blocked splits, in which trials in a given half of the data are are contiguous and arise from from different portions of the experiment (separated by an average of 150 trials), in Modular splits, the trials in a given half are taken from the full range of the experiment. Modular splits-half across-subject reliabilities were much higher than those for Blocked split-half analyses \((r=0.97 ; t(22)=18.7, p<0.001-\) the difference is highly significant using the Fisher r-to-z transform: \(z=-2.74, p=0.0061)\).

The difference between Modular and Blocked split-half reliability is our first indication that the slope of the magnitudenumber mapping function is not stable within individuals over the experimental session: If the slopes we estimate for the mapping function drift over time, we expect that Blocked splits should yield a lower split-half across-subject reliability than Modular splits, because the Blocked splits are taken from different points in time, and would reflect different states of drift of the mapping function, while Modular splits would not.

\section*{Does the mapping function vary over time?}

We argue that some of the increase in variability of estimates with increasing number arises from variability of the mapping function over trials, rather than simple misperception of the approximate magnitude of an individual array. In this section we argue for this view because the internal mapping function drifts slowly over the course of many trials, and we can measure its variation over the course of an experimental session.

To more precisely measure the drift of the mapping function over time, we generalize the Blocked vs. Modular splithalf analysis to Blocked vs. Modular split- \(n\) ths for \(n=\) \(\{3,5,10,15,20,30\}\) (e.g., for split-30th we divide our 300 trials into 30 subsets, each one comprising 10 trials, for instance, the 5th Blocked split-30th subset will contain trials 41-50, while the 5th Modular split-30th subset will contain the 10 trials: \(5,35,65,95,125,155,185,215,245,275)\). By obtaining split- \(n\)th reliability for Blocked subsets taken from different portions of the experimental session, we can assess how the reliability of the number-mapping slope decreases as a function of time.

We calculate the across-subject slope reliability across different subsets (represented as a matrix in Figure 4), the Blocked split- \(n\)th reliability between subset 1 and subset 2 measures the across-subject correlation of slopes estimated from two adjacent periods of time in the session which are on average separated by \(300 / n\) trials. In general if we calculate the correlation between subset \(i\) and subset \(i+k\) from a Blocked split- \(n\)th analysis, those subsets are separated by \(300 * k / n\) trials. Thus, if slopes are gradually drifting over the
course of the experimental session, we would expect acrosssubject reliability of slope estimates to decrease with \(k\) - the separation between Blocked subsets. Nothing of this sort should happen for Modular subsets which contain overlapping trials intermixed over the whole session.

Figure 5: (Top) We can assess the average across-subject correlation in slope estimates as a function of distance between blocks for different splits of the data. A blocked split of the data into thirds yields a two measures of the slope-correlation at an average distance of 100 trials (1st to 2nd block and 2nd to 3rd block) and one measure of the correlation at a distance of 200 trials ( 1 st to 3rd block). If we split the data more finely (here going up to 30ths, as seen in figure , we can more finely measure the drop-off of average correlation as a function of distance. Distance is meaningless for Modular (points in black) splits, but the same analysis can be carried out to measure how much the correlation drops merely as a function of using fewer trials for each slope estimate. (Bottom) we can normalize both blocked (red) and modular (black) correlations to the average of the modular split correlations to make the decrease in correlation with distance as seen in the red lines comparable across splits with different numbers of trials per subset. Correlations drop off with distance very slowly, but even when separated by 290 trials, 10 -trial estimates of subjects' mapping function slopes show reliabilities well above 0 .

Figure 5(top) shows the split- \(n\)th reliability for Blocked (red) and Modular (black) subsets as a function of their separation ( \(k\) ). For instance, we estimate the average Blocked split-10th correlation at a separation of \(k=2\) as the average of the across-subject correlations taken between the 8 subset comparisons separated by 2 : subset 1 and subset 3 , subset 2 and subset \(4, \ldots\) subset 8 and subset 10 . This average would appear at \(x=300 / n * k=300 / 10 * 2=60\). Several features are apparent from the changes in slope reliability across sub-
sets separated by more time: (1) when we split into more subsets both Modular and Blocked correlations drop, since each subset necessarily contains fewer trials to estimate the slope; (2) as expected, only Blocked correlations decrease as a function of distance between subsets. To more clearly display the decrease in reliabilities as a function of subset distance, while factoring out the reduced reliability due to smaller trialcounts within each subset, by normalizing reliabilities by dividing them by the average reliability seen across Modular splits. This yields Figure 5(bottom), which shows the slow decrease in reliabilities over the 300 trials.

A linear regression on the raw correlations in the Blocked split- \(n\) ths as a function of separation (measured in trials) is significantly negative ( \(95 \%\) confidence interval on the slope: \((-0.0015,-0.0012)\) change in correlation per trial, \(F(1,22)=358, p<0.001)\). Despite this highly significant decrease, it is very slow over the course of the session, and even mapping function slope estimates based on 10 trials separated by 290 trials show significant across-subject reliability ( \(r=0.57 ; t(22)=3.254, p=0.002\) ).

Together, these results indicate that subjects' mappings of magnitudes onto verbal numbers drift slowly over time.

\section*{Conclusions}

We have shown that subjects map numbers onto the verbal number line via a piecewise-linear function in logarithmic representations (piecewise consistent with Stevens' power law). Our results are consistent with two-transformations mapping physical numbers onto number estimates: first physical numbers are represented logarithmically in the approximate number system, and then the approximate number system is mapped onto the verbal number line through an unstable mapping. For small numbers, the mapping appears to be fairly stable and veridical, perhaps due to the considerable amount of evidence people have previously seen for small number estimates. For higher numbers, the mapping is not veridical, and tends to drift slowly over the course of many trials; the variability of the mapping function over time causes increasing estimation variance for large numbers, and may thus resolve theoretical disagreements about the constancy of variability in the approximate number system.

\begin{abstract}
There is controversy concerning the question of whether meaning can be extracted from a parafoveal word during reading and whether this might occur in an overlapping fashion with the lexical processing of the currently-fixated word. We suggest that previous attempts to investigate this have been bedevilled by problems associated with the use of priming methodology. Instead, we used an eye movement contingent change technique and manipulated the plausibility of the parafoveal preview, resulting in it being either valid, a plausible alternative, anomalous, or an illegal letter string. The results showed (a) a meaning-based parafoveal-on-foveal effect, (b) preview benefits driven by both orthographic and semantic influences, and (c) continuing disruption associated with orthographically dissimilar previews. We suggest that this pattern is most consistent with models of eye movement control that allow for distributed attention during reading.
\end{abstract}

\section*{Introduction}

The nature of Preview Benefit (PB) - the advantage accruing to the reader from an accurate parafoveal preview of the following word - critically informs our understanding of the reading process, indicating those features which are, and are not, extracted from an as yet unfixated word. Using the boundary paradigm (Rayner, 1975), many studies have shown that both orthographic and phonological features appear to be extracted from parafoveal words (see Schotter, Angele \& Rayner, 2012, for a review); however, evidence for a semantic PB remains controversial (see Radach \& Kennedy, 2013; Rayner, White, Kambe, Miller \& Liversedge, 2003).

While both serial (e.g., E-Z Reader; Reichle, Warren, \& McConnell, 2009) and parallel (e.g., SWIFT; Engbert, Nuthmann, Richter \& Kliegl, 2005) models of eye movement control during reading provide accounts of orthographic and phonological PB, only parallel models appear capable of accounting for semantic PB. In serial models, lexical processing is restricted to one word at a time, with attention moving to the parafoveal word only when the currently fixated word has been fully identified. Serial models therefore typically only accommodate very early stages of word recognition occurring on parafoveal words before a saccade remarries fixation location with attention. In contrast, in parallel models, all words within
the perceptual span can be processed simultaneously, up to and including the level of semantic processing.

Studies investigating semantic PB have typically manipulated the sematic relatedness of the preview and the target word, on the basis that responses to semantically related word pairs are facilitated compared to unrelated pairs (Meyer \& Schvaneveldt, 1971). By extension, it is suggested that semantically related previews should facilitate target viewing compared to unrelated previews. Using the boundary paradigm, Rayner Balota and Pollatsek (1986) asked participants to read sentences such as "My younger brother has brilliantly composed a new song for the school play", in which the pre-fixation preview of "song" was either "song" (valid), "tune" (related), "door" (unrelated), or "sorp" (a visually similar nonword). Only once the eye passed an invisible boundary, located before the critical word, did the target word "song" appear. Despite showing that their critical words produced facilitation in a classic priming experiment, Rayner et al found no evidence for a semantic PB during reading. However, in this example sentence, we see that the word to the left of the target contains only three letters, and as short words are frequently skipped (Rayner \& McConkie, 1976), the prior fixation may in fact have fallen two words to the left of the target, seriously reducing the chance of it eliciting a semantic PB.

A more general problem with experiments investigating semantic PB using associative previews is that while there may be semantic facilitation, there is also a word change that might be expected to give rise to some form of inhibition. Semantically related word pairs, such as northsouth, rattle-bottle and arms-legs, (from Rayner et al, 1986), have very different meanings, and this could exert an inhibitory effect on on-going sentence interpretation. Rayner et al (1986) attempted to test this possibility by asking participants to rate their sentence pairs for similarity of meaning and reanalysing the results from only the 20 sentence pairs rated as most similar in meaning. Since this analysis again failed to show a semantic PB, they dismissed this as an explanation for their null result. However, a measure of overall sentence meaning does not necessarily capture the extent to which a local change in word meaning might have disrupted the reading process at the point at which it occurred. We conclude, therefore, that interference resulting from word change remains a possibility.

Altarriba, Kambe, Pollatsek and Rayner (2001) used a variant of this technique with fluent English-Spanish bilinguals. They employed semantically related previews which were translations with virtually the same meaning as the targets, thereby reducing the possibility of interference. All changes involved a word preview from the other language that was either: cognate (orthographically and semantically similar), noncognate (semantically similar but orthographically dissimilar), pseudocognate (semantically unrelated but orthographically similar), or control (unrelated orthographically and semantically). They found no evidence for a semantic PB in the absence of orthographic similarity. However, it remains possible that facilitation might not cross over between the lexica of the two languages, and as Hohenstein, Laubrock and Kliegl (2010) point out, since the previews and targets were in different languages, switching costs (Meuter \& Allort, 1999) might mask any semantic PB.

Hohenstein et al (2010) suggest that the elusive nature of semantic PB may result from a lack of control over the preview duration of masked words. To test this possibility, they used fast priming (Sereno \& Rayner, 1992) and the boundary paradigm in a novel way. Prior to landing on the pretarget word, the target was masked with an illegal letter string. Once the eye landed on the pre-target word, this illegal nonword preview changed to either a semantically related or unrelated prime for durations of 35 ms , 80 ms or 125 ms , after which point, the target was displayed. Hohenstein et al report a significant semantic PB only when the prime duration was 125 ms (Experiments \(1 \& 2\) ). When primes were presented in bold typeface, a significant effect was observed with 80 ms primes, although, the 125 ms effect was no longer significant (Experiment 3). Given the transient nature of the effects and variability across experiments, these results would benefit from replication.

An alternative way to explore when the meaning of a word becomes available is to investigate plausibility effects. For example, Murray and colleagues (Kennedy, Murray \& Boissiere, 2004; Murray, 2006; Murray, 1998; Murray \& Rowan, 1998) recorded eye movements in a series of experiments where plausibility was manipulated. Participants read a sentence and then pressed a button, triggering another sentence to be displayed; the task being to indicate whether the two sentences were the same or different. These studies showed effects of the plausibility of the combination of the initial noun phrase with the verb, for example, "The hunters stacked...." vs "The bishops stacked...", and in a number of the studies, this was reflected not only in fixations falling on the verb, but also in some eye movement measures before the verb was directly fixated, suggesting the extraction of meaning from words in the parafovea. However, Rayner et al (2003) report being unable to replicate one of Murray et al's findings in a reading study and suggest that their results may have been task specific.

Starr and Inhoff (2004; Experiment 1) also investigated the consequences of providing a contextually inappropriate word to the right of fixation. They masked a critical word
with itself, a contextually inappropriate word, or a legal or illegal nonword. In addition to finding clear orthographic parafoveal-on-foveal effects, a trend also emerged in which a contextually inconsistent word in the parafovea reduced gaze duration by 22 ms on the pre-target word compared to an accurate preview. However, a subsequent analysis excluding the \(45 \%\) of cases where fixations fell near the ends of the pre-target words (possibly as a result of oculomotor error) showed no reliable effect. The contextually inconsistent preview also gave rise to inflated fixation times when the target was fixated, but this effect could be attributed to a lack of orthographic overlap, rather than any extraction of parafoveal meaning.

While plausibility related parafoveal-on-foveal effects remain controversial, it is widely accepted that the plausibility of words within a sentence can have an immediate impact on fixation durations falling on the word. For example, Rayner, Warren, Juhasz and Liversedge (2004) presented participants with a series of sentences in which a critical noun was either plausible (likely), implausible (unlikely) or anomalous (inappropriate), given the preceding sentence context. They found that anomalous words had an immediate impact on gaze duration, while effects of implausibility were reflected only in later measures. Interestingly, they also discovered a plausibilityrelated parafoveal-on-foveal effect, with gaze duration on the word preceding the anomalous one being 17 ms and 14 ms longer than in the control and implausible conditions, respectively. The authors, however, attribute this effect to oculomotor error.

Whether or not one questions the interpretation of apparent semantic parafoveal-on-foveal effects, it is clear that manipulating the plausibility of a word can produce robust effects on the reading pattern when that word is fixated. This study capitalised on that finding and presented participants with sentences in which a critical word ( \(\mathrm{n}+1\) ) was masked prior to receiving a direct fixation by either a (a) valid (identical), (b) plausible but different, or, (c) anomalous word, or (d) an illegal nonword. Once the eye passed an invisible boundary located before word \(_{n+1}\), all previews were replaced with the valid preview. If meaning is extracted from the parafovea, it would be expected that an anomalous preview should exert an immediate impact on word \(_{n+1}\) fixations compared to the plausible preview condition. Conversely, if the meaning of the parafoveal word is not extracted while fixating word \(_{n}\), then plausible and anomalous previews should both produce the same cost, as a result of their lack of orthographic overlap with the target. The illegal nonword served as a baseline against which the magnitude of PB could be judged.

\section*{Method}

\section*{Participants}

Twenty-eight native English speakers with normal or corrected to normal vision took part for course credits or \(£ 5\) payment.

\section*{Materials and Design}

Ninety-six experimental sentences were constructed. As can be seen in the example below, each contained a critical word pair, comprising a 6 letter verb \(\left(\right.\) word \(\left._{n}\right)\) followed by a 6 or 7 letter noun \(\left(\operatorname{word}_{n+1}\right)\). To facilitate processing, word \(_{n}\) was always high frequency (mean 135 occurrences per million, by Kucera \& Francis, 1967). Word \(_{n+1}\) was assigned one of four pre-fixation previews, all chosen to be very low in predictability: valid (e.g. "dinner" - identical), plausible (e.g., "coffee" - an alternative that fitted the preceding context), anomalous (e.g. "caught" - a word that produced a semantic or grammatical violation), or an illegal nonword (e.g., "fumeio" - a letter string containing combinations not found in the English dictionary, in this case "eio"). The frequency of these three preview words did not differ (means 132, 144 and 140 per million respectively, all \(t s<1\) ). Previews were displayed until the eye passed an invisible boundary located prior to the space before word \(_{n+1}\), shown below with a "|". When the eye crossed this boundary, the target word was then displayed.
The mother was making| dinner in the kitchen for her two children and her husband.

Plausibility ratings were provided by 12 participants, who did not take part in the eye tracking experiment. Participants rated all three versions of each sentence up to and including word \(_{n+1}\) (illegal letter strings were not included). They used a rating scale from 1 (low) to 7 (high) plausibility. Additionally, they could use "U" instead of providing a numerical rating if they felt the sentences were ungrammatical; " \(U\) " scores were coded as 0 for purposes of analysis. The valid and plausible fragments were both rated as highly plausible (means \(=6.3\) and 6.2 , respectively), with no significant difference between these conditions \((t(95)=.85, p=.40)\). The mean rating for the anomalous condition was 1.0 which differed significantly from both the valid \((t(95)=44.63, p<.001)\), and plausible conditions \((t(95)=45.90, p<.001)\).

Four counterbalanced item lists were created, each containing the 96 experimental sentences together with 19 filler and 8 practice items and 20 comprehension questions. Word \(_{n+1}\) previews initially masked the target, with each item list containing an equal number of valid, plausible, anomalous and illegal nonword previews. Each participant was presented with the items in a different randomised order.

\section*{Apparatus}

A dental composition bite bar and chin rest were used to minimise head movements. Sentences were displayed on a VDU screen in white monopitch font on a black background. At a viewing distance of 50 cm , each character subtended approximately 0.3 degrees of a visual angle. Reading was binocular, but only eye movements from the right eye were recorded using a "Dr. Bouis" infrared pupil-
centered computation device sampled with a 12 -bit A-D at 2 ms intervals. The apparatus was calibrated after every fourth sentence. In order to answer questions, right-hand ("yes") and left-hand ("no") button boxes were provided.

\section*{Procedure}

Verbal and written instructions were provided. Calibration consisted of looking at a series of horizontally aligned numbers. Once optically set up and calibrated, participants fixated a cross, which after receiving a 100 ms stable fixation, triggered display of a sentence. Participants were asked to read for comprehension, but not to adjust their usual reading style. If presented with a question, they were asked to respond using the button boxes.

\section*{Results and Discussion}

Data were analysed treating both participants \(\left(F_{1}\right)\) and items \(\left(F_{2}\right)\) as random variables. In all analyses item file was treated as a between-groups dummy factor. Analysis focused on the pretarget word (n), the target word ( \(\mathrm{n}+1\) ) and a spillover region comprising the following three words. A number of eye movement measures are reported for each region: the duration of the first and last fixations, gaze duration (summed duration of all fixations until the eye exits the region in either direction), go-past time (summed duration of all fixations, including regressions until the following region is first fixated) and first pass skipping probability. Participants clearly read carefully, with \(86 \%\) overall accuracy on the comprehension questions.

\section*{Effects of Word \({ }_{n+1}\) Preview on Word \(_{n}\)}

The probability of fixating word \(_{n}\) did not vary across conditions (both \(F \mathbf{s}<1\) ) and first fixation duration, gaze and go-past time showed no reliable effect of preview type (all \(F \mathrm{~s}<1.3\) ). A trend did however emerge in last fixation duration \(\left(F_{l}(3,72)=2.81, p<.05 ; F_{2}(3,276)=2.05, p=.11\right)\) with shorter fixations when the preview was either an illegal nonword or an anomalous word. While first and last fixation durations constitute overlapping sets, the two measures potentially tap into differing processes. It is not surprising, therefore, to find a trend emerging statistically only for those fixations which were the last to fall on the word. For this measure, pairwise comparisons showed no significant difference between the valid and plausible conditions ( \(F_{1}\) \(\left.(1,24)=2.07, p=.16, F_{2}(1,92)=2.21, p=.14\right)\), however, when these two conditions were combined and compared to the anomalous condition, durations were reliably shorter in the anomalous condition \(\left(F_{1}(1,24)=5.30, p<.05, F_{2}(1,92)\right.\) \(=4.29, p<.05)\), suggesting that this preview attracted attention from word \({ }_{n}\). The same trend emerged when an illegal nonword fell to the right of fixation, although the difference between the combined valid and plausible conditions and the illegal nonword preview was only reliable over subjects \(\left(F_{1}(1,24)=4.54, p<.05, F_{2}(1,92)=\right.\) 1.10, \(p=.30\) ). The pattern overall, however, suggests that readers respond similarly to both orthographic illegality and
anomaly to the right of fixation. This speed-up seems similar to the finding by Starr and Inhoff (2004) of a trend towards shorter gaze durations on the pre-target word when the target preview was contextually inconsistent.

Table 1: Fixation times (ms) and skipping probability (\%) on word \({ }_{n}\) as a function of word \(_{n+1}\) preview
\begin{tabular}{lccccc}
\hline & FFD & LFD & Gaze & Go-Past & Skip \\
\hline Valid & 257 & 257 & 274 & 301 & 8 \\
Plausible & 263 & 264 & 280 & 305 & 8 \\
Anomalous & 255 & 253 & 278 & 305 & 8 \\
Illegal & 258 & 253 & 268 & 296 & 10 \\
\hline
\end{tabular}

Interestingly Rayner et al (2004) reported an effect of parafoveal anomaly on word \({ }_{n}\) in the opposite direction, with longer fixations when there was an anomalous word to the right of fixation. They concluded this must result from mislocated fixations, with the reader staying and processing word \(_{n+1}\) from a sub-optimal parafoveal location. But a reduction in fixation duration does not permit the same interpretation. These results and the pattern apparent in Starr and Inhoff's contextually inconsistent condition appear more consistent with Kennedy's \((1998,2000)\) attractor hypothesis, in which something unexpected in the periphery attracts attention, resulting in shorter fixation durations on the preceding word. Parafoveal-on-foveal effects have frequently been reported as a consequence of orthographic peculiarities to the right of fixation; however, here we see it, to an equivalent extent, as a consequence of meaning.

\section*{Word \(_{n+1}{\text { Preview Effects on } \text { Word }_{n+1}}^{1}\)}

There was no reliable effect of preview on the skipping of \(\operatorname{word}_{n+1}\left(F_{1}(3,72)=1.50, p=.22 ; F_{2}(3,276)=1.70, p=.16\right)\). There was, however, a consistent effect of prior preview in all durational measures: first \(\left(F_{1}(3,72)=7.43, p<.001 ; F_{2}\right.\) \((3,276)=5.81, p<.01\) ), and last fixation durations ( \(F_{1}(3,72)\) \(\left.=4.69, p<.01 ; F_{2}(3,276)=3.5, p<.05\right)\), gaze duration \(\left(F_{1}\right.\) \(\left.(3,72)=8.87, p<.001 ; F_{2}(3,276)=8.71, p<.001\right)\), and gopast time \(\left(F_{1}(3,72)=7.65, p<.001 ; F_{2}(3,276)=9.29\right.\), \(p<.001\) ). As can be seen from Table 2, the longest durations were associated with words previously masked by an illegal nonword, followed by anomalous then plausible previews, with valid previews associated with the shortest durations.

Table 2: Fixation times (ms) and skipping probability
(\%) on word \({ }_{n+1}\) as a function of word \(_{n+1}\) preview
\begin{tabular}{lccccc}
\hline & FFD & LFD & Gaze & Go-Past & Skip \\
\hline Valid & 267 & 267 & 298 & 331 & 5 \\
Plausible & 277 & 275 & 299 & 345 & 6 \\
Anomalous & 281 & 277 & 313 & 370 & 7 \\
Illegal & 287 & 283 & 331 & 389 & 4 \\
\hline
\end{tabular}

Pairwise comparisons revealed that a preview of an illegal nonword increased fixation durations across all measures: first \(\left(F_{1}(1,24)=47.02, p<.001 ; F_{2}(1,92)=18.06, p<.001\right)\);
and last fixation durations ( \(F_{1}(1,24)=21.87, p<.001 ; F_{2}\) \((1,92)=14.97, p<.001)\); gaze duration \(\left(F_{1}(1,24)=23.00\right.\), \(\left.p<.001 ; F_{2}(1,92)=23.68, p<.001\right)\) and go-past time ( \(F_{1}\) \(\left.(1,24)=15.69, p<.001 ; F_{2}(1,92)=26.67, p<.001\right)\).

Readers also appear to have noticed the change from the plausible preview to the valid target, reflected in a reliable increase in first fixation duration ( \(F_{1}(1,24)=5.66, p<.05\); \(\left.F_{2}(1,92)=5.00, p<.05\right)\). However, the similar trends in last fixation duration and go-past time failed to achieve statistical significance \(\left(F_{1}(1,24)=3.22, p=.08 ; F_{2}(1,92)=\right.\) \(2.62, p=.11\) and \(F_{1}(1,24)=3.70, p=.06 ; F_{2}(1,92)=1.73\), \(p=.19\), respectively) and there was no effect in gaze duration (both \(F \mathbf{s}<1\) ). Overall, this pattern suggests that the change from a different, though plausible, word was noticed immediately and resulted in an increased probability of regressing, as reflected in go-past time, but not in gaze duration, since this is terminated by the regressive movement. It is not clear, however, whether this is an effect of meaning change, since it could equally be a consequence of the lack of orthographic overlap between the plausible preview and target.
A test of the effect of meaning can, however, be found in the contrast between plausible and anomalous previews, since both involve a change in orthography. The results here suggest that the meaning of word \(_{n+1}\) was indeed extracted while fixating word \({ }_{n}\). While both first and last fixation duration showed no evidence of an increased cost of anomaly (all \(F \mathrm{~s}<1\) ), the 14 ms increase in gaze duration was significant by-subjects and approached significance byitems \(\left(F_{1}(1,24)=4.78, p<.05 ; F_{2}(1,92)=2.99, p=.08\right)\) and with regressions taken into account, the 25 ms increase in go-past time was significant by-subjects and very close to significant by-items ( \(F_{1}(1,24)=5.88, p<.05 ; F_{2}(1,92)=\) \(3.51, p=.06\) ).
As can be seen in Table 3, an increase in go-past time following anomalous previews also arose in the spillover region (see below). Combining word \(_{n+1}\) and the spillover regions, the difference in go-past between the plausible ( 898 ms ) and anomalous ( 946 ms ) conditions was significant by both subjects and items ( \(F_{1}(1,24)=7.29, p<.05 ; F_{2}\) \((1,92)=6.17, p<.05)\). This effect - an immediate and robust slowing in the anomalous condition - is in the expected direction based on, for example, the findings of Rayner et al (2004), who suggest that anomalous words "hit the reader over the head" (p. 1297). It seems from these results however, that the genesis of this effect can be parafoveal, with the reader detecting anomaly far earlier than previously thought.
It could be suggested that these results stem from word \({ }_{n}\) receiving full lexical access, allowing an attention shift to word \(_{n+1}\) which also received full lexical access and semantic interpretation, all prior to word \(_{n+1}\) being fixated. While possible, this seems extremely unlikely with both the low predictability and length of word \({ }_{n+1}\) conspiring against such rapid parafoveal identification.
These results strongly suggest that parafoveal preview effects are not restricted to the extraction of orthographic
and phonological features, but rather, that higher level linguistic processing can be engaged when previewing words to the right of fixation, and when the input changes, as happened here, this interferes with later comprehension.

\section*{Word \(_{n+1}\) Preview Effects in the Spillover Region:}

As shown in Table 3, the spillover region was rarely skipped, with little difference between the preview conditions (both \(F \mathbf{s}<1\) ). Both first and last fixation durations were unaffected by word \({ }_{\mathrm{n}+1}\) preview type (all \(F \mathbf{s}<1\) ), as was gaze duration \(\left(F_{1}(3,72)=1.56, p=.21 ; F_{2}(3,276)=1.62\right.\), \(p=.18\) ). There was, however, a highly significant effect of word \(_{\mathrm{n}+1}\) preview on go-past time \(\left(F_{1}(3,72)=6.98, p<.001\right.\); \(\left.F_{2}(3,276)=10.48, p<.001\right)\), with higher durations when word \(_{n+1}\) had been changed.

Table 3: Fixation times (ms) and skipping probability (\%) in the spillover region as a function of word \({ }_{n+1}\) preview
\begin{tabular}{lccccc}
\hline & FFD & LFD & Gaze & Go-Past & Skip \\
\hline Valid & 256 & 247 & 465 & 505 & 1 \\
Plausible & 254 & 249 & 480 & 553 & 0 \\
Anomalous & 254 & 254 & 486 & 576 & 1 \\
Illegal & 255 & 250 & 485 & 541 & 1 \\
\hline
\end{tabular}

Pairwise comparisons show go-past time significantly higher following an illegal nonword compared to a valid preview \(\left(F_{1}(1,24)=7.65, p<.05 ; F_{2}(1,92)=5.99, p<.05\right)\). This finding is difficult to reconcile with models such as EZ Reader in which orthographic extraction occurs during the first stage of lexical processing on a word \(\left(\mathrm{L}_{1}\right)\). \(\mathrm{L}_{1}\) can commence on word \({ }_{\mathrm{n}+1}\) if the word is parafoveally available while fixating word \({ }_{n}\). However, if preview is denied, \(L_{1}\) is delayed until word \({ }_{n+1}\) is fixated, resulting in the standard \(\operatorname{word}_{n+1}\) PB. But as soon as \(L_{1}\) is complete, a saccade is programmed to word \(_{\mathrm{n}+2}\), at which point the second stage of lexical processing ( \(\mathrm{L}_{2}\) ) commences. Since it is postulated that this stage follows orthographic extraction, the time for attention to shift to word \(_{n+2}\) should only ever be a function of later linguistic processing and not delayed by difficulties with orthographic extraction. According to the E-Z Reader model, therefore, it should never be the case that fixation durations are inflated after word \(_{n+1}\) has been passed - unless of course they are 'mislocated', but in that case the response should be to stay and process, rather than to regress, as seen here.

While the 48ms increase following a plausible compared to a valid preview was significant \(\left(F_{1}(1,24)=20.68\right.\), \(p<.001 ; F_{2}(1,92)=17.53, p<.001\), the 23ms increase following an anomalous compared to a plausible preview was not \(\left(F_{1}(1,24)=1.70, p=.21 ; F_{2}(1,92)=2.47, p=.12\right)\). Somewhat surprisingly, spillover effects relating to a lack of orthographic overlap between preview and target appear to show a longer time course than effects of parafoveal meaning, with the latter exerting a more immediate impact, mostly reflected in the cumulative duration measures on word \(_{n+1}\).

\section*{General Discussion}

This study set out to investigate whether PB is restricted to the orthographic and phonological properties of a parafoveal word or whether meaning can also be extracted before a word is directly fixated. Prior research has failed to show much evidence for a semantic PB, but we suggest this may be due to the use of semantically related previews, with the word change interfering with target processing, rather than facilitating the recognition process. By varying the plausibility of previews, we have found two important semantic effects.

First, we found evidence that an anomaly in the parafovea can attract attention, resulting in shorter fixation durations on pre-target words. While others have reported anomalyrelated parafoveal-on-foveal effects (Kennedy, Murray \& Boissiere, 2004; Murray, 1998; Murray \& Rowan, 1998; Rayner et al, 2004; Starr \& Inhoff, 2004), this appears to be the first study to find a reliable effect that cannot be attributed to a potentially mislocated fixation. As Liversedge, Paterson and Pickering (1998) point out, when faced with difficulty the reader has three options: (a) stay and resolve the problem, (b) make a regression, or (c) proceed, in anticipation that later words will help resolve the difficulty. It seems that here readers have had a tendency to opt for the latter option, which as Liversedge et al point out, can result in reduced fixation durations.

Second, word \({ }_{n+1}\) PB was influenced by the plausibility of the preview. This effect cannot be explained in terms of orthographic overlap since both the plausible and anomalous word previews differed from the target. The nature of the effect was distinctly different depending on whether a plausible or anomalous preview was employed; with anomalous previews exerting a more immediate and robust effect on word \({ }_{n+1}\) viewing times. Since these previews were only available prior to word \(_{n+1}\) receiving a direct fixation, the results clearly provide evidence for the extraction of meaning from a word in the parafovea.

A proponent of serial word processing might attempt to explain these findings with the suggestion that the meaning effects arose when attention moved to word \({ }_{n+1}\) following foveal identification of word \({ }_{n}\), but before the eye movement was executed. However, this would necessitate that there is enough of a lag between the shift of attention and the eye movement not only to enable the \(L_{1}\) stage of processing of word \(_{n+1}\) to be completed, resulting in a potential skip, but that there was enough time for \(\mathrm{L}_{2}\) also to be completed, allowing meaning extraction to occur. However, word \(_{\mathrm{n}+1}\) was skipped rarely and no more often when it had been anomalous, and in any case, it seems rather unlikely that all this processing could somehow be shoehorned into the time between the termination of lexical processing of word \(_{n}\) and the execution of the saccade out of it.

Given the form of the word \({ }_{n+1}\) effects found here, it seems that the approach of looking for meaning effects using semantic associates is likely flawed. Even if there is some semantic facilitation from the associated word preview, the magnitude of this would appear to be more than outweighed
by the interference generated by a word change. This sort of combination of facilitation and inhibition might possibly explain why Hohenstein et al (2010) only found a semantic PB with a fast prime duration of 125 ms on the pre-target word (unless the prime's saliency was enhanced). Shorter prime durations might not allow time for semantic processing to occur, while longer durations might strengthen the interference.

A final important finding relates to the continued effect of masking word \(_{n+1}\) with an orthographically dissimilar preview, shown in longer fixation durations in the spillover region. While serial models can account for shorter fixation durations in the spillover region - since longer fixation durations on word \({ }_{n+1}\) following an invalid preview would allow more word \({ }_{n+2}\) preview to accrue - the finding of a continuing increase in fixation duration cannot be afforded the same interpretation.

Overall, the results of this study are difficult to reconcile with models of eye movement control that allow only strictly serial sequential lexical processing. Rather, they seem more compatible with a perspective in which multiple words may be lexically processed in an overlapping fashion.

\title{
Later events lie behind her, but not behind you: Compatibility effects for temporal sequences along the sagittal axis depend on perspective
}

\begin{abstract}
Perspective plays a large role in how we think about space. Does perspective also influence how we think about abstract concepts, such as time, which have been shown to be closely associated with how we think about space? Linguistic patterns suggest that speakers talk about temporal sequences from two perspectives: field-based and ego perspective (Moore, 2011). However, the psychological reality of these mappings beyond their use in language is unclear. The present study examines whether sequential reasoning recruits the sagittal (front-back) axis differently, depending on the perspective adopted for the task. We manipulated perspective by using pronouns meant to evoke a field-based or ego perspective ("her" vs "your" high school graduation, respectively). Participants made earlierthan or later-than judgments about event sequences using a mouse in front of or behind their body. We observed an interaction between pronoun, temporal reference, and response location. Participants map space onto time differently depending on the frame of reference from which temporal sequences are interpreted.
\end{abstract}

Keywords: spatial construals of time; perspective; pronouns; compatibility effects; sequence time

\section*{Introductions}

Spatial perspective plays an important role in how people think about and comprehend the world around them (e.g., Tversky, 2003, 2005) and humans are quite flexible in the spatial perspectives they are able to adopt. Indeed, individuals are not only able to think about and interpret scenes from their own perspective, but are also able to adapt their perspective to that of another person (Tversky \& Hard, 2009). Furthermore, language can also influence the perspective from which one interprets a scene. For example, the use of a single pronoun influences the perspective from which readers simulate actions described in narratives (Brunyé, Ditman, Mahoney, Augustyn, \& Taylor, 2009). Brunyé et al. (2009) demonstrated that when participants read sentences such as "You are cutting the tomato" versus "He is cutting the tomato", they were faster to match the sentence to the corresponding picture if the pronoun matched the spatial perspective from which the picture was taken. As such, it appears that one's embodied simulation of actions in the world is sensitive to the perspective from which those actions are described. However, is it also the case that the use of different pronouns influences the perspective from which one thinks about more abstract concepts, which have been suggested to obtain their
conceptual structure from our embodied experience of moving through and interacting with the world around us (e.g., Lakoff \& Johnson, 1980)? One candidate that may help provide insight into such a question is time-the conceptualization of which appears tightly tied to how we think about space.

Across the world's languages, people use space to talk about time. Nevertheless, there's diversity in precisely how languages spatialize time-what axis they use, and how they map time onto that axis (Clark, 1973; Haspelmath, 1997; Núñez \& Sweetser, 2006). Moreover, the use of space to structure time isn't merely a matter of language, it's also a matter of thought-a large literature suggests that conceptualizations of time are also strongly linked to thought about space (e.g., Casasanto \& Boroditsky, 2008). Indeed, from linguists to philosophers to psychologists, scholars have discussed at length the ways in which time recruits spatial structure. This research has produced a large body of findings in language (Clark, 1973; Traugott, 1975; Moore, 2006; 2011), gesture (Cooperrider \& Núñez, 2009; Casasanto \& Jasmin, 2012), and psychological experiments (Santiago et al., 2007; Torralbo et al., 2007; Weger \& Pratt, 2008; Ouellet et al., 2010).
Scholars have long noted that there exist at least two distinct spatial construals of time: deictic and sequence (McTaggart, 1908; Núñez \& Sweetser, 2006). Deictic time conceptualization reflects past/future relationships and centers around the present moment, or "now," as a reference point. Sequence time, on the other hand, does not use "now" as a reference point. Instead, one event becomes the reference point for another event, capturing "earlier" or "later" relationships in time. Experimental research on this topic has often overlooked this distinction, pooling deictic with sequential judgments, but because the two types of time judgment relate to space differently (Casasanto \& Jasmin, 2012; Walker, Bergen, \& Núñez, 2013), the present study will focus only on sequence time.

Sequence time has been shown to recruit the transversal (left-right) axis in a systematic manner. In gesture, English speakers often sweep their hand to their left when talking about earlier events and to the right when talking about later events (Cooperrider \& Núñez, 2009; Casasanto \& Jasmin, 2012). Furthermore, space-time compatibility effects are widely reported for this axis in a variety of languages (e.g., in Spanish: Santiago, Lupiañez, Perez, \& Funes, 2007; in

English: Weger \& Pratt, 2008; in German: Ulrich \& Maienborn, 2010). For example, English-speakers are faster to respond to earlier events on their left and to later events on their right (Weger \& Pratt, 2008). Interestingly, this pattern reverses in languages that write right-to-left. Hebrew speakers show the opposite patterns and are faster to respond to earlier events on their right and later events to their left (Fuhrman \& Boroditsky, 2010). These consistent patterns are likely the product of our long history of experience with various cultural practices, suggesting a strong role of such practices like graphical notation and writing direction in the recruitment of the transversal axis. By contrast, linguistic patterns reveal the spatialization of temporal sequences along a sagittal (front-back) axis, and how such temporal sequences are mapped onto the sagittal axis in language appears to depend on the frame of reference from which it is interpreted.

Moore (2011) observes that, in language, temporal sequences can be interpreted from two different reference frames: ego-perspective and field-based. An ego-perspective depends on the perspective of the ego, as in the sentence "It looks like there are sunny days ahead" (of now). In this example, "sunny days" are described as lying ahead of the present moment, which is co-located with the speaker's ego. This is clearly a case of deictic time, where the deictic center is the present moment and ahead refers to the space in front of the speaker, which is then interpreted as in the future or later-than-now. On the other hand, while egoperspective frames depend on the perspective of the ego (as in deictic time), field-based frames are deictically neutral, meaning they do not require a deictic center, and do not change if an observer's perspective changes. For example, Moore (2011) considers people waiting in line: no matter which way you look at the line, there is a front and back to that line, dictated by convention. Those in front of others will be served earlier than those who are later in line. This can also be seen in the linguistic example, "Polls showed a widening lead for the Democrats ahead of last month's elections" (example from Moore, 2011). From this frame of reference, "ahead" is interpreted to mean "ahead of some reference event", which is subsequently interpreted as "earlier than some reference event". Thus, how sequences of events in time map onto space in language appears to depend on the frame of reference from which they are interpreted.
While patterns in language suggest that these two perspectives differ in how they use spatial terms such as "ahead", does this mean that speakers are actually using space differently when thinking about these sequences of events? Recent work has shown that, at least in deictically neutral settings, the earlier-in-front/later-in-back mapping observed in field-based frames in language emerges in experimental paradigms. Walker et al. (2013) had participants listen to a series of two events presented from a speaker that was either in front of or behind them. Participants were then asked to vocally respond whether the second event they heard happened earlier or later than the
first event they heard (e.g., after hearing her high school graduation, her college graduation, participants would respond "later" into the microphone). Results indicated that participants were faster to make earlier judgments to stimuli presented in front of them and faster to make later judgments that were presented behind them. However, the stimuli in that study all used the pronoun "her", and thus it is unclear whether the results reflect how sequences generally map onto the sagittal axis or whether they were due to the use of deictically neutral stimuli, which, according to patterns in language, elicit such a mapping. Thus, in order to determine whether perspective influences how one interprets the relationship between earlier/later and sagittal space, we'd need to know whether manipulating the perspective from which participants interpret deicticallyneutral sequences changes the pattern of space-time mappings.

In the present study, we used the same basic design as described above (Walker et al., 2013). However, stimuli were presented visually instead of auditorily and participants responded using a mouse click instead of responding vocally. Participants made judgments about deictically-neutral sequences along the sagittal axis. Critically, we manipulated the pronoun that preceded each of the events in order to examine whether differences in person perspective induces differences in the frame of reference that participants use to think about the sequences of events. Participants received the pronoun "her" for two blocks, while in the other two blocks they received the pronoun "your".

If temporal sequences are simply mapped onto space in a manner consistent with a field-based frame of reference, we would expect to see no difference in the time-space mappings recruited for each of the pronouns-both pronouns would elicit a clear earlier-in-front, later-in-back sequential mapping. Alternatively, the use of different pronouns may lead to the use of different space-time mappings. While making a judgment about whether your high school graduation is earlier or later than your college graduation need not involve any deixis or reference to the present moment, the inclusion of the pronoun "your" may automatically bring forth thoughts about your location in time. Conversely, the use of the pronoun "her" in sequences would keep them deictically neutral. If this is the case, then the use of the pronoun "her" should lead to time-space mappings consistent with a field-based interpretation (earlier-in-front/later-in-back) while the use of the pronoun "your" should encourage the use of time-space mappings consistent with an ego-perspective (earlier-in-back/later-infront). More specifically, we would expect a three-way interaction between the pronoun used, temporal reference, and location of response.

\section*{Methods}

\section*{Participants}

Forty-two undergraduates at the University of California, San Diego participated for partial course credit. Eight participants were removed due to low levels of accuracy ( \(<80 \%\) ), leaving 36 participants for analysis.

\section*{Materials and Design}

The stimuli were composed of forty pairs of typical life events (e.g., "her/your high school graduation, her/your college graduation"). Twenty pairs required "earlier" judgments while twenty required "later" judgments. Stimuli for earlier judgments were no different in length than those presented for later judgments, \(\mathrm{p}=.72\).
The experiment was programmed using E-Prime (Psychology Software Tools, Pittsburgh, PA, USA). Each participant completed a total of four blocks of forty trials of sequential judgments. During two of the blocks, each event was preceded with the pronoun "her" and during the other two blocks, events were preceded with "your". Participants completed two blocks of trials (one block for each response mapping) with each pronoun, followed by another two blocks of trials using the other pronoun. Response mappings and pronoun order were counterbalanced across participants.

\section*{Procedure}

Participants held two computer mouses, one in each hand, with each of their thumbs over one of the mouse buttons. One mouse's button was covered with red tape, while the other mouse's button was covered with yellow tape. Participants held one mouse directly in front of their body and the other mouse behind their back (see Figure 1). Which hand was in front (right or left) was counterbalanced across participants.

Before each block, participants were presented with instructions that explained the stimulus-response mappings they would use for that block. The yellow mouse was always in front of the participant, while the red mouse was always behind the participant. Which judgment required pressing a button on which mouse was changed after each block. Participants were instructed to judge whether the second event they saw in a sequence was earlier or later than the first event, and to indicate their decision by pressing either the yellow or red mouse. They were told to complete the judgments as quickly and accurately as possible. They then completed four practice trials, followed by forty randomly ordered experimental trials. There were a total of 160 trials (four blocks of 40 trials) and 16 practice trials (four practice trials per block).

On each trial, participants were presented with a fixation cross for 1000 ms , followed by the first event in the sequence. After 2000 ms , the first event was removed from the screen and a white screen was presented for 500 ms . The second event was then presented and remained on the screen until the participant responded, up to a maximum of 5000 ms . Reaction times were measured from the onset of the
second event. After each block, participants received new instructions for how to respond during the next block.

Figure 1: Participants held one mouse in front of their body and one mouse behind their body. Which hand was in front was counterbalanced across participants.

\section*{Analyses}

All analyses were conducted in \(R\) ( R Development Core Team, 2005). Incorrect trials ( \(5.8 \%\) of the data) as well as trials that were 2.5 standard deviations from each subject or item's mean ( \(3.7 \%\) of the data) were excluded from analysis. Response times were fitted with a series of linear mixedeffect models with subjects and items as crossed random effects using the lme4 library (Bates, Maechler, \& Bolker, 2011) in \(R\) ( R Development Core Team, 2005). P-values were obtained using the pvals.fnc function in the languageR package (Baayen, 2011). To investigate whether the different pronouns elicited different spatial construals of temporal sequences, a linear mixed-effects model with temporal reference (earlier, later), response location (front, back), and pronoun (her, your) as fixed effects was fitted to the response times. As needed, appropriate follow-up tests were conducted, as reported below. Models were all significantly different from their respective null models.

\section*{Results}

The overall model revealed a two-way interaction between temporal reference and response location, \(\beta=253.53\), \(\mathrm{SE}=43.14, \mathrm{p}<.001\). Follow-up tests indicated that overall, participants responded faster to later events when responding on the mouse located behind them than the mouse in front of them ( \(\beta=90.36, \mathrm{SE}=22.17, \mathrm{p}<.001\) ) and responded faster to earlier events when responding in front than in back ( \(\beta=-69.86, \mathrm{SE}=20.97, \mathrm{p}<.001\) ). There was also
a main effect of response location, \(\beta=-88.78, \mathrm{SE}=43.14\), \(\mathrm{p}<.001\). Participants were overall faster to respond by clicking on the mouse in front of them than the mouse behind them. No other main effects were significant.
Critically, there was also a three-way interaction between pronoun, temporal reference, and response location, \(\beta=-\) 184.70, \(\mathrm{SE}=60.99, \mathrm{p}=.003\). Follow-up analyses indicated that this interaction was driven by a strong interaction between temporal reference and response location on trials using the pronoun "her", \(\beta=254.03, \mathrm{SE}=41.71, \mathrm{p}<.001\). This interaction was not reliably significant for the pronoun "your", \(\beta=69.63, \mathrm{SE}=42.15, \mathrm{p}=.10\) (see Figure 2).
To examine whether participants' responses were affected by which pronoun they received first, we ran further exploratory analyses. We divided the data by which pronoun participants received first (her or your) and then created a model with spatial location and temporal reference as fixed effects and subject and items as random effects. Results are presented in Figure 3. For participants who were presented with the pronoun "her" first, there was no longer a threeway interaction between temporal reference, location, and pronoun, \(p=.31\). However, the interaction between temporal reference and location remained, \(\beta=279.48, \mathrm{SE}=61.38\), \(\mathrm{p}<.001\), and the earlier-in-front/later-in-back mapping was revealed for both "her" \((\beta=274.42, \mathrm{SE}=60.65, \mathrm{p}<.001)\) and "your" \((\beta=198.38, \mathrm{SE}=59.09 \mathrm{p}<.001)\). On the other hand, participants who were tested with the pronoun "your" first demonstrated a three-way interaction between pronoun, temporal reference, and location, \(\beta=-283.32, \mathrm{SE}=83.58\), \(\mathrm{p}<.001\). While the earlier-in-front/later-in-back pattern remained for the pronoun "her", \(\beta=231.73, \mathrm{SE}=57.53\), \(\mathrm{p}<.001\), no clear pattern emerged for the pronoun "your", \(\mathrm{p}=.38\).

Figure 2: Mean response times for earlier and later judgments along the sagittal axis. The left graph displays the results for the pronoun "her". The interaction between response location and temporal reference is significant. The right graph displays the results for the pronoun "your".

Error bars represent standard error.

Figure 3: Mean response times for earlier and later judgments along the sagittal axis when split by which pronoun participants received first: the top-left graph shows responses to the pronoun "her" when it came first; the bottom-left graph shows responses to the pronoun "your" when it came after "her"; the top-right graph shows responses to the pronoun "your" when it came first; the bottom-right graph shows responses to the pronoun "her" when it came after "your".

\section*{General Discussion}

We investigated whether the use of different pronouns ("her", "your") would lead participants to interpret temporal sequences from different perspectives and therefore lead to differences in how individuals mapped temporal sequences onto space. If participants simply systematically map sequences of events onto the sagittal axis in a manner consistent with patterns in language (earlier-in-front/later-in-back), the use of different pronouns should have no effect on the space-time mappings used by the participants. However, we observed a three-way interaction between pronoun, response location, and temporal reference: spacetime mappings recruited for temporal sequences involving "her" were different than those recruited for the pronoun "your".
The spatialization of temporal sequences along a bodycentered sagittal axis in the present study is intriguing for multiple reasons. First, sequence time does not make reference to the present moment (as in deictic time). As a result, events in a sequence are generally not co-located with a speaker's body in gesture as they are in deictic time. Indeed, sagittal gestures are rarely observed when talking about sequential time (Casasanto \& Jasmin, 2012). Second, even though sagittal language (e.g., ahead) is used to talk about sequences of events, this language is often used to refer to the location of one event with respect to another event, independent of the speaker's location in space (or time, for that matter) and thus does not reflect a sagittal axis that is centered around the speaker's body. Rather, sequential time is often talked about from an external perspective (Núñez \& Cooperrider, 2013). However, it is
interesting to consider what may be happening in the present experiment, where one's body is, by virtue of the experimental design, forced into the same sagittal axis as the rest of the events in the sequences. One potential outcome as a result of this design is that participants simply map the types of responses (earlier, later) onto the spatial locations (back, front) in a manner consistent with deictic time, which is associated with a body-centered sagittal axis. However, the present data, as well as the results of previous work by Walker et al. (2013) do not support such an interpretation. Rather, it appears that the body may be acting as an anchor for the first event in the sequence, leading participants to map earlier or later events on to the inherent "frontness" and "backness" of their bodies, with earlier events lying ahead of their body and later events lying behind, consistent with the "earlier events lie ahead of later events" structure found in deictically neutral sequential language. This finding is consistent with findings by Núñez, Motz, and Teuscher (2006), who demonstrated that participants appear to interpret sequential relationships in time by using the frontback relationship that is intrinsic to the spatial organization of whatever is anchoring the sequential construal, which, in the case of the present experiment, is the body. However, as revealed in the present study, this pattern of mappings can be flexible.
While we predicted a three-way interaction between pronoun, temporal reference, and response location, we did not observe the exact interaction pattern we expected. Though participants recruited an "earlier-in-front, later-inback" mapping for the pronoun "her", we did not see \(a\) reversal of this mapping when the stimuli were preceded with "your". What might explain the lack of an interaction between response location and temporal reference for the "your" stimuli? One possibility may be due to the fact that the pronoun "you" in English can be interpreted in two ways: either as the second person "you", referring to the interlocutor, or as the indefinite pronoun "you", which refers to a generic person (or people), as in "exercise is good for you". Thus, while some participants may be interpreting the sequence "your high school graduation, your college graduation" relative to their own lives, others may interpret it from a third person perspective, similar to "her high school graduation, her college graduation". Any effects for the pronoun "your" would then be masked by averaging and thus no interaction would emerge.
One potential factor that could have pushed participants to adopt either a personal or an indefinite interpretation of "your" could have been the order in which they completed the blocks in the experiment. Participants who started the experiment by making judgments to events that used the pronoun "her" might have been primed by that experience to subsequently interpret the sequences using "your" as not pertaining to themselves, but rather to be indefinite. By contrast, participants who started by making judgments to "your" events might have been more likely to adopt a personal second-person interpretation.

When the present data were divided by which pronoun participants received first, as described above, this very pattern of results emerges. Participants who received "her" first demonstrated an earlier-in-front/later-in-back mapping for events containing both "her" and "your". On the other hand, no consistent space-time mapping was observed for "your" events by participants who received "your" first while the earlier-in-front/later-in-back pattern was again demonstrated for the "her" events. Though these analyses are exploratory and must be interpreted with caution, they provide preliminary evidence that the pronoun that was presented first influences the pattern of space-time mappings for each of the pronouns in a manner consistent with the explanation offered above. Future investigations may want to examine whether a between-subjects design elicits a clearer difference in space-time mappings for each of the pronouns.
One question that remains from this pattern of results is why, even when "your" is presented first, the pronoun "your" does not reveal space-time mappings consistent with an ego-perspective. If "your" can be interpreted from these two different perspectives and can be primed by the pronoun "her", as the data above suggests, then it is plausible that no clear effect emerged because participants are interpreting the "your" in different manners from the beginning. Thus, in order to better understand the nature of these mappings, future work must examine what factors are responsible for this lack of effect. For example, teasing apart whether "your" is interpreted from second person as opposed to the indefinite may resolve some of the ambiguities expressed here.
In conclusion, the present study demonstrates that participants are sensitive to the perspective from which temporal sequences are framed. While the pronoun "her" encourages a strong pattern of space-time mappings for sequential time, consistent with a field-based perspective (Moore, 2011), the pronoun "your" does not. This observed difference in how participants map sequences of time onto the sagittal axis reveals that while time often recruits space in systematic and regular patterns in language, these mappings are flexible and interact with the spatial perspective from which one thinks about time.

\begin{abstract}
Extensive research effort has been invested in building neurocomputational models for face and object recognition. However, the relationship between the recognition model and the development of the visual system is rarely considered. Research on the development of contrast sensitivity shows that human infants can only perceive low spatial frequency information from visual stimuli, but their acuity improves gradually with age. Also, the right hemisphere (RH) develops earlier than the left hemisphere (LH), and is dominant in infants. Here we show that these constraints, coupled with a desire on the part of the infant to individuate its caretakers and family, leads naturally to the right hemisphere bias for face processing. We propose a developmental model for face and object recognition using a modular neural network based on Dailey and Cottrell (1999). This neural network represents the two hemispheres using two modules, with a competitive relationship between them mediated by a gating mechanism. The strong RH and low spatial frequency bias for face recognition emerges naturally in the model from the interaction of the slow development of acuity and the early dominance of the right hemisphere. Remarkably, this strong asymmetry does not appear to hold for the other object categories that we tried.
\end{abstract}

Keywords: face recognition; developmental model; contrast sensitivity; modular neural network.

\section*{Introduction}

Computational models have been used extensively to instantiate hypotheses regarding face and object perception from a neurocomputational perspective (Dailey \& Cottrell, 1999; O'Reilly \& Munakata, 2000; Riesenhuber \& Poggio, 1999). Due to their social importance and frequency, faces as a stimulus class have been studied most extensively. fMRI studies have shown that the fusiform face area (FFA) is activated in response to faces more than other stimuli, and this activation is found to be stronger in the right hemisphere (Kanwisher, McDermott, \& Chun, 1997). This right hemisphere lateralization is supported by electrophysiological studies, which show a stronger face-specific wave 170 ms after the stimulus onset over the right hemisphere (Bentin, Allison, Puce, Perez, \& McCarthy, 1996). In addition, according to neuropsychological data, the lesioning of the right FFA will result in prosopagnosia, a deficit in face recognition (Bouvier \& Engel, 2006). To account for such hemispheric asymmetry, Ivry and Robertson (1998) proposed the Double Filtering by Frequency (DFF) model which postulates differential frequency filtering on task-relevant frequency bands in each hemisphere, with a bias for low spatial frequency in the RH.

Hsiao, Shieh, and Cottrell (2008) implemented this DFF theory using a computational hemispheric model, and showed that the model could account for the left-side bias in face recognition.

All neurocomputational models so far investigate the effects of structural constraints, such as the visual field split, the interaction between the two hemispheres, and the localized nature of the FFA. Temporal constraints, such as the development of the brain through childhood, are rarely considered in these models. By including consideration of the developmental changes, we may generate new hypotheses concerning the lateralization of face processing.

We consider two main constraints. First, studies in human infants have shown that the right hemisphere develops its function earlier than the left hemisphere (Chiron et al., 1997). By measuring the regional cerebral blood flow (rCBF) changes at rest using single photon emission computed tomography (SPECT), Chiron et al. observed a right hemisphere predominance of the blood flow between 1 and 3 years of age, with the asymmetry shifting to the left hemisphere after 3 years.

The second constraint has to do with the development of visual acuity. Studies have shown that the contrast sensitivity function (CSF), a measure of the ability to distinguish between different levels of luminance in static images, changes radically over time. The CSF of a 3-month-old infant is over \(1.0 \log\) units lower than the adult (Peterzell, Werner, \& Kaplan, 1995). By age 4, children's contrast sensitivity is still reduced by about \(0.5 \log\) units when compared to that of adults (Atkinson, Braddick, \& Moar, 1995; Gwiazda, Bauer, Thorn, \& Held, 1997). The studies regarding the time of contrast sensitivity maturity have obtained somewhat disparate results. They range from claims of maturity between 6 to 10 years of age (Bradley \& Freeman, 1982; Mayer, 1977), to evidence of immaturity in 8-15 year old children (Arundale, 1978). More recent studies suggest that contrast sensitivity attains adult levels in all frequencies by age 7 (Ellemberg, Lewis, Liu, \& Maurer, 1999), or 8 (Leat, Yadav, \& Irving, 2009).

Combining these two constraints, we propose a neurocomputational developmental model for object and face recognition. The model is based on a previous study of the development of hemispheric asymmetry by Dailey and Cottrell
(1999). Dailey \& Cottrell used a mixture of experts architecture (Jacobs, Jordan, \& Barto, 1991), a neural network with two modules to represent the two hemispheres. The output of the modules is gated based on their contribution to the overall performance. Dailey \& Cottrell also suggested that low acuity, and the need to individuate faces, would lead to right hemisphere dominance. However, in their model, they assumed the right hemisphere would receive low spatial frequencies, and the left hemisphere high spatial frequencies, which is an unrealistic assumption. Furthermore, their model did not change its visual acuity over time. Here, we model the changes in children's contrast sensitivity by low-pass filtering the data set, and gradually improving the fidelity of inputs over training iterations (i.e., as the model "ages"). To model the asymmetric developmental pattern of the brain, we give the two modules different learning rates over time. A detailed description of this methodology will be given in next section. In the result section, we will discuss the network's general performance on different objects, and the strong right hemisphere bias for face processing which emerges naturally from the interaction of the developmental trends.

\section*{Methods}

We will first describe the structure of the modular neural network, and then discuss the modifications to create the development model.

\section*{The Model}

Each input image goes through a two-step preprocessing stage: Gabor filtering and Principal Component Analysis (PCA). The biologically motivated 2-D Gabor filter (Daugman, 1985) is constructed by using a two-dimensional sinusoid localized by a Gaussian envelope. By tuning to particular spatial frequency and orientations, the Gabor filter magnitudes can be used to simulate the responses of complex cells in primary visual cortex (V1). Following Gabor filtering, PCA reduces the dimensionality of the information by simulating the information extraction mechanism beyond V1, up to the lateral occipital regions level. After these preprocessing steps, each image is represented by a vector of relatively low dimension to be fed into the modular neural network.

The mixture of experts architecture has been in development since 1990 (Dailey \& Cottrell, 1999; Jacobs, Jordan, \& Barto, 1991; Jacobs, Jordan, Nowlan, \& Hinton, 1991). Our particular variant of the model is presented in Figure 1. The modular neural network has three components: two side-by-side hidden layers (the "modules"), an output layer and a gating layer. The hidden layers are used to learn features for a given task adaptively, and develop more sophisticated representations for the input stimuli; if the task is face recognition, we can consider the hidden layer as corresponding to FFA. There is one hidden layer for each of the hemispheres. There are sufficient hidden units in each network to perform the tasks. The output layer provides us with the labels of the input stimulus to perform the final object recognition task.

Figure 1: Architecture of Dailey and Cottrell's (1999) modular neural network model.

Because the labels to be discriminated have a strong influence on the hidden layer representation through the learning process, the discrimination level of the output layer will drive the representation developed by the hidden layer through error feedback. The gating layer has two nodes whose activity modulates the output of the hidden layers by multiplying the connection weights from the hidden layer to the output layer. We use a softmax function at the output of the gating network to ensure that the gating weights always sum to one. The network is trained using online backpropagation. During learning, the gating nodes act like a competitive selection mechanism and direct more information (error feedback) to the module that has more contribution to performance and better ability to process a given pattern. For example, if the task is better performed by module 1 , the gating network will learn to weight the module 1 outputs more highly, and the hidden units of module 1 will also receive more training as a result. Thus there is a "rich get richer" effect.

Dailey and Cottrell (1999) trained this modular neural network to account for the development of the FFA. Based on the evidence that the right hemisphere has a relatively low spatial frequency preference and the left hemisphere has a relatively high spatial frequency bias (Sergent, 1982), they gave different spatial frequency information from each stimulus to each module by weighting the frequency component differently in the PCA step. When the model's goal was to individuate different faces while categorizing the other classes of stimuli, they observed a strong specialization of the low spatial frequency module to processing faces; no other tasks showed a similar specialization. Hence, they took these results as support for the hypothesis that the FFA developed as a natural consequence of the infant's low visual acuity, and the need to individuate faces.

\section*{Modeling Infant's Developmental Patterns}

Although Dailey and Cottrell (1999) successfully modeled the right hemisphere lateralization of FFA for face recognition, their consideration of the developmental facts is inade-
quate. First, although the right hemisphere (RH) has a low spatial frequency (LSF) bias, both the left and right hemispheres should receive the same frequency information from the input stimuli, as psychophysical results show equal CSF's in the two visual fields. We hypothesize that the selectivity arises as a consequence of competition during the developmental period, rather than assuming it is already in force during development. Hence, instead of manually weighting the information provided by each spatial frequency differently in each module, in this work we give both modules the same images over time. Instead of manipulating the spatial frequencies so that they are different, we give the modules different learning rates, in accord with the data that the right hemisphere is dominant during the first three years (Chiron et al., 1997). We model this as a wave of plasticity in each hemisphere that is slightly out of phase, as in Figure 2. The right hemisphere will thus do more learning earlier than the left. This will drive the right hemisphere network to reach convergence more quickly, which in turn will make it win the competition and obtain a higher gating node value in the gating network. We used two Gaussians with different mean values and the same variance followed by a straight line to represent the evolution of the learning rate. At earlier epochs, module 1 has a higher learning rate than module 2. After a certain number of iterations, the learning rate of module 2 starts to increase and prevails over module 1. Finally, both learning rates drop to a small constant value until the end of training. This represents the maturity of both hemispheres, but they continue to learn into "adulthood."

Figure 2: Learning rate example. Module 1 (dashed line) learns earlier than module 2 (solid line) and they converge to same value after 30 iterations.

Since the contrast sensitivity of infants is relatively low (Atkinson et al., 1995; Gwiazda et al., 1997; Peterzell et al., 1995), they can only obtain the low spatial frequency information of a given visual stimuli instead of receiving the full frequency details. As they grow older, their contrast sensitivity will reach adult levels, and then they will receive the full spatial frequency information from the input. To model
this change of children's contrast sensitivity over time, we low-pass filtered the dataset before sending them to the Gabor filter in the modular neural network model. We gradually improved the fidelity of the input as the training iteration increases. To be more specific, we used a 2-D circular averaging filter with decreasing radius \(r\) to filter the dataset. We set the largest radius be 6 pixels, and gradually decreased the radius by a same interval till it reached zero (unfiltered). Figure 3 shows the result of a image filtered by a disk filter with high to low radius.

Figure 3: Result of a sample image filtered by disk filter with radius decrease from 6 (leftmost) to 0 (rightmost).

\section*{Experiments and Results}

\section*{Face/Object Stimuli and Preprocessing}

Our studies used four category of objects: faces, books, cups, and handwritten digits. For the faces, books and cups, we collected the images from 12 different individuals for each category from the Cottrell and Metcalfe (1991) database. For digits \(0-9\), we utilized the MNIST handwritten database (LeCun, Bottou, Bengio, \& Haffner, 1998) and sampled 20 images for each digit. Each image was transformed to grayscale and cropped to size of \(64 \times 64\). In the Gabor filtering step, we adopted the classical Gabor filter bank (Lades et al., 1993) with 5 different scales and 8 orientations ranging from 0 to \(7 \pi / 8\). This step resulted in a 40 -dimensional vector at each point in the image. After normalizing the response values across orientations and subsampling these vectors in a \(8 \times 8\) grid, we computed the magnitude of the complex numbers and got a 2560 -dimensional vector to represent the image. To extract a smaller number of features and maintain a segregation of responses from each scale of Gabor filter, we performed PCA separately on each spatial frequency component of the pattern vectors. Since we had 5 different scales, we extracted the subvectors corresponding to each scale from every pattern in the training set, computed the eigenvectors of the covariance matrix, and projected these subvectors onto these basis vectors. Here we used the Turk and Pentland trick (Turk \& Pentland, 1991) to reduce the computational cost. We retained the eight most significant coefficients of each scale according to the eigenvalue, reassembled the pattern and finally obtained a 40-dimensional vector for each input image.

\section*{Network Training}

Based on the task manipulations performed by Dailey \& Cottrell, we trained the modular neural network to perform three tasks:
1. 4-Class basic-level classification on faces, books, cups and digits: 4 outputs in total.
2. Face expert: subordinate classification on 10 different faces, together with basic-level classification on books, cups and digits: 13 outputs in total.
3. Non-face expert: subordinate classification on 10 different digits (0-9), cups or books, together with basic-level classification on other 3 categories: 13 outputs in total.

For each task, we performed two experiments. As a control condition, we used the same learning rate \(\lambda\) for both modules. In the experimental condition, we assigned different learning rate over time to each module to model the asymmetric development pattern over 30 iterations, as in Figure 2:
\[
\begin{aligned}
& \lambda_{\text {module } 1}=0.015 \times \mathcal{G}(\text { iteration }, 10,5) \\
& \lambda_{\text {module } 2}=0.015 \times \mathcal{G}(\text { iteration }, 20,5)
\end{aligned}
\]
where \(\mathcal{G}\) (iteration, 10,5 ) means a Gaussian distribution with mean 10 and variance 5 evaluated at iteration. After 30 iterations, we set the constant learning rate \(\lambda=1.5 \times 10^{-4}\) for both modules. In all experiments, we considered module 1 to be the right hemisphere, which learns earlier, and module 2 to be the left hemisphere. To model the development of contrast sensitivity, we utilized 9 different filtered datasets from low to full spatial frequency (see Figure 3), changing the dataset every three epochs. While the mapping is arbitrary, we assume for now that three epochs correspond to a year, so that the contrast sensitivity matures around the "age" of 9 , or 27 epochs. At that point, the dataset with full spatial frequency is used to train the model to convergence.

We used stochastic gradient descent (online learning) to train the neural network. We used a small momentum term, set to 0.01 in all experiments. The number of output nodes equals the number of categories to be classified. We performed a 10 -fold cross validation on the training set to find the optimal settings for the number of nodes in hidden units and the stopping criteria based on the model's performance on the hold-out set. In the 4 -way classification task, we used 48 images from each class to form the training set, and 12 im ages to form the test set. We determined that a mean squared error (MSE) of 0.001 was an adequate threshold to stop training: the value of the gating nodes was stable and the network reached good performance on the test set. For the face expert and non-face expert experiments, due to limitations on how many images we had of individual faces, we reduced each class to have 20 training images and 4 testing images, and the MSE threshold was set to 0.02 to avoid overtraining. Both hidden layers are determined to have 15 nodes as the model's performance is good and stable when we set it between 10 and 20 . The connection weights between input layer, hidden layer and output layer were set randomly, while the weights between input to gating layer were all set to have the same value to give the softmax layer of the two gating nodes the same initial value of 0.5 .

For each of the \(3 \times 2\) experimental conditions, we ran the experiment 12 times and recorded the softmax output of the gating layer for each class after convergence. This indicated

(a) 4-way classification (control)

(c) Face expert (control)

(e) Number expert (control)

(g) Cup expert (control)

(b) 4-way classification (split learning rate)

(d) Face expert (split learning rate)

(f) Number expert (split learning rate)

(h) Cup expert (split learning rate)

Figure 4: Average weights assigned to each module for each stimulus class. In control condition (left column), each module receives the same learning rate. We can see the average weights are almost symmetric in all tasks. In the experimental condition(right column), each module receives different learning rate. We can see a strong RH bias for face expert task, but no such bias exists in number and cup expert task. The error bar denotes the standard deviation.
the lateralization of each module for different classes of objects. Figure 4 displays the result for three of the tasks.

In the control condition, both modules receive the same learning rate, so it is expected that there is no preference for either module over any class of stimuli. Even if at certain
time one module wins for a given category, the average gating value for each module will be equal when averaged over many runs. As a result, no matter what the task is, no bias exists in the control task, so the average weights should be symmetric, as can be seen in the left column of Figure 4.

When we assigned different learning rate for each module, the task of recognizing different faces (face expert) shows a consistently strong bias for module 1 (right hemisphere). From Figure 4 (d), the average weight of RH reaches 0.96, 24 times higher than the LH weight value. However, this strong hemisphere lateralization does not occur on the task of differentiating the non-face objects, where the average weights for both hemispheres are close. We have also performed the equivalent experiment with a book expert, and this experiment only shows the weak right hemisphere bias (See Figure 5). Additionally, we have also performed the experiment using different learning rates and training epochs per dataset, and this RH lateralization for face recognition appeared very robust.

\section*{Brain Development, Contrast Sensitivity and RH Bias for Faces}

The finding of a strong RH bias for face recognition directly raises two questions: at which point during the learning process (brain development) did the bias appear? What is the difference between face recognition and object recognition? To investigate the relationship between brain development and RH bias, we ran another face expert experiment, and kept track of the softmax value of the gating nodes for each class separately until they are stable. The result of gating node value vs. time is shown in Figure 5.

We observed some interesting phenomena. First, for all non-face objects, the value of the gating node for the RH increases rapidly before the 10th epoch. This is consistent with the fact that the learning rate for the RH is much higher than the LH (see Figure 2). In addition, a significant drop for RH value and an increase for LH value appear between 10-20th iteration for these same objects, when the learning rate switches to the LH. Thus these objects track the learning rate closely. However, the impact of the increased learning rate for the left hemisphere does not affect the allocation of face processing to the RH , as the gating node value for RH remains high and stable. Considering the hidden layer of the RH network to be analogous to the FFA, these findings are also consistent with the fact that the FFA is RH lateralized (Kanwisher et al., 1997). Combined with the fact that we mainly utilized the low spatial frequency (LSF) information to train the RH network before 10th iteration, and full spatial frequency thereafter, we've shown that in our model, face recognition has a strong LSF preference. The hypothesis then is that this strong LSF and RH lateralization of face recognition is a natural result of the interaction between children's brain development and contrast sensitivity maturity.

Finally, we investigated the relationship between the rate of contrast sensitivity development and RH bias for faces. By varying the step size of our circular filter to make smaller

Figure 5: Gating node value vs. time for all objects in the experiments. We took the average value across all individuals in the same category to get the result for the corresponding expert tasks. The solid line represents the node value of RH and the dashed line represents the node value of LH. The dotted line set a middle threshold of 0.5 . We set the maximum value at horizontal axis as 100 because the node value is stable afterwards.
or greater increments, we varied the rate of development. We built different numbers of filtered datasets ranges from 6 to 14 to test the effect on the degree of bias. All filtered datasets have the same range of filtering coefficients, and a larger number of dataset means a smaller interval step. We ran the training 12 times on each group of filtered datasets and recorded the value of RH and LH nodes when the network converges. We computed the mean value and standard deviation of both hemispheres. The results are shown in Table 1 .

Table 1: Relationship between age of contrast sensitivity matures and the RH bias for face recognition
\begin{tabular}{|c||c|c||c|c|}
\hline "Age" & RH Value & std(RH) & LH Value & std(LH) \\
\hline 6 & 0.7908 & 0.0908 & 0.2654 & 0.0968 \\
8 & 0.8088 & 0.0269 & 0.1912 & 0.0269 \\
10 & 0.8989 & 0.0241 & 0.1011 & 0.0333 \\
12 & 0.8467 & 0.1042 & 0.1533 & 0.0709 \\
14 & 0.8352 & 0.0533 & 0.1648 & 0.0525 \\
\hline
\end{tabular}

The result shows the RH bias for face recognition is obvious regardless of rate of contrast sensitivity changes. However, we can observe a peak in the lateralization at 10 "years." This suggests that there could be an "optimal" age of CSF maturity with respect to lateralization.

\section*{Conclusion}

In summary, we built a face and object recognition model, using a developmentally-inspired implementation. Our model suggests that the strong right hemisphere lateralization for face processing can arise from the interaction of two developmental facts: That the right hemisphere matures earlier than the left, and that visual acuity increases gradually over development. We should also note that, as in Dailey \& Cottrell's 1999 model, there is a strong effect of task as well. Simply categorizing faces as faces does not lead to right hemisphere specialization. Hence the drive by the infant to individuate its parents, other caretakers, family and friends, leads to the right hemisphere specialization. In addition, as we observe a mild right hemisphere lateralization more or less for all expert experiments, we predict that both the task and the low spatial frequency nature of certain objects should contribute to the RH bias. Future work includes doing more analysis of the model to discover why the strong RH bias happens for faces, investigating the relationship between CS development and RH bias in more detail, and extending the model to other important classes of stimuli, such as word recognition, which shows a left hemisphere bias.

\begin{abstract}
Manipulation of environmental constraints has been shown to influence the relative amounts of voluntary and involuntary control employed by a person to complete a task, as well as the resulting structure of performance variability. Generally, the voluntary control required when no constraints are present leads to self-similar changes in performance, some constraint provides involuntary control that leads to random fluctuations in performance, and constraint which provides feedback about performance accuracy can result in anti-persistent variability. The current study investigated whether providing two groups of individuals with different intentions for the same task would produce changes in voluntary and involuntary control similar to that observed following the manipulation of task constraints. Results indicated that a difference in intention does result in divergent uses of voluntary and involuntary control and distinctly different structures in performance variability.
\end{abstract}

Key words: intention; fractal structure; voluntary and involuntary control; motor control

Over the past decade, a substantial amount of research has focused on determining what information can be gained about human cognitive and motor processes by assuming that they are inextricably linked through what is often referred to as the 'interaction-dominant dynamics' of human behavior (Holden, Van Orden, \& Turvey, 2009; Ingber, 2003; Turvey, \& Moreno, 2006; Van Orden, \& Holden, 2002; Van Orden, Holden, \& Turvey, 2003; Van Orden, Holden, \& Turvey, 2005). As noted by Van Orden (2010), absolute independence of these processes would allow for random variability in performance within each process, while dominance by one process over all others would cause highly regular fluctuations across processes. Standard, linear statistical methods for assessing performance are based on an assumption of random variability, or noise, in performance and, necessarily, the belief that whatever process is being evaluated can be thought of as independent from all other contemporaneous processes. However, methods for assessing potential structure within variability over time reveal that while fluctuation in performance is
sometimes strictly random, more often variability is characterized by patterns occurring at a variety of different timescales (Ferrer-i-Cancho \& Elvevag, 2010; Kiefer, Riley, Shockley, Villard, \& Van Orden, 2009; Eke, Herman, Kocsis, \& Kozak, 2002; Eke, Herman, Bassingthwaighte, Raymond, Percival, Cannon, Balla, Ikrenyi, 2000; Gilden, 2001; Holden et al., 2009; Kuznetsov \& Wallot, 2011; Phillipe, 2000; Rhodes \& Turvey, 2007; Wallot \& Van Orden, 2011a, b; Warren, Carciun, \& Anderson--Butcher, 2005). This type of variability is neither strictly random, nor strictly regular, but is rather somewhere in between the two, and therefore suggestive of both competitive and cooperative interactions between the different cognitive and motor aspects of the behavior under observation (Van Orden, 2010).

The patterned variability in performance described above is defined by a fractal structure, in that self-similarity in fluctuations is apparent at multiple timescales (Mandelbrot, 1982; Brown \& Liebovitch, 2010; West \& Deering, 1995). This type of variability is typically referred to as 'pink' noise, in contrast to the 'white' noise of random fluctuation (Van Orden, 2010). In order to determine what kind of variability is occurring for a given task, it is important to repeatedly measure some aspect of that task as performance unfolds over time. The resulting series can then be broken down into several composite, sinusoidal series each with a different amplitude and frequency. A Power-Spectral Density (PSD) analysis can then be used to give an assessment of variability (Delignieres, Ramdani, Lemoine, Torre, Fortes, \& Ninot, 2006; Holden, 2005; Marmelat \& Delignieres, 2011). The slope of a regression line fit to a plot of the logarithm of the power (amplitude squared) of changes with the logarithm of their corresponding frequencies provides a unique scaling relation between the size and frequency of changes in the performance time series. This scaling relation ( S ) is related to a characteristic scaling exponent ( \(\alpha\) ), where \(\alpha=-S\) (Holden, 2005). It is this scaling exponent which is used to give a qualitative assessment of the type of variability being observed. Since there will be no systematic relationship between the size and
frequency of change with random variability, or 'white noise', \(\alpha \approx 0\). In contrast, the scaling relation for pink noise reflects an inversely proportional relationship between the power and frequency of variation such that the scaling exponent associated with fractal variability is \(\alpha \approx 1\). It is also possible to obtain negative values for the scaling exponent. This indicates a directly proportional relationship between the size and frequency of changes in performance, and occurs as a result of anti-persistent variation (Delignieres \& Torre, 2009; Hausdorff, Peng, Ladin, Wei, \& Goldberger, 1995; Schmidt, Beek, Treffner, \& Turvey, 1991).

Strong support for interaction-dominant dynamics is provided by the fact that the kind of variability observed in a given task appears to be sensitive to a variety of task characteristics (Chen, Ding, \& Kelso, 2001; Delignières, Torre, \& Lemoine, 2009; Hausdorff, Purdon, Peng, Ladin, Wei, \& Goldberger, 1996; Holden, Choi, Amazeen, \& Van Orden, 2011; Jordan, Challis, \& Newell, 2007a; Jordan, Challis, \& Newell, 2007b). Specifically, the level of task constraint imposed by an experimental setup appears to be directly predictive of variability structure, with greater constraint resulting in white noise ( \(\alpha \approx 0\) ), and less constraint leading to pink noise ( \(\alpha \approx 1\) ) (Chen et al., 2001; Delignières et al., 2009; Hausdorff et al., 1996). This phenomenon has led to the suggestion that environmental constraint in the context of a specific task demand provides some external control, while the absence of constraint given the same task requires additional voluntary control on the part of the actor (Van Orden, 2010).

One way to summarize the effects of voluntary and involuntary control on variability is to examine different conditions within rhythmic motor tasks. Previous studies have demonstrated that by providing some sort of rhythmic stimulus (e.g. metronome) while participants are required to maintain a consistent movement pattern, spontaneous entrainment between participant and stimulus will constrain behavior and thus reduce the need for voluntary control of movements, ultimately resulting in the random variations in performance characterized by white noise ( \(\alpha \approx 0\) ) (Chen et al., 2001). However, it appears that when participants are explicitly instructed to coordinate with a rhythmic stimulus, an altogether different pattern of variability emerges (Delignières et al., 2009; Hausdorff et al., 1996). One might imagine that the requirement to synchronize would introduce the need for additional voluntary control but, more importantly, it also appears to provide the participant with feedback about the accuracy of their movements with respect to the goal of the task (Van Orden, 2010). Accuracy feedback has been considered a unique form of involuntary control, and the constraint emerging from corrective processes results in performance characterized by antipersistent, dependent fluctuations ( \(\alpha \approx-1\) ) (Delignieres \& Torre, 2009). An equivalent task to the two previous, but requiring voluntary control, can be constructed through the use of a continuation paradigm. Here the participant has the
opportunity to match their movement to an experimental stimulus for several seconds at the beginning of a trial, and then must maintain that movement pattern for the duration of the trial without any involuntary control provided gained through task constraint. Several studies have demonstrated that the use of a continuation paradigm in this manner leads to the self-similar variability of pink noise ( \(\alpha \approx 1\) ) (Chen et al., 2001; Gilden, Thornton, \& Mallon, 1995; Lemoine, Torre, \& Delignieres, 2006; Torre, \& Delignières, 2008).

While previous findings have demonstrated an association between voluntary or involuntary control and performance variability, the potential influence of intending to control a specific task dimension has yet to be examined. The current study was designed to determine the effect of being asked to control one of two task dimensions on performance variability. In order to achieve this, a simple arm-swinging task was employed during which participants were instructed to control either the frequency or amplitude of their movements, while being provided with flashing dots to help control their performance. This ultimately created the single underlying task of maintaining a comfortable, consistent movement, allowing for an isolated evaluation of the effects of intention on constraint and performance.

\section*{Method}

\section*{Participants}

Seventeen University of Cincinnati undergraduate students participated in this experiment, eight in the amplitude intention condition and nine in the frequency intention condition. Participants ranged in age from 18 to 28 years.

\section*{Procedure and Design}

At the beginning of the experiment, participants were instructed to stand at a distance 3.5 feet in front of a flat screen television, facing toward the screen. The experimental task consisted of holding one's upper right arm flush with the side of the body and swinging the forearm in an arc about the elbow, while keeping the forearm parallel to the floor. The right hand was to be held in a fist with the first two fingers extended to point toward the screen and with the knuckles facing toward the right, away from the participant's body. Initially, two red dots (5.5 cm in diameter) appeared on the screen, centered vertically and separated by a distance of 57 cm (see Varlet, Coey, Schmidt, \& Richardson, 2011 for information on determining the ideal stimulus amplitude for visuomotor entrainment).

Eight participants were asked to control the amplitude of their movements by traveling the same distance with every arm swing. The other nine participants were asked to control the frequency of their movements by maintaining a constant speed while swinging. All participants participated in two trials, each six minutes in length. The first trial involved a continuation paradigm, with the red dots appearing for the first \(10-12\) seconds (timed manually), followed by a blank
screen for the duration. This trial was collected as a baseline. The red dots were set to flash in an alternating pattern at a frequency of 1 Hz , (with a dot appearing on one or the other side of the screen every 500 ms ) throughout the time they were visible. Participants were instructed to use the dots to help control their designated task dimension, and to do their best to maintain the same movement for the duration of the trial once the dots had disappeared. In the second trial, the flashing dots were displayed for the full six minutes and participants were instructed to use them over the entire trial to help achieve consistency in their designated task dimension. This was the test trial.

By using a comfortable movement frequency for the flashing dots, we expected participants in the frequency intention condition to use the dots to gain feedback about the consistency of their speed in order to engage in corrective processes. For those participants in the amplitude intention condition we expected the stimulus to provide the opportunity for spontaneous entrainment, but not enough feedback about the size of their movements to allow for corrective processes.

The display was generated by an application written using C/C++ and displayed using OpenGL. Data was collected using a magnetic tracking system (Polhemus Fastrak, Polhemus Corporation, Colchester, VT), with the sensor attached to the outside of the extended first two fingers of the right hand. The OpenGL program was also used to record the movement data collected by the tracking system, with a sampling rate of 60 Hz .

\section*{Data Analysis}

All participant movement time-series were low-pass filtered using a 10 Hz Butterworth filter and the first and last 5 s of each trial were discarded to remove transients.

For the PSD analysis, the peak to valley intervals and valley to peak intervals were extracted from the movement time-series for each trial. The PSD analysis was then used to assess fractal characteristics of the resultant interval timeseries. As the preliminary step to this process each timeseries was submitted to a Fourier transform, during which it was broken down into several composite sinusoidal series with varying amplitudes and frequencies. The slope of a regression line fitted to the spectral plot of the logarithm of the power vs. the logarithm of the frequency for each sinusoidal series yielded a unique value \(S\), for which the characteristic scaling exponent of the series, \(\alpha\), is equal to \(-S\) (Holden, 2005).

In order to assess possible entrainment of participants' movement to the frequency of the flashing stimulus we found, for each trial, the distribution of relative phase angles occurring between the participant and stimulus time-series. This distribution was based on the proportion of discrete relative phase (DRP) angles between the two time-series which fell into each of nine bins \(\left(0^{\circ}-20^{\circ}, 20^{\circ}-40^{\circ}, 40^{\circ}-60^{\circ}\right.\), \(60^{\circ}-80^{\circ}, 80^{\circ}-100^{\circ}, 100^{\circ}-120^{\circ}, 120^{\circ}-140^{\circ}, 140^{\circ}-160^{\circ}\), and \(\left.160^{\circ}-180^{\circ}\right)\). DRP values were calculated at each oscillatory
peak of the movement time-series. Perfect, inphase coordination between participant and stimulus would result in a relative phase of \(0^{\circ}\), while antiphase coordination, in which participants exactly matching the frequency of stimulus movement but pointed at the side of the screen opposite the dot each time, would lead to a relative phase of \(180^{\circ}\).

The stability of any unintentional coordination was established by calculating the circular variance of the relative phase angles found between the participant and stimulus time-series for each trial. This measure provides an index of synchronization on a scale from 0 to 1 , with 0 reflecting a situation in which there is no coordination between participant and stimulus movements, and 1 indicating absolute synchronization between the two (Batschelet, 1981; Oullier, de Guzman, Jantzen, Lagarde, \& Kelso, 2008).

\section*{Results}

A 2 (intention) x 2 (trial) mixed model ANOVA on circular variance values revealed a significant main effect for trial, \(F\) \((1,15)=39.93, p=.001, \eta_{\mathrm{p}}^{2}=.73\), and a significant interaction between intention and trial, \(F(1,15)=6.21, p=\) \(.03, \eta_{\mathrm{p}}^{2}=.29\). This interaction appears to be driven by the fact that the effects of intention are different for the baseline and test conditions (see Figure 1). While there did not appear to be a significant change in coordination stability for those with the intention to contol amplitude, the difference for those in the frequency intention condition between baseline and test was significant, \(t(8)=-10.13, p\) \(=.001\).

A 2 (intention) x 2 (trial) x 9 (relative phase bin) mixed model ANOVA on the DRP between participant and stimulus movements revealed a main effect for relative phase bin, \(F(8,15)=81.86, p=.001, \eta_{\mathrm{p}}^{2}=.85\), significant two-way interactions between intention and relative phase bin, \(F(8,15)=4.62, p=.001, \eta_{\mathrm{p}}^{2}=.24\), and trial and relative phase bin, \(F(8,15)=105.76, p=.001, \eta_{\mathrm{p}}{ }^{2}=.88\), and a significant three-way interaction between intention, trial and relative phase bin, \(F(8,15)=2.06, p=.045, \eta_{\mathrm{p}}{ }^{2}=\) .12. Follow-up analyses revealed a significant interaction between intention and relative phase bin for the test trials, \(F\) \((8,120)=4.64, p=.001, \eta_{\mathrm{p}}^{2}=.24\), but not for the baseline trials (see Figure 2). A comparison of the proportion of time spent in the DRP bin associated with inphase coordination ( \(0^{\circ}-20^{\circ}\) ) during the test trial between the two intention conditions revealed that significantly more in-phase entrainment occurred for those participants instructed to control movement frequency, \(F(1,15)=6.96, p=.02, \eta_{\mathrm{p}}{ }^{2}=\) 32. There was no significant difference in the proportion of time spent in the DRP bin associated with antiphase coordination \(\left(160^{\circ}-180^{\circ}\right)\) between the two intention conditions.

The results of a 2 (intention) x 2 (trial) mixed model ANOVA on scaling relations (S) from the PSD analysis were similar to those of the ANOVA on circular variance.

There was a significant main effect for trial, \(F(1,15)=\) 46.83, \(p=.001, \eta_{\mathrm{p}}^{2}=.76\), and a significant interaction between intention and trial, \(F(1,15)=5.12, p=.04, \eta_{\mathrm{p}}^{2}=\) .25. As seen in Figure 3, this interaction appears to be driven by the difference in the effects of intention between the baseline and test conditions, with a much larger increase in \(\alpha\) occurring in the frequency intention than the amplitude intention. The \(\alpha\) values for both intention conditions during the baseline trials were closest to the region associated with pink noise ( \(\mathrm{S} \approx-1, \alpha \approx 1\) ). The \(\alpha\) values for those intending to control amplitude during the test condition were characteristic of white noise ( \(\mathrm{S} \approx 0, \alpha \approx 0\) ), while those for participants asked to control movement frequency were closer to the region associated with anti-persistent, dependent behavior ( \(\mathrm{S} \approx 1, \alpha \approx-1\) ).

Given evidence that the effects of intention condition were most apparent during the test trials for both coordination strength and scaling relation, we chose to conduct a regression to determine whether circular variance could account for variation in scaling relation above and beyond that accounted for by intentional condition. A forward regression indicated that intention explained a significant proportion of variation in scaling relation, \(R^{2}=\) \(.42, F(1,15)=10.86, p=.005\), and was significantly predictive of scaling relation, \(b=.65, t(15)=3.30, p=\) .005, for the test trials. However, the predictive contribution of circular variance was not significant, as it only accounted for an additional \(2.8 \%\) of the variance in scaling relation above and beyond that accounted for by intention.

\section*{Discussion}

The task in the current study was constructed to demonstrate the effects of assigning participants different intentions for a simple motor task, as examined in performance variability and the employment of voluntary and involuntary control.

Figure 1. Mean circular variance for each of the intention conditions (Amplitude, Frequency), and under both trial conditions. Error bars show standard error.

Figure 2. a) Mean proportion of trial spent in each DRP bin during baseline trials for each intention condition (Amplitude, Frequency). b) Mean proportion of trial spent in each DRP bin during test trials for each intention condition (Amplitude, Frequency). Note: DRP bins are labeled by the midpoint of the range of relative phase values they contain, except for the \(0^{\circ}-20^{\circ}\) bin and the \(160^{\circ}-180^{\circ}\), which are referred to be the lowest and highest possible DRP values, respectively.

The two different intention conditions introduced are essentially equivalent with respect to a participant's resulting movement; maintaining a consistent speed will result in relatively consistent spacing between movements, and vice versa. As such, one might predict that providing participants with the instruction to control speed versus distance would have no effect on the amount of voluntary or involuntary control required to complete the task, and therefore no effect on the structure of performance variability. This does appear to be the case for the baseline trials. Consistent with previous use of continuation paradigms, measures of performance variability structure for
both intentions during the baseline trials fell within the region associated with self-similar, pink noise thought to indicate the use of voluntary control (Chen et al., 2001;

Figure 3. Mean scaling exponents for movement frequency in each of the intention conditions (Amplitude, Frequency), and under both trial condition, as assessed through PSD analysis. Error bars show standard error.

Gilden et al., 1995; Lemoine et. al, 2006; Torre, \& Delignières, 2008).

The equivalency in performance variability structure between the intention conditions was not, however, maintained during the test trials. In this case, past research universally predicts that the presence of a rhythmic stimulus will provide a source of involuntary control for the movement task (Chen et al., 2001; Delignieres \& Torre, 2009). As previously described, the difference in participant instructions with respect to the use of a rhythmic stimulus can result in two distinct kinds of structure in performance variability. While the mere presence of a rhythmic stimulus results in entrainment and random variability (Chen et al., 2001), the instruction to synchronize with the stimulus and the resulting opportunity to gain accuracy feedback about one's performance leads to anti-persistent changes (Delignieres \& Torre, 2009). In the current study, the instructions about use of the stimulus were the same for all participants; they were simply told to use the stimulus to help control their movement, following an explanation about what their intention for the task should be. The difference in intention alone appears to have affected the influence, and constraint, of the rhythmic stimulus on the structure of performance variability.

For those participants who were asked to control the amplitude of their movements, changes in performance during the test trial were found to be random, corresponding to white noise. This suggests that for someone intending to control the amplitude of their movements, the rhythmic stimulus provided involuntary control, but did not allow for sufficient accuracy feedback for corrective anti-persistent movement modulation. In contrast, for the participants
intending to control the frequency of their movements, measurements of variability structure were in the range associated with anti-persistent behavior. It therefore appears that the stimulus did allow for enough accuracy feedback about the timing of movements to support corrective processes by the participant. It is worth noting that the difference in intention conditions during the test trials was associated with differences in coordination, as well as the structure of performance variability. While there was significantly more inphase coordination between participant and stimulus movements for those intending to control frequency, any variation in performance associated with changes in coordination stability appears to be accounted for by intention.

In conclusion, our study has shown that the manipulation of intention alone appears to affect the use of voluntary and involuntary control for an environmentally constrained motor task, as reflected by differences in performance variability. These results also demonstrate that intending to control one specific task dimension over another can substantially alter the influence of any present environmental constraints. Therefore, in addition to identifying the role of intention in performance variability as an area worth further exploration, this study also sounds a cautionary note for research that aims to better understand the recruitment of voluntary and involuntary control and performance variability.

\begin{abstract}
In inductive learning, the order in which concept instances are presented plays an important role in learning performance. Theories predict that interleaving instances of different concepts is especially beneficial if the concepts are highly similar to each other, whereas blocking instances belonging to the same concept provides an advantage for learning lowsimilarity concept structures. This leaves open the question of the relative influence of similarity on interleaved versus blocked presentation. To answer this question, we pit withinand between-category similarity effects against each other in a rich categorization task called Physical Bongard Problems. We manipulate the similarity of instances shown temporally close to each other with blocked and interleaved presentation. The results indicate a stronger effect of similarity on interleaving than on blocking. They further show a large benefit of comparing similar between-category instances on concept learning tasks where the feature dimensions are not known in advance but have to be constructed.
\end{abstract}

Keywords: category learning; order effects; similarity

\section*{Introduction}

Inductive learning is an essential cognitive ability which, by abstracting from specific examples, allows the transfer of experience to new, similar situations. There is a significant body of evidence from cognitive psychology suggesting that comparison of multiple cases represents a particularly promising avenue for inductively learning difficult, relational concepts (Loewenstein \& Gentner, 2005). Comparison not only takes representations as inputs to establish similarities, but also uses perceived similarities to establish new representations (Hofstadter, 1996; Medin, Goldstone, \& Gentner, 1993; Mitchell, 1993). When we compare entities, our understanding of the entities changes, and this may turn out to be a far more important consequence of comparison than simply deriving an assessment of similarity. In this paper, we are interested in identifying optimal ways of organizing these comparisons, and the kinds of cases that should be optimally compared.

One major line of argument is that comparing instances of a concept with very dissimilar features should lead to the best
induction and generalization for the concept. If comparison serves to highlight commonalities between instances of the same concept while de-emphasizing differences, comparing instances that share irrelevant features could result in those features being retained in a learner's mental representation. This notion, called "conservative generalization" by Medin and Ross (1989) is that people will generalize as minimally as possible, preserving shared details unless there is a compelling reason to discard them. This, in turn, could limit generalizability to new, dissimilar cases. Some research is consistent with this conclusion. For example, Halpern, Hansen, and Riefer (1990) asked students to read scientific passages that included either "near" (superficially similar) or "far" (superficially dissimilar) analogies. The passages that included far analogies led to superior retention, inference and transfer compared to those featuring superficially similar comparison, which showed no benefit at all.

The conservative generalization principle predicts that increasing the similarity of simultaneously presented instances from one category will inhibit people's ability to discover the rule that discriminates between the two categories. The true, discriminating rule will need to compete with many other possible hypotheses related to the many other features shared by the compared instances. By this account, decreasing the similarity of the compared instances that belong within a category will make it more likely that the proper grounds for generalization are inferred, by eliminating misleading common features that lead to incorrect categorization rules.

Results of Rost and McMurray (2009) on young infants learning to discriminate pairs of similar words point into the same direction. These authors found that increasing the within-category variability of the to-be-learned words by having different speakers repeat them increases the infants' ability to discriminate between the words. One of the potential explanations they give for their results is that young infants might still be unsure about what feature dimensions are relevant for the task and the variability in the irrelevant dimen-
sions helps the infants to focus on the relevant, stable ones.
Another line of argument is that concepts which are highly similar to each other are better learned when instances of different concepts are interleaved. When learning to distinguish between several similar concepts, one major difficulty lies in identifying the subtle differences between them. Birnbaum, Kornell, Bjork, and Bjork (2012) suggested, in their discriminative contrast hypothesis, that interleaving instances of different concepts enhances the discriminative contrast between them and therefore helps with the task of spotting their differences, see also (Carvalho \& Goldstone, 2012; Kornell \& Bjork, 2008; Kang \& Pashler, 2012). Additionally, comparing very similar instances from different categories has the advantage that there are fewer random, irrelevant differences that compete for attention with the defining difference (see Winston, 1970, on "near misses").

In summary, the two lines of arguments described above predict that high similarity supports between-category comparison, while low similarity supports within-category comparison. Both types of comparisons are potentially important in learning concepts, but one might be more effective than the other for a specific learning task, depending on the specific task, context, experience, and structure of concepts (Goldstone, 1996).

In this paper, we compare the effect that similarity has on learning performance in blocked and interleaved presentation schedules. Carvalho and Goldstone (2012) recently conducted an experiment with a similar purpose. They manipulated the category structures in a perceptual categorization task towards more or less similarity, both within and between categories, and found this modulates the advantage of blocking and interleaving in the expected directions.

Our approach is different in three important ways. First, we manipulate similarity by grouping concept instances into either similar or dissimilar comparison, instead of switching between two separate sets of categories. Second, we designed the blocked and interleaved schedules in a way that they would enhance within- and between-category comparison, respectively, while still allowing for both types of comparisons. Therefore, the two argument lines above make opposite predictions on whether high similarity of instances shown closely together should help or hurt the induction and will allow for a direct comparison of effect strengths. Third, we use an inductive learning task, Physical Bongard Problems (PBPs), with a much larger feature-space.

This problem domain is inspired by the Bongard problems (Hofstadter, 1979; Bongard, 1970) and was recently introduced by Weitnauer and Ritter (2012) to study concept learning and categorization of dynamic, physical situations. Each problem consists of two sets of 2D physical scenes representing two concepts that must be identified. The scenes of one concept are on the left side, the scenes of the other concept on the right side. Figure 1, 2 and 3 show three example problems. What makes PBPs particularly interesting as a domain for concept learning is their open-ended feature space. Peo-
ple do not know in advance which features a solution might be based on (or indeed what the features are), and while some of the problems rely on features that are readily available such as shape or stability, others require the construction of features as a difficult part of the solution (e.g., the time an object is airborne or the direction a particular object in the scene is moving in) \({ }^{1}\). This intricate situation in which both features and concepts have to be identified at the same time is quite common in real life and people deal with it impressively well, while it is still considered a very hard problem in the Artificial Intelligence community.

Figure 1: PBP 08. The task is to identify the two concepts A and B represented by the scenes on the left and on the right side, respectively. This is the similarity version in which similar scenes are grouped by rows. The concept labels were not shown during the study. See the end of paper for the solution.

\section*{Experiment}

In this experiment we analyze the effects of different presentation schedules and similarity groupings on concept learning performance. We selected 22 PBPs and extended them by additional scenes so that the problems consist of sixteen training scenes and 8 test scenes each. Half of the scenes are shown on the left side and belong to category A (we name them A 1 , ..., A10) while the other half of the scenes are shown on the right side and belong to a different category B (we name them B1, ..., B10). All scenes were designed to fit into five similarity groups \(\{\mathrm{A} 1, \mathrm{~A} 2, \mathrm{~B} 1, \mathrm{~B} 2\},\{\mathrm{A} 3, \mathrm{~A} 4, \mathrm{~B} 3, \mathrm{~B} 4\},\{\mathrm{A} 5, \mathrm{~A} 6\), B5, B6\}, \{A7, A8, B7, B8\} and \(\{\mathrm{A} 9, \mathrm{~A} 10, \mathrm{~B} 9, \mathrm{~B} 10\}\), so that within-group similarity between the scenes is high, whereas between-group similarity is low.

During presentation, two scenes are always displayed simultaneously so that for each problem a sequence of six train-

\footnotetext{
\({ }^{1}\) Solutions can be based on a great variety of features and feature combinations, as geometrical or physical object features, the way a physical scene evolves over time, relations between the objects, or even potential interactions with the scene. Additionally, focusing on a subset of objects and aligning the scenes with each other is required to find some of the solutions.
}

Figure 2: PBP 18. This is the dissimilarity version in which similar scenes are positioned far from each other. See the end of paper for the solution.
ing scene pairs is shown to the participant. We vary the presentation order of scenes along two dimensions with two values each, resulting in four conditions. The first dimension, similarity grouping, controls whether similar scenes are shown temporally close to each other ("111122223333") or temporally far from each other ("132121323213"). We will refer to the former as "grouped by similarity" or "similar" and to the latter as "grouped by dissimilarity" or "dissimilar". Figure 4 depicts how scenes are positioned for both cases.

The second dimension, presentation schedule, controls whether the scenes that are shown simultaneously are from the same or from different categories (AA-BB-AA-BB-AA\(B B\) vs. \(A B-A B-A B-A B-A B-A B\), see Figure 5). We will refer to the former as "blocked" condition \({ }^{2}\) and to the latter as "interleaved" condition. In the blocked condition while within-category comparisons are facilitated by presenting scenes from the same category simultaneously, betweencategory comparisons can still be made between successive scene pairs, but involve higher memory demands. Analogously, the interleaved condition enhances between-category comparisons but still allows for within-category comparison across successive scene pairs.

We expected to find that grouping by similarity should improve learning performance for the interleaved condition and grouping by dissimilarity should improve performance for the blocked condition.

\section*{Subjects}

We conducted the experiment on Amazon Mechanical Turk \({ }^{3}\). Sixty-seven participants, all US-citizens, took part in the ex-

\footnotetext{
\({ }^{2}\) We use the term "blocked" to refer to a slightly different presentation schedule than it is usually done. Instead of showing all instances of one category before switching to the next, we only block two instances of one category and interleave these blocked pairs.
\({ }^{3}\) See Mason and Suri (2012) for an introduction to using Mechanical Turk as a platform for research.
}

periment in return for monetary compensation. Of these, we excluded 27 who did not finish all problems (most of them dropped out after seeing only a few) and another two that did not get at least one solution correct across the entire task. There was no need to use catch trials, because the subjects were required to write down the solutions as free text. Any cheating or automated answers would have become immediately apparent during our hand-coding of the solutions. The data from the remaining 38 participants was used in the following analyses. On average, participants solved 8.6 out of the 22 problems presented.

\section*{Material}

For each of the 22 problems, the training scenes were arranged in three rows, each with four scenes. We prepared two versions of each problem by placing the scenes at different positions. In the "grouped by similarity" version, the scenes were arranged in such a way that the scenes inside

Figure 5: The scene presentation schedule for blocked (top) and interleaved (bottom) presentation. The participant manually proceeds through the six states. In each state, two scenes (in white) are shown while the other scenes (in gray) are hidden.
each row are similar to each other. In the "grouped by dissimilarity" version, similar scenes were distributed over all rows. Figures 1 and 2 show an example of a dissimilarity and similarity version, respectively.

\section*{Design}

We used a \(2 \times 2\) factorial design. The study condition (presentation schedule: \(\{\) blocked, interleaved \(\} \times\) similarity grouping: \{similar, dissimilar\}) was randomly chosen for each problem in a within-subject manner.

\section*{Procedure}

The participants were first given a brief introduction to PBPs including an example problem with a solution. During the experiment, they could proceed through the scene pairs of each problem at their own pace by pressing a key. After they had viewed all scenes once, they were asked whether they thought they had found a solution. Then they needed to classify six test scenes which were randomly drawn from the eight available test scenes. The test scenes were shown one by one. Finally they had to type in a description of their solution or their best guess. Before moving on to the next problem, they were shown the problem with all training scenes at once together with the official solution. There was no time limit to the task. At the end of the experiment participants were debriefed on the study objectives and variables. The original experiment is available online at Weitnauer (2013).

\section*{Results}

We used two separate measures to evaluate learning success. First, we hand-coded the accuracy of each textual solution given by the participants. Some of the participants had difficulties remembering which side was left and which side was right, so they provided a correct solution but with sides swapped (e.g., writing "left: all objects are squares" and "right: all the objects are circles" when in fact the left-side objects were all circles and the right-side objects were all squares). These cases were counted as correct solutions.

The second measure is based on the proportion of test scenes that were classified correctly. Using this directly would be misleading for cases in which participants mixed up the sides. We therefore developed a consistency measure instead. This consistency measure is defined as \(\max (c, 6-c)-\)

3 , where \(c\) is the number of correctly classified scenes being minimally zero and maximally six. The consistency can take values between zero and three, where the latter corresponds to cases where either all test scenes were classified correctly or were all (consistently) classified wrongly. Figures 6 and Figure 7 show the average of these two measures for all four conditions.

Figure 6: Mean proportion of correct answers for blocked and interleaved presentation schedules and grouping of scenes by similarity or dissimilarity. There is a significant effect of similarity.

Figure 7: Mean consistency of test scene classifications for blocked and interleaved presentation schedule and grouping of scenes by similarity or dissimilarity. There is a highly significant effect of similarity.

We applied two separate \(2 \times 2\) repeated measures ANOVAs with presentation schedule (blocked vs. interleaved) and similarity grouping (similar vs. dissimilar) as factors to the proportion of correct responses and consistency measures. These analyses revealed a significant effect of similarity condition, \(F(1,37)=5.32, p=.03\) for the proportion of correct answers measure and \(F(1,37)=15.7, p=.0003\) for the consistency measure. There was no effect of schedule of presentation, or
interaction between the two factors for any of the measures (all \(p>.05\) ).

\section*{Discussion}

The data analysis revealed a positive effect of grouping scenes by similarity, independent of whether they were presented in a blocked or an interleaved schedule. We argue that this is explained by a strong positive effect of similarity on interleaving which more than compensates for any possible negative effect that similarity had on blocking.

The advantage of similarity for interleaving is in line with our expectations. Goldstone (1996) and the discriminative contrast hypothesis of Birnbaum et al. (2012) predict that direct comparison of instances from different categories highlights their differences (see also Carvalho \& Goldstone, 2012). Identifying differences between highly similar scenes is especially effective, as there are fewer superficial differences to compete with the defining one. This insight is already present in the desirable "near misses" in Winston (1970) work, where instances from different concepts that differ by just one feature are ideal for his algorithmic learner. Near misses provide clear evidence about what features are critical, concept-defining ones. Another possible contributing effect is that it is easier to structurally align two similar scenes than two very different scenes and this alignment process promotes noticing differences (Markman \& Gentner, 1993).

What might seem surprising at first is that similarity also improves learning performance in the blocked condition, given that theories like "conservative generalization" by Medin and Ross (1989) predict that similarity for blocked scenes will lead to many superficial similarities and therefore inferior performance compared to dissimilar scenes. However, the results can be explained in a way compatible with these theories. We designed both scheduling conditions in a way that allows for within- and between-category comparisons. Given this, negative effects of similarity on the former and positive effect of similarity on the latter will compete with each other. In the blocking condition, within-category comparisons were facilitated by showing scenes of the same category simultaneously, while scenes of different categories had to be compared sequentially.

Still, a strong positive effect of similarity on betweencategory comparison could mask a small negative effect of similarity on within-category comparison and lead to the overall improvement due to similarity that we found. What is indeed surprising is that, although learners were pushed towards attending to similarities with a paired comparison, they still exploited between-pair differences to find the solution.

We believe that one important reason for this might be found in the type of categorization task that was used. Due to its open ended feature space, participants had to identify or construct relevant feature dimensions as a major part of the challenge. Comparing similar scenes from different concepts provides the additional advantage of highlighting such feature
dimensions, an advantage that blocking of dissimilar scenes does not provide.
Implications for an Algorithmic Learner An interesting question is how the presented results could inform the implementation of a computational model of concept learning in open feature-spaces. A general observation is the fact that presentation order matters at all. This means that attending to the first scenes changes the way the following scenes are perceived and solution hypotheses that are formed. The limited memory capacity of humans makes it impossible to keep a detailed representation of all instances or a large number of hypotheses in mind and forces a decision on which aspects of an instance one should concentrate on and which information should be retained. The big challenge is that these decisions have to be made before knowing the answer to the problem and therefore before knowing what aspects are actually important. In open-ended feature spaces algorithmic learners could face similar problems because the \(a\)-priori construction of all possible features might be infeasible due to a combinatorial explosion, so dynamic processes that discover feature dimensions and concepts at the same time might be necessary.

The main insight from the present experiment is that between-category comparisons of similar instances are especially beneficial, as they promote learning, both by making new, potentially relevant feature dimensions more salient and by increasing the likelihood that a perceived difference is a defining one. Between-category comparisons should therefore play a privileged role in how active learning algorithms choose the next training example.
Pedagogical Implications Birnbaum et al. (2012) showed the benefit of interleaving for several concept learning tasks, and Carvalho and Goldstone (2012) proposed that this benefit is modulated by how similar the concepts are, so that in low-similarity cases blocking can be better. The current work provides a slightly different perspective. Our results suggest no direct advantage of interleaved or blocked presentation, but instead a greater potential of between- compared to within-category comparisons. This holds even for situations in which the between-comparison relies on sequentially shown instances while within-comparison can be made on the basis of simultaneously shown instances. A result that might directly inform the design of learning material is the big benefit of comparing similar scenes from different categories. The grouping of instances by similarity - instead of relying on a single similarity measure for a whole set of concepts - is a new, interesting dimension along which presentation order can be manipulated to optimize learning.

\begin{abstract}
Although Bilingual First Language Acquisition research has increased considerably over the past few decades, there is still much controversy regarding the rate of development, i.e. the question whether bilinguals lag behind their monolingual peers in various aspects of language. Some studies have found similar rates of development, whereas others have found that bilingual children lag behind their monolingual peers. The current study contributes to this discussion of (dis)similar rates of development by investigating bilingual children's acquisition of German complex sentence constructions involving adverbial clauses (ACs). Our findings are consistent with usage-based approaches to language acquisition, which predict that bilingual acquisition should proceed slower due to learners having less exposure, on average, to each language.
\end{abstract}

Keywords: bilingual first language acquisition; language production; rate of development; complex constructions

\section*{Introduction}

\section*{Bilingual First Language Acquisition (BFLA)}

There has been an increasing interest in early bilingual language acquisition. Commonly, this interest involves the question of whether the cognitive and developmental path (course of development) and time course (rate of development) of language learning by bilingual children is the same as that of their monolingual peers. Although prevailing theoretical models of language acquisition have different views regarding the influence of endogenous and exogenous factors on the acquisition of abstract linguistic structures and patterns, they agree upon the idea that monolingual and bilingual language learning is qualitatively equivalent in that children go through the same series of developmental phases, starting off with single word productions, followed by two and multi-word utterances before they finally develop the capacity to produce complex sentences (de Houwer, 1995, 2009; Meisel, 1986). Prior research comparing the rate of development in monolingual and bilingual learners has produced somewhat mixed
results. Some studies have found similar rates of development (cf. Paradis, Crago, \& Genesee, 2005/2006; Paradis, 2010; Pearson \& Fernández, 1994), whereas others have found that bilingual children lag behind their monolingual peers (Gathercole, 2002a, 2002b, 2007; Nicoladis, Palmer, \& Marentette, 2007; Pérez-Leroux, Pirvulescu, \& Roberge, 2009). The current study contributes to this discussion of (dis)similar rates of development by investigating the bilingual acquisition of complex sentences involving adverbial clauses (ACs) in German, which mark the last stage in a series of milestones mentioned above.

\section*{Usage-based theory and BFLA}

Usage-based (UB) theories belong to a family of emergentist models, which assume that the development of language competence is contingent on the experience with language (O’Grady, 2008; Tomasello, 2003; Lieven, \& Tomasello, 2008). A conservative assumption about BFLA is that bilingual children, on average, receive less language input per language than their monolingual peers. UBtheories thus predict that reduction in overall exposure to a language should negatively affect children's rate of acquisition (Gathercole, \& Hoff, 2007; Paradis, Nicoladis, Crago, Genesee, 2011).

\section*{Usage-based theory and the acquisition of complex sentences}

Complex sentences are grammatical assemblies consisting of multiple clauses. Two types of clauses are distinguished: (i) sentences including coordinate clauses and (ii) sentences including a matrix clause and a subordinate clause. Complex sentences containing subordinate clauses can be further subdivided into three basic sub-types: constructions with complement clauses, relative clauses and adverbial clauses. The most comprehensive study on the acquisition of complex sentences framed within UB-theory is Diessel (2004). Diessel proposes that complex sentences develop through two different types of processes: Complex
sentences involving complement and relative clause constructions develop through a process termed clause expansion. Complex sentences containing adverbial clauses develop through a process termed clause integration, in which two independent sentences are merged into a single bi-clausal unit. The earliest adverbial clauses produced by children are thus free-standing (isolated) clauses introduced by an adverbial subordinator, which are only pragmatically linked to a previous utterance. Over time, children learn to elaborate these structures and integrate them with a matrix clause. The last step in mastering complex sentences involves developing the capacity to produce sentence initial subordinate clauses, which impose greater demands on (verbal) working memory as initial clauses require that the producer has planned the entire complex structure at the onset of the utterance (Gibson, 1998; Hawkins, 2004; Temperley, 2007). Initial adverbial clauses thus develop later and their frequency, at first, is limited to specific subordinators. Another finding of Diessel's (2004) study is that children's early productions of complex sentences are tied to specific lexical expressions. The emergence of more schematic representations of such constructions takes place only after children have been exposed to a sufficient number of types to generalize over. This is reflected in the fact that children only gradually elaborate their repertoire of adverbial subordinators and overextend already learned types to situations where those types are semantically inadequate (e.g. use of a causal subordinator to express concessive or other adverbial relations). Two additional, more general indicators of language proficiency are the mastery of syntactic differences in German main and subordinate clause (verb second in main clauses vs. verbfinal positioning in subordinate clauses) (cf. Clahsen \& Muyskens, 1986; Miller, 1976; Park, 1981; Roeper, 1973) and mean length of utterance (MLU). MLU has been shown to be an important measurement of a child's gross language development and was found to correlate with the development of morphological and syntactic skills in young children (Brown, 1973; Parker, \& Brorson, 2005). Building on this research, the present study sets out to derive statements about differences in the rate of development of complex sentence constructions from measurements of five indicators of language proficiency:
1. Proportion of isolated/integrated adverbial clauses
2. Proportion of sentence-initial adverbial clauses
3. Proportion of misused subordinators
4. Proportion of correct verb position in sub clause
5. (Log) length of adverbial construction (MLU)

\section*{Method}

All relevant data were elicited by having children watch a 6.5 minutes episode of a popular stop-motion animated children's television series. The children were then given a visual cue to a particular scene and asked to describe what happened in that scene. The children's' responses were audio-recorded and transcribed.

\section*{Participants}

A total of 50 children from 4 to 6 years old participated in the study: 25 bilingual child participants (German in combination with another language) and a control group consisting of 25 monolingual children. \({ }^{1}\) All bilingual children have started learning both languages before the age of three (McLaughlin, 1984). The children participating in the study were selected from several kindergartens with families from different socioeconomic backgrounds (SES; low SES ( \(\sim 5 \%\) ), middle SES ( \(\sim 75 \%\) ), high SES ( \(\sim 20 \%\) ). The final proportional distributions of monolingual and bilingual children across these three categories exhibit minor, statistically insignificant asymmetries (the proportion of bilinguals was a little greater than expected assuming statistical independence in high and low SES categories). All parents and kindergartens, agreed to participate in the study.

\section*{Data}

The elicitation procedure resulted in 27,301 word tokens produced by monolingual learners and 21,023 word tokens produced by bilingual learners. From these corpora, all instances of the target constructions were extracted by way of manual inspection of the corpus data, yielding a total of 1,023 data points (601 from monolinguals, 422 from bilinguals). The extracted data were annotated with information pertaining to the indicators of language competency listed in the preceding section. Table 1 presents relevant descriptive statistics of the sample.

Table 1: Descriptive Statistics
\begin{tabular}{ccc}
\hline & monolingual & bilingual \\
\hline age (mean) & \(5 ; 4\) & \(5 ; 5\) \\
age (SD) & 7.16 & 6.87 \\
number of ACs total & 601 & 422 \\
ACs integrated & \(62.73 \%\) & \(50 \%\) \\
ACs in initial position & \(23.34 \%\) & \(13.74 \%\) \\
subordinator misused & \(1 \%\) & \(17.77 \%\) \\
correct verb position & \(72.38 \%\) & \(66.11 \%\) \\
length (mean) & \(12.36 \%\) & 10.55 \\
length (SD) & 7.2 & 5.91 \\
\hline
\end{tabular}

The language proficiency levels of the monolingual and bilingual children were compared with respect to five indicators of language proficiency. To test whether and to what extent the proficiency levels of mono- and bilingual learners differ, we asked: Does competence indicator x differ significantly between bilingual and monolingual children after controlling for age? The data were analyzed using linear and logit mixed effects models in which each of

\footnotetext{
\({ }^{1}\) There are total of 12 different language pairs within the data. German was acquired in combination with one of the following languages: Albanian, Arabian, Bosnian, English, French, Hungarian, Kurdish, Persian, Russian, Spanish, Turkish or Vietnamese.
}
the five indicators of language proficiency was modeled as a function of the Boolean predictor BILINGUAL (monolingual vs. bilingual), a control variable AGE (measured in months) and SUBJECT as a random effect. \({ }^{2}\). We checked for normality and homogeneity by visual inspections of plots of residuals against fitted values. For all models, the significance of the predictor BILINGUAL was assessed through model comparison: For each model, we conducted likelihood ratio tests to see if a model including BILINGUAL is significantly better than the corresponding model containing only AGE and the random effect (SUBJECT).

Model 1: Length
Linear Mixed Model fit by REML approximation; p-values estimated via Markov Chain Monte Carlo (MCMC) sampling ( \(n=10.000\) ). Outcome variable (log) length of utterance.

Table 2: (Log) Length Model
\begin{tabular}{cccc}
\hline Random effects: & & Variance & Std.Dev. \\
\hline child & (Intercept) & 2.09 & 1.44 \\
\hline Fixed effects: & Estimate & MCMCmean & pMCMC \\
\hline (Intercept) & 1.21 & 1.23 & 0.0001 \\
bilingual & \(\mathbf{0 . 1 7}\) & \(\mathbf{0 . 1 7}\) & \(\mathbf{0 . 0 1 5}\) \\
age & 0.01 & 0.01 & 0.0012 \\
\hline
\end{tabular}

Figure 1: Effect of BILINGUAL on (log) LENGTH of construction

The analysis reveals that the there is a weak but statistically significant effect of BILINGUAL on the (logged) length of the construction (a log likehood ratio test comparing null model and model including bilingual yields \(\operatorname{Pr}(\) Chi) < 0.05). The positive coefficient estimate in Table 2 indicates that the average construction length of monolingual learners is greater than that of bilingual learners, when age is controlled for.

Model 2: Integration
Mixed Logit Model fit by Laplace approximation. Outcome variable is proportion of integrated (= non-isolated) adverbial clauses.

\footnotetext{
\({ }^{2}\) All data were analyzed using R (R Core Team, 2012) and the functions provided in the R packages lme4 (Bates \& Maechler, 2009) and languageR (Baayen, 2009)
}

Table 3: Integration Model
\begin{tabular}{cccc}
\hline Random effects: & & Variance & Std.Dev. \\
\hline child & (Intercept) & 2.09 & 1.44 \\
\hline Fixed effects: & Estimate & SE & \(\operatorname{Pr}(>|\mathbf{z}|\) ) \\
\hline (Intercept) & -5.64 & 1.87 & 0.00254 \\
bilingual & \(\mathbf{1 . 3 0}\) & \(\mathbf{0 . 4 6}\) & \(\mathbf{0 . 0 0 4 6 1}\) \\
age & 0.07 & 0.03 & 0.01469 \\
\hline
\end{tabular}

Figure 2: Effect of BILINGUAL on proportion of integrated adverbial clauses (AC)

The analysis reveals a weak but statistically significant effect of BILINGUAL on the proportion of integrated adverbial clauses (a log likehood ratio test comparing null model and model including bilingual yields \(\operatorname{Pr}(\mathrm{Chi})<0.01)\) : Monolingual learners produce significantly more complex constructions (integrated ACs), when age is controlled for.

Model 3: Verb Position in Subordinate Clause
Mixed Logit Model fit by Laplace approximation. Outcome variable is proportion of adverbial clauses with correct (=clause final) verb position.

Table 4: Verb Position Model
\begin{tabular}{crcc}
\hline Random effects: & & Variance & Std.Dev. \\
\hline child & (Intercept) & 1.61 & 1.27 \\
\hline Fixed effects: & Estimate & \(\mathbf{S E}\) & \(\mathbf{P r}(>|\mathbf{z}|)\) \\
\hline (Intercept) & 0.94 & 1.61 & 0.56 \\
bilingual & \(\mathbf{0 . 4 6}\) & \(\mathbf{0 . 4 0}\) & \(\mathbf{0 . 2 5}\) \\
age & -0.01 & 0.03 & 0.75 \\
\hline
\end{tabular}

Figure 3: Effect of BILINGUAL on correct verb position in adverbial clauses (AC)

The analysis reveals a tendency for monolingual learners to produce a greater number of correct verb position but the effect is not statistically significant (a log likehood ratio test comparing null model and model including bilingual yields \(\operatorname{Pr}(\) Chi) \(>0.25)\).

Model 4: Subordinator Misuse
Mixed Logit Model fit by Laplace approximation. Outcome variable is proportion of incorrectly used subordinators

Table 5: Subordinator Misuse Model
\begin{tabular}{cccc}
\hline Random effects: & & Variance & Std.Dev. \\
\hline child & (Intercept) & 5.90 & 2.43 \\
\hline Fixed effects: & Estimate & SE & \(\operatorname{Pr}(>|\mathbf{z}|)\) \\
\hline (Intercept) & 2.49 & 4.10 & 0.54 \\
bilingual & \(\mathbf{- 3 . 7 4}\) & \(\mathbf{1 . 0 5}\) & \(\mathbf{0 . 0 0 0 3 1}\) \\
age & -0.08 & 0.06 & 0.22 \\
\hline
\end{tabular}

The analysis reveals a medium sized and statistically significant effect of BILINGUAL on the proportion of correctly used subordinators (a log likehood ratio test comparing null model and model including bilingual yields \(\operatorname{Pr}(\) Chi) < 0.001): Bilingual learners produce significantly more semantically inadequate subordinators.

Figure 4: Effect of BILINGUAL on misuse of adverbial subordinator

Model 5: Adverbial Clause Position
Mixed Logit Model fit by Laplace approximation. Outcome variable is proportion of sentence-initial adverbial clauses. This model was fit to the subset of the data that contains only those utterances that contain at least two clausal constituents, so that the adverbial clause can either precede or follow the main clause ( \(\mathrm{N}=588\) ).

Table 6: AC Position Model
\begin{tabular}{crrc}
\hline Random effects: & & Variance & Std.Dev. \\
\hline child & (Intercept) & \(5.39 \mathrm{E}-20\) & \(2.32 \mathrm{E}-10\) \\
\hline Fixed effects: & Estimate & SE & \(\operatorname{Pr}(>|\mathbf{z}|\) ) \\
\hline (Intercept) & 0.21 & 1.17 & 0.8546 \\
bilingual & \(\mathbf{0 . 5 6}\) & \(\mathbf{0 . 2 4}\) & \(\mathbf{0 . 0 1 9 9}\) \\
age & -0.03 & 0.02 & 0.0755 \\
\hline
\end{tabular}

Figure 5: Effect of BILINGUAL on proportion of sentenceinitial ACs

The analysis reveals a weak but statistically significant effect of BILINGUAL on the proportion of sentence-initial adverbial clauses (a log likehood ratio test comparing null model and model including bilingual yields \(\operatorname{Pr}(\) Chi) < 0.05): Bilingual learners produce significantly fewer sentence initial adverbial clauses.

\section*{Discussion}

Prior research into the rate of bilingual and monolingual development has produced somewhat inconclusive results. While some studies have found similar rates of development, other studies found that bilingual children lag behind their monolingual peers in various aspects of language. Furthermore, the majority of research on the accuracy of bilingual production has been devoted to earlier phases of grammatical development such as the acquisition of the past tense (e.g. Paradis et al., 2011), the acquisition of mass/count nouns (Gathercole, 2000a) or the acquisition of grammatical gender (Gathercole, 2000b). Our findings contribute to this area of research by providing additional evidence from later stages of grammatical development, namely complex sentences, which constitute the last milestone in the acquisition of grammar (cf. Clahsen, 1986).

The research question guiding our analysis was as follows: Are bilingual children less proficient than their monolingual peers in the production of German complex sentences with adverbial clauses? Experience-driven or usage-based theories of language predict that bilingual children's acquisition of complex sentences should proceed slower due to them having less exposure, on average, to each language. We tested this general prediction across multiple dimensions. The five dimensions that served as responses in our models jointly define the space in which we measured language proficiency of monolingual and bilingual learners. We observed that bilinguals in fact lag behind in four out of five dimensions: their adverbial constructions are shorter, less often integrated into a complex sentential structure and when they are integrated, they are less often placed in sentence-initial position. Furthermore, bilingual productions exhibited a greater amount of violations of the semantic usage conditions of adverbial subordinators. This suggests that bilingual children have not yet developed a very nuanced set of words to link verbalizations of two events.

Overall, the present work clearly indicates that bilinguals around age five have not caught up on their monolinguals peers in the domain of complex sentences. The only dimension where performance was equivalent across the two groups concerns the positioning of the finite verb in German subordinate clauses. However, as both groups are still quite removed from adult-level performance ( \(<80 \%\) correct usages in both groups), this finding cannot be attributed to the children's having mastered this grammatical domain. Our results also display a considerable amount of inter-individual differences as evidenced by rather pronounced intercept adjustments in the models. Some bilingual children even outperform some monolingual children across all dimensions. While some variation is expected to result from inter-individual differences in learning performance, prior research suggests that a large portion of the observed differences may also relate to various types of group-level differences (cf. Werker, \& Byers-Heinlein, 2008, for an overview). These include variation due to specific language pairs (Döpke, 2000; Holm, \& Dodd, 1999; Müller, 1999; Müller \& Hulk, 2001; Nicoladis, 2003; Paradis, \& Navarro, 2003; Yip \& Matthews, 2000), contexts of exposure (Kazuya, 1998), social status of the languages (De Houwer, 2007; Pearson, 2007), socioeconomic status (Morton, \& Harper 2007), and language dominance (Cutler, Mehler, Norris, Segui, 1989; Flege, MacKay, \& Piske, 2002; Gathercole, \& Môn Thomas, 2009). Disentangling the effects of these variables from the effects of an individual's learning performance is subject to further investigation.

Acknowledgments
We thank the children who participated in this study, their parents for their permission to conduct the study and all nursery school teachers for their cooperation.

\begin{abstract}
The Bridge dilemma (pushing a heavy man from a bridge in front of a train that would otherwise kill five persons) and the Switch dilemma (redirecting a train that would otherwise kill five persons onto another track where it kills one person) are presumably the two best-known moral dilemmas in philosophy and psychology. In this paper we claim that people's intuitions about what to do in Bridge are robust, while intuitions about Switch can be influenced rather easily. In doing so, we strongly disagree with Broeders and colleagues (2011) who recently argued for exactly the opposite claim. We discuss their interpretation of previous findings that were supposed to motivate their claim, present findings from previous studies that strongly support my claim, and report on failed attempts to replicate and present an experiment in which participants were willing to revise their judgment for Switch but not for Bridge.
\end{abstract}

Keywords: moral judgment; trolley dilemmas; robustness of moral intuitions; priming; transfer effects.

\section*{Introduction}

Bridge and Switch are presumably the two best-known hypothetical moral dilemmas. They were first extensively used as thought experiments in moral philosophy and later also in empirical studies in moral psychology (cf. Waldmann, Nagel, \& Wiegmann, 2012; Gräfenhain \& Wiegmann, 2012).

In both scenarios five people are threatened by an out of control train. In Bridge the only possibility to save the five persons is to throw a heavy person from a bridge in front of the train, resulting in killing the heavy person and saving the five (Thompson, 1985). In Switch the threatening train can be redirected away from the five onto another track where one person would die in the collision with the train (Foot, 1967). Research in moral psychology has shown that the majority of people disapprove intervening in Bridge while they tend to approve the action in Switch (Waldmann et al., 2012).

In their recent paper, Broeders, Bos, Müller, and Ham (2011) make extensive use of these two dilemmas. They argue that previous research, especially the research by Greene and colleagues (Greene, Sommerville, Nystrom,

Darley, \& Cohen, 2001; Greene, Nystrom, Engell, Darley, \& Cohen, 2004) indicates that people's decision in Switch is made fast and without hesitation, while it takes them longer and they are more hesitate to make a decision in Bridge. Following this line of argument, Broeders and colleagues (2011) claim that people’s judgments in Bridge can easily be manipulated by priming them with rules as "save lives" and "do not kill", while this kind of priming supposedly has no effect on people's judgment in Switch. In three experiments they seemingly confirm this claim.

In this paper we argue for an opposite claim: Judgments concerning Switch can be manipulated rather easily while judgments concerning Bridge are rather robust.

\section*{Arguing against Broeders and colleagues’ interpretation of previous findings}

Broeders and colleagues' (2011) claim is motivated by the following line of argument. Research by Greene and colleagues (Greene et al., 2001, Greene et al., 2004) suggests that when people have to deal with Bridge the anterior cingulated cortex (ACC) shows increased activity. Activation of the ACC is assumed to indicate people's feeling of uncertainty. Moreover, people’s longer reaction times in Bridge, as compared to Switch, are also assumed to indicate uncertainty. This uncertainty is then interpreted as people's struggling to choose between the two rules "Do not kill" and "Save Lives". Hence, by priming one of the rules and thereby making it more accessible to subjects, their intuition about what to do in Bridge allegedly follows the primed rule. In contrast to Bridge, Switch elicits low ACC activity and people respond fast to it, supposedly indicating certainty. Hence, judgments concerning Switch are assumed to be robust and not to follow the primed rule.

At first glance, this line of reasoning sounds plausible. However, a closer look at the cited studies reveals that they do not provide compelling evidence in support of Broeders’ and colleagues' (2011) claim that people are uncertain of what to do in Bridge. Remember that this claim is based on two observations, namely people's longer reaction times and higher ACC activation in Bridge as opposed to Switch. However, there is no evidence that people's reaction-times
were longer for Bridge. While in their first fMRI study, Greene and colleagues (2001) did not report reaction times for Bridge, they explicitly state in their follow up study (Greene et al., 2004) that reaction times for Bridge were short.

What about the other finding that was also interpreted as people feeling uncertain about what to do in Bridge, namely the high ACC activation when people respond to this dilemma? First of all, the reported results in the fMRIstudies by Greene and his colleagues \((2001,2004)\) are based on brain activity averages for groups of dilemmas (about twenty in each group). Hence, to inferring conclusions from these averages to specific cases are just not valid.

Secondly, Greene and colleagues (2004) do not interpret high ACC activation as indicating uncertainty but as a conflict of emotion and cognition or, more precisely, cognitive effort to override a prepotent emotional response (cf. Stroop effect, Stroop, 1935). Their interpretation explains the aforementioned finding of people’s longer reaction-times when choosing an utilitarian (cognitive) option in personal moral dilemmas, because people have to override a strong emotional response not to intervene (Greene et al., 2001). In the same way, Greene's et al. interpretation of ACC activity as indicating a conflict of emotional and cognitive (utilitarian) considerations can explain why reaction times were only longer for people under cognitive load, which were namely those who chose the utilitarian option (Greene, Morelli, Lowenberg, Nystrom, \& Cohen, 2008). In contrast, interpreting ACC activity as indicating uncertainty cannot account for these findings because it would predict longer reaction times in dilemmas with high ACC activity independently of the option (cognitive vs. emotional) people choose.

Thirdly, it is simply not the case that the cited studies provide any evidence for higher ACC activation in Bridge, as compared to Switch. In their first fMRI study (Greene et al., 2001) ACC activation is not measured at all. In the follow-up study (Greene et al., 2004) ACC activity in difficult and easy personal moral dilemmas was compared. Since Switch was in neither of these groups, we do not have any evidence on the level of ACC activation in this dilemma. Moreover, due to relatively fast reaction times, Bridge was classified as an easy personal dilemma and it was found that ACC activity in these dilemmas was significantly lower than in difficult moral dilemmas.

\section*{Previous research indicating intuitions about Bridge to be robust - but not about Switch}

So far, we have dismissed Broeders and colleagues’ (2011) argument that was supposed to motivate their claim that Bridge is easy to influence, as compared to Switch. Now we shall present empirical findings that strongly speak in favor of my claim, that is, if any of the two dilemmas can be influenced rather easily then Switch is the one.

Lanteri, Chelini, and Rizello (2008) presented participants with the Switch and the Bridge dilemma. In one condition, participants first had to judge Switch and then Bridge
afterwards. In the other condition, Switch was preceded by Bridge. Although responses to Bridge remained unaffected by the order of presentation, fewer participants were willing to intervene in Switch when Switch was preceded by Bridge. The authors interpret their results as evidence that Switch may be perceived in more than one way, while they speculate that the emotions triggered by Bridge may be evolutionarily sound and hard wired into our species, making it more robust than reactions to Switch that are assumed to be a result of moral reasoning.

Lombrozo (2009) conducted a very similar experiment. The only difference to Lanteri et al. (2008) was that participants were allowed to read both dilemmas before they were asked to judge them. Again, participants who saw Switch first provided higher permissibility ratings than those who saw it after Bridge. Responses for Bridge were unaffected.

Petrinovich and O’Neill (1996) conducted several experiments in which participants were asked to judge a sequence of moral dilemmas, among them Switch and Bridge, where the order of presentation was manipulated between subjects. While ratings for Switch often significantly differed as a function of whether it was presented as the first or last dilemma, ratings for Bridge remained unaffected.

Finally, Wiegmann, Okan, and Nagel (2012) also found that people's judgments for Switch can be influenced by first presenting other scenarios, while people's judgments for Bridge were not affected. Moreover, Wiegmann, and Okan (2012) tried and failed to raise ratings in favor of the proposed action in Bridge. In one experiment they urged participants to justify their ratings in Switch, assuming that subjects' justification is something like "save as many lives as possible" and that this forced justification would raise subjects' ratings for Bridge. In another experiment, they tried to raise subjects’ ratings for Bridge by first presenting them with a scenario in which there was only enough time to pull one of two switches. One switch prevented one person, the other three persons from being killed. Presenting this scenario first was also supposed to make a rule like "save the most lives possible" salient. However, neither attempt succeeded in influencing ratings for Bridge.

\section*{Replication Experiments}

What follows are two attempts to replicate Broeders and colleagues' (2011) findings of their first experiment. We limit my replication attempts to their first of the total of three experiments for the following reason. All three experiments are based on the same rationale, namely to prime participants with one of the two rules. The only way the three experiments differ is how priming was implemented. In their first experiment, priming was implemented by asking participants to read a story and to answer two questions about the rule "Save lives" or "Do not kill". In Experiment 2 participants were asked to solve a sliding puzzle that resulted in a symbol supposed to prime participants with one of the two rules. In the third
experiment participants were subliminally primed. Hence, their first experiment is very similar to the experiments described in the preceding section. It might be possible, if unlikely, that the findings in their second and third experiment can be replicated even if it is not possible for the findings in their first experiment. However, since priming in their second and third experiment was implemented in a rather subtle way, as compared to reading a story in the first experiment, failing to replicate the findings in the first experiment would already strongly limit the scope of the claim that intuitions about Bridge can rather easily be manipulated while intuitions about Switch are rather robust.
In the light of what has been said so far, what prediction is to be made regarding Broeders and colleagues’ (2011) experiment in which participants had to read stories designed to prime them with the rule "Save lives" vs. "Do not kill"? Surely, everything points to the prediction that Bridge will not be affected by their manipulation. With regards to Switch things are not that clear, because there are no previous experiments in which it was tried to influence ratings for Switch by priming rules.

\section*{First Replication Attempt}

Participants 352 subjects, each receiving \(£ 0.50\), were recruited via an online database located in the U.K. They were invited via an email. The email contained a link that directed them to the experiment. Mean age of the participants was 47 years and 4 months ( \(S D=15\) years, 7 months), \(61 \%\) were female.

Design, Procedure, and Materials Participants were randomly assigned to one of the conditions of a 2 (primed rule: "Save lives" vs. "Do not kill") \(\times 2\) (dilemma: Bridge vs. Switch) factorial design.

After reading a cover story participants were asked to read a short story which was supposed to prime them with either the "save lives" or "do not kill"-rule. The "save lives" story goes as follows:
During missions abroad soldiers have to apply to certain rules. This is called a mandate. During a conflict in 1994 in Congo, Africa, the mandate of the UN peace keeping force present in the country was to use armed violence to end the conflict. As a result of several warnings beforehand and during the conflict by the UN commander in chief on the spot, the Canadian lieutenant-general Roméo Dallaire, UN-soldiers were allowed to conduct offensive actions. They were both allowed to use their weapons to protect the civilian population, as well as when they themselves were attacked. The mandate was based on the principle "Save lives".
For the "Do not kill" version participants read:
During missions abroad soldiers have to apply to certain rules. This is called a mandate. During a conflict in 1994 in Congo, Africa, the mandate of the UN peace keeping force present in the country was not to use any armed violence to end the conflict. Despite several
warnings beforehand and during the conflict by the UNcommander in chief on the spot, the Canadian lieutenant-general Roméo Dallaire, UN-soldiers were not allowed to conduct any offensive actions. They were only allowed to use their weapons when they themselves were attacked. The mandate was based on the principle "Do not kill".
Afterwards, they were first asked to write down how they would act in line with the corresponding rule. Furthermore, they were asked to write down what the specific rule meant for them in their daily lives. Subsequently, participants were asked to rate how they feel at the moment on the 20 items of the PANAS, an instrument to collect self-report measures of emotion (Watson, Clark, \& Tellegen, 1988). The PANAS was included as a filler task, as well as to determine whether the primes triggered any unwanted positive or negative affective reaction.

The PANAS was followed by asking participants to read and respond to either the Bridge or the Switch dilemma.
Bridge reads as follows:
You are standing on a footbridge crossing a railroad track. While you are standing next to a stranger, suddenly a runaway trolley comes hurtling down the railroad track. Further down the railroad track five people are working and they cannot possibly leave the railroad track in time. If the trolley proceeds on its present course it will crash into the five railroad workers and they will be killed in a fatal accident. The only way to save the five people is to push this man off the bridge and into the path of the trolley. The body of this person will break the speed of the trolley as a result of this the trolley will stop and the five persons will survive. The person thrown from the footbridge will certainly die.
Switch reads:
You are standing beside the switch of a railroad track. Suddenly a runaway trolley comes hurtling down the tracks. Further-on down the railroad track five people are working and they cannot possibly leave the railroad track in time. If the trolley proceeds on its present course it will crash into the five railroad workers and they will be killed in a fatal accident. You can save these five people by diverting the trolley onto a different set of railroad tracks. The different railroad track has only one person on it, into which the trolley will crash.
This person will be killed as a result of this.
After reading the dilemma participants were asked eleven questions about their willingness to intervene which they could indicate on a scale ranging from 1 (certainly not) to 7 (certainly yes). All items were then averaged to form a reliable scale indicating the willingness to intervene in the dilemma ( \(\alpha=.80\) ).

Finally, participants were asked four questions to find out whether they were aware of the purpose of the experiment.

Results and Discussion Eleven subjects were excluded because at least one of two independent raters coded them as being aware of the purpose of the experiment.

As in the study by Broeders and colleagues (2011), the prime did not have an effect on the positive or negative subscale of the PANAS.

Figure 1 clearly shows that neither Bridge nor Switch was affected by a priming scenario. A \(2 * 2\) ANOVA yielded the typical main effect of dilemma, \(F(1,337)=80.70\), \(p<.000001, \eta_{p}^{2}=.19\). However, there was no main effect of prime ( \(p>.75\) ) and no significant interaction ( \(p>.6\) ). Hence, Broeders and colleagues' finding could not be replicated although many more subjects participated in this experiment, resulting in a higher test power

Figure 1: Willingness to intervene (on a scale from 1 to 7) in Bridge and Switch as a function of manipulated accessibility of the rules "Save lives" and "Do not kill". Higher bars indicate greater willingness to intervene. Error bars represent standard error of means.

\section*{Second Replication Attempt}

This time we tried to replicate Broeders’ et al. (2011) findings in our experimental lab in Goettingen. This was done to counter objections claiming that online experiments are not reliable (although the typical main effect of dilemma was found). The design and procedure was the same as in the first replication attempt with two exceptions. The PANAS was left out to strengthen the influence of the primes, and participants were only asked two questions concerning their willingness to intervene in Switch or Bridge since the correlation of the eleven questions asked in

Figure 2: Willingness to intervene (on a scale from 1 to 7) in Bridge and Switch as a function of manipulated accessibility of the rules "Save lives" and "Do not kill". Higher bars indicate greater willingness to intervene. Error bars represenB762 standard error of means.

Broeders and colleagues’ and in my first replication attempt was very high.

Participants 220 participants, mostly psychology students, were recruited via the institute's database. Participants were credited with course credit or paid \(7 €\) /hour. Mean age of the remaining \(N=172\) participants was 24 years and 7 months ( \(S D=6\) years, 6 months), \(77 \%\) were female.

Results and Discussion 48 participants were excluded from the analysis because they knew the dilemmas (41) or seemed to identify the purpose of the experiment. Figure 2 clearly shows that neither Bridge nor Switch was affected by a priming scenario. A \(2 * 2\) ANOVA yielded the typical main effect of dilemma, \(F(1,168)=47.55, p<.001, \eta_{\mathrm{p}}{ }^{2}=.22\). However, there was again no main effect of prime ( \(p>.45\) ) and no significant interaction ( \(p>.6\) ).

\section*{Judgment Revision Experiment}

This experiment aims to investigate the robustness of Switch and Bridge by giving participants the chance to later revise their initial judgment.

Participants 158 subjects, each receiving \(£ 0.50\), were recruited via an online database located in the U.K.

Design, Procedure, and Materials The experiment was conducted on the Internet. Upon clicking on a link they received via e-mail, participants were redirected to a website containing the experiment. They read general instructions familiarizing them with the rating scale and asking them to read the following scenario carefully and to take their task seriously. Afterwards, they were randomly assigned to one of two conditions. In Bridge_Switch participants were first presented with Bridge and then Switch, in Switch_Bridge ist was the other way around. In both conditions participants had the chance to revise their judgment for the first scenario after they had seen the second scenario. Both scenario descriptions were accompanied by an illustration of the initial situation.

For each scenario participants were asked whether the proposed action should be done. To indicate their judgment participants could mark one point on a 6-point likert scale ranging from 1 ("certainly no") to 6 ("certainly yes").

After participants were given the chance to revise their judgment for the first scenario, they were asked some demographic questions and a simple logical question to identify participants who did not take the experiment seriously.

Results and Discussion 27 participants were excluded from the analysis because they did not finish the experiment, finished it in less than 40 seconds, or failed to answer the logical question. As it can easily be seen in Figure 3 the aforementioned asymmetrical transfer effect between Bridge and Switch was replicated. While the ratings for Bridge did not differ significantly depending on whether it was
presented first ( \(M=2.4, S D=1.51\) ) or second ( \(M=2.60, S D=\) 1.64), \(t(129)=.74, p=.46\), ratings for Switch were significantly decreased when Switch was presented second ( \(M=3.02, S D=1.50\) ), as compared to ratings for Switch when presented first ( \(M=4.45, S D=1.36\) ), \(t(129)=4.18, p<.00001\).

When we consider the difference of a scenario's first rating vs. the revision rating a similar picture arises. The first rating for Bridge \((M=2.4, S D=1.51)\) did not significantly differ from the revision rating \((M=2.44\), \(S D=1.59\) ), \(t=.35, p=.73\). In contrast to this, the revision rating for Switch ( \(M=3.88, S D=1.63\) ) did significantly differ from the first rating for Switch ( \(M=4.45, S D=1.36\) ), \(t=4.32\), \(p<.0001\).

The results strongly suggest that people's intuitions about Bridge are robust while their intuitions about Switch were significantly influenced when Switch was preceded by Bridge or when Bridge was presented after Switch and people were then given the chance to revise their judgment for Switch.

This pattern of results contradicts Broeder's et al. (2011) claim that people's intuitions about Switch are robust but not for Bridge.

Figure 3: Willingness to intervene (on a scale from 1 to 6 ) in Bridge and Switch as a function of whether the scenario was shown first or preceded by the other scenario (first vs. second rating). The dashed lines represent revised ratings for the first scenario after participants were presented with the second scenario. Higher bars indicate greater willingness to intervene. Error bars represent standard error of means.

\section*{Conclusion}

In this paper we argued that people's intuitions about Bridge are rather robust while their intuitions about Switch are rather easy to influence. This claim stands in sharp contrast to Broeders and colleagues' (2011) claims. We argued that Broeders and colleagues’ interpretation of previous findings that were supposed to motivate claim is not sound. Moreover, we reviewed previous findings that strongly point in the opposite direction.

In line with my claim, replicating the findings of Broeder's et al. first experiment failed online as well as in the lab. Furthermore, the results the revision experiments also count in my favor.

Given the important role that Bridge and Switch play in philosophy as well as in psychology, it is important that wrong claims about them are swiftly corrected to avoid that new research is based on false premises.

\section*{Funding}

This research was supported by a grant of the Deutsche Forschungsgemeinschaft (DFG WA 621/21-1), and the Courant Research Centre 'Evolution of Social Behaviour', University of Göttingen (funded by the German Initiative of Excellence).

\begin{abstract}
Learning-by-invention is an approach to mathematical instruction where small groups explore possible methods of solution before learning the "right answer" (e.g., Schwartz \& Martin, 2004; Kapur \& Bielaczyc, 2011). In a series of studies we have been investigating the effects of group composition in terms of math ability on learning by invention. An initial result showed that groups consisting of a mix of both high and low math ability students generated a broader range of solution attempts when asked to invent a formula for standard deviation compared to more homogeneous math ability groups. Moreover, this wider range of solution alternatives predicted better performance on quizzes following a lesson on the topic. Subsequent work is suggesting that who emerges as the leader of the group matters. Ongoing analyses are also exploring which features of the collaborative discourse are critical for students to take advantage of the affordances of learning by invention.
\end{abstract}

Keywords: Collaboration, Learning, Problem Solving.

\section*{Introduction}

It is said that the road to success is paved with failure. It's also said that those who do not learn from their mistakes are destined to repeat them. The provocative implication of these aphorisms is that there may be ways in which failure may be instrumental for successful learning, as long as one is able to take something away from the failure experiences. This is the premise behind learning-by-invention activities. In learning-by-invention, students are asked to attempt to create a mathematical formula to accomplish a goal before an instructional lesson is provided about the canonical approach. The experience of working in a problem space before being told a correct answer may lay the groundwork for future conceptual understanding, and thereby prepare
students for future learning. And, these benefits might accrue when solvers become aware of what approaches do not work, or become aware of constraints, obstacles, or desired properties for a solution through previous failures. There is now substantial evidence that having students engage in learning-by-inventions activities in small groups can lead to better understanding of new mathematical and statistical formulas compared to more traditional, direct methods of instruction (e.g., Schwartz \& Martin, 2004; Kapur, 2012; Kapur \& Bielaczyc, 2011). One main question for our investigations is whether the composition of the small groups in terms of their relative expertise or math ability might affect the likelihood that group members are able to take advantage of learning-by-invention activities. A second main question is whether there are critical features of the group interactions, such as in who emerges as a discourse leader, or what is said during group discussions, that can be shown to facilitate learning.

Although one could expect that groups where all members possess superior math skills would be more successful at any mathematical problem solving activity, another hypothesis is that there may be advantages to being in a group where there are a variety of backgrounds, perspectives or viewpoints that can be contributed. In particular, these investigations are exploring whether diversity in small groups may be one key to unlocking the potential benefits of learning-by-invention activities.

Obviously working in groups with students with more advanced math skills or knowledge may help students with less advanced skills or knowledge by exposing them to advanced math concepts or ideas that they might not consider when working alone. However, it is also possible that collaborating with students with less math knowledge
might contribute to more successful problem solving or learning by students with more math knowledge. The work of Webb and others has suggested that more skilled students may benefit from teaching or explaining math concepts to others (e.g. Webb, 1980). In addition, to the extent that students with different mathematical backgrounds might approach problem solving in different ways, then diverse groups may help all members think about a broader range of possible solution approaches which may be particularly important when creative, inventive or innovative thinking is required (Canham, Wiley, \& Mayer, 2012; Dunbar, 1995; Wiley \& Jensen, 2005; Wiley \& Jolly, 2003).

Previous research on learning-by-invention tasks has suggested that groups who generate the widest range of possible solution attempts during the invention phase experience the best learning from the activity (Kapur \& Bielaczyc, 2011). Based on this, we predict that the composition of the group in terms of their math expertise should matter, and that there may be special affordances to working in diverse groups. In addition, for groups whose members demonstrate the best understanding of the new principle following learning-by-invention, we explore what features of their discussion may have contributed to their success.

\section*{Consistency in Tea}

Small groups of undergraduates worked together on an invention activity before receiving a lesson on the standard deviation formula. For the invention activity, students were given data sets representing yearly antioxidant levels for 5-6 years of tea grown by three tea growers. Students were told that a company wished to buy tea from the grower with the most consistent levels of antioxidants from year to year and the company has asked for the students' help. They were prompted to generate as many invented formulas or step-bystep instructions as they could for how they could compute the consistency of antioxidant levels for each tea grower.

\section*{Methodology}

Two populations of undergraduate Psychology students at the University of Illinois at Chicago participated in this study \({ }^{1}\). Complete data are available for 25 triads who participated as part of a Research Methods course, and 20 triads from an Introductory Psychology course.
Math ability/expertise was estimated based on a mediansplit derived from historical data from this student population. Students with Math ACT scores of 24 or below were considered to have relatively low skill, and those with

\footnotetext{
\({ }^{1}\) Participants from the Research Methods Sample, who were more advanced in their studies, were found to outperform the Introductory Psychology Sample on the quiz, \(F(1,125)=5.90, p<\) \(.02, \eta^{2}=.05\). Importantly, this did not interact with the group composition factor, \(\mathrm{F}<1.07\), which meant the two samples could be collapsed in order to increase power, while the sample variable was retained as a covariate in all aggregated analyses reported below (for analyses of samples separately, see Wiedmann, Leach, Rummel, \& Wiley, 2012).
}
scores of 25 or above were considered to have relatively high skill. A score of 25 puts students in the 80th percentile in national norms. Students categorized as having low ( \(M=21.1, \quad S D=2.91\) ) versus high math skill ( \(M=28.5\) \(S D=2.78\) ) differed significantly on the Math ACT, \(t(122)=\) \(14.46, p<.001\). Of the 45 groups, all students were considered to have low math skill in 11 groups, all students were considered to have high skill in 9 groups, and 25 groups had a mix of high and low skill members. Students were not informed about the nature of their group compositions.

Groups first worked on the invention task for 30 minutes, and discussions were video recorded for the Introductory Psychology groups. For all groups, the worksheets from the invention activity were collected. Following the invention activity, participants individually read through an overview of the standard deviation formula and a worked example of how to compute standard deviation. Following instruction, all students were given a quiz to assess learning outcomes. Two items asked students to apply the formula of standard deviation to a new problem about the weather, and a third item required them to use standard deviation to invent standardized scores in order to compare two students' test performances across different courses. Each item asked students to explain the mathematical reasoning behind their answers. This quiz served as the assessment of learning outcomes from the activity.

\section*{Solution Attempts and Quiz Performance}

Coding The group worksheets from the invention activity (and video protocols when available) were coded for their inclusion of a variety of different solution approaches to the problem. An initial coding scheme was developed based on categories used by Kapur (2012). It included 5 main categories: 1) computing central tendencies and sums, 2) graphical representations, 3) frequency counts, 4) computing differences between adjacent scores, and 5) computing ranges and deviations from the mean. The final coding scheme with 22 subcategories was established post hoc based on an examination of the solutions that were actually obtained so that each distinct solution type had its own subcategory. To score the data, coders assigned each solution attempt to one of the 22 codes. They then determined whether an instance of each subcategory was represented in the written artifacts or not using 0,1 coding. The total number of different solution approaches was computed by adding the number of subcategories that had at least one instance present in the worksheet or discussion (i.e., the total of the 0,1 coding across the 22 categories).

In addition, a task analysis of understanding the standard deviation formula was used to identify several critical insights that students might reach during their discussions. The first is that methods such as noticing a high score, graphing histograms or bar graphs, summing scores or computing central tendencies will not help or are not sufficient to quantify consistency. Noticing differences in the range of values across data sets is an important first step
toward understanding variance. Two other key insights are that variance is best computed in relation to some reference point (such as a mean), and that somehow variations in positive and negative directions need to be preserved so that they do not cancel out when summed. Based on this analysis, solution attempts that included recognition of range, deviations from the mean, and the need to consider absolute values were all categorized as being of higher quality, and a subtotal of higher quality solution approaches was computed in addition to the overall total number of different solution approaches.

Quiz responses were scored by categorizing each explanation according to the mathematical concept that was referenced. The same basic categories were applied across the 3 problems. Explanations that focused on central tendencies, sums, or maximum scores earned 1 point. Explanations that focused on ranges or differences between scores earned 2 points. If explanations included an incorrect approximation of the SD formula, they received 3 points. If explanations demonstrated a correct use of the SD formula they received 4 points. Combining across the three items, a maximum of 12 points could be reached and the final explanation quality composite score was computed as a proportion of that total. Cronbach's \(\alpha\) among the three quiz items was .80. Krippendorff's \(\alpha\) indicated good interrater reliability on all coding metrics ( \(>.77\) ).

Quiz Performance An ANCOVA showed a significant effect of group composition on quiz performance, \(F(2,123)\) \(=12.41, p<.01, \eta^{2}=.17\). Planned comparisons indicated that students in the all-low math groups had lower scores on the quizzes than students in either the mixed or all-high groups, who did not differ in quiz performance.
A follow-up analysis was performed to see if group heterogeneity affected low-skill and high-skill students differently. As shown in Figure 1, both high- and low-skill members seemed to benefit from participation in mixed groups. A \(2 \times 2\) ANCOVA (Math Skill \(x\) Group Heterogeneity) revealed two significant main effects. As might be expected, high skill students did better than low skill students, \(F(1,122)=28.44, p<.01, \eta^{2}=.19\). In addition, the main effect for group heterogeneity, \(F(1,122)\) \(=6.29, p=.01, \eta^{2}=.05\), and the lack of a significant interaction, \(F<1\), indicated that both high-skill and lowskill students benefited from working in heterogeneous (mixed) groups.

Solution Attempts Average totals of different solution approaches as a function of group composition are shown in Figure 2. Examples of the inscriptions made on worksheets during the different kinds of solution attempts are shown in Figure 3. An ANCOVA on the total number of different solution approaches showed a significant effect of group composition, \(F(2,41)=8.55, p=.001, \eta^{2}=.29\). Planned comparisons indicated that the mixed groups considered significantly more different solution approaches than the alllow and all-high groups, who did not differ.

Figure 1: Quiz performance by group composition
When only higher quality solution approaches were considered, a different pattern emerged. An ANCOVA on the number of higher quality representations included in the group worksheets showed a significant effect of group composition, \(F(2,41)=9.47, p<.001, \eta^{2}=.32\). Planned comparisons indicated that the all-low groups considered fewer different high-quality solution approaches than the all-high and mixed groups, who did not differ. Although the mixed groups also tended to include higher numbers of lowquality solution approaches, this effect did not reach significance, \(F(2,41)=2.76, p<.08, \eta^{2}=.12\).

Figure 2: Solution attempts by group composition
Mediational analyses suggested that it was the discussion of a wide range of solution approaches during learning-byinvention activities, including the number of higher quality solution attempts, that mediated the effects of group composition. Heterogeneity predicted the variety of representations, \(B=1.83(S E=.27), t(126)=6.61, p<.05\), and variety of representations predicted quiz performance, \(B\) \(=.02(S E=.01), t(126)=2.47, p<.05\). The total effect of heterogeneity on quiz performance was also significant, \(B=\) \(.09(S E=.03), t(126)=2.84, p<.05\). However, this relationship decreased to non-significance when the mediating influence of the variety of representations was included in analysis, \(B=.04(S E=.04), t(126)=1.23, p=\) . 22 .

Figure 3: Example inscriptions from solution attempts

In addition, the indirect effect (the mediated effect) of heterogeneity on quiz performance through representation variety was 0.05 ( \(\mathrm{SE}=0.02\) ), and the \(95 \%\) bias-corrected confidence intervals for the size of the indirect effect did not include zero, (.01, .08) which shows that the indirect effect was significant at a \(\mathrm{p}=.05\) level (Preacher \& Hayes, 2004, 2008; Shrout \& Bolger, 2002). Taken together, these findings provide evidence for full mediation. This analysis suggests that heterogeneity in groups led to better quiz performance because it affected the variety of solutions that were discussed during the learning-by-inventing activity. Additional analyses showed that the benefits of solution diversity during group discussion were demonstrated to contribute to better quiz performance even when the math ability of the students was taken into account.

\section*{Analyses of Group Interactions}

The second phase of analyseshas been attempting to understand conditions led to the success of the more diverse groups. In this pass through the data, the potential effects of group interactions, such as who emerges as a discussion leader, as well as the quality and content of group discussions, on learning outcomes are examined. Research on decision making groups using hidden profile paradigms has demonstrated the important role of leaders and experts in information sharing. For example, recognition of expertise has been found to be critical for increasing contributions to the group by expert members (Franz \& Larson, 2002). In addition, group members are more likely to share valuable information when they are assigned a high status position, such as a group leader (Wittenbaum, Hollingshead, \& Botero, 2004). This supports the hypothesis that the expertise of group leaders may be an important predictor of effective information sharing in learning-by-invention tasks that can subsequently influence learning outcomes. Differences in the group discourse and their relation to learning outcomes are also being explored.

Coding Discourse coding was performed on the 14 mixed group discussions for which video recordings were available. Leadership was operationalized by identifying the group member who contributed the largest proportion of utterances to the group discussion. Seven of the groups in the sample had a leader high in math skill, and seven of the groups had a leader low in math skill.
A second goal for the discourse analyses was to explore the content and nature of the discourse acts. Each utterance made by a group member was coded into one of the following categories: (a) solution proposal, (b) clarification request or response, (c) evaluative comment, (d) comment related to group task coordination, (e) calculation, (f) comment on expertise, (g) comment about being stuck or at impasse, or (h) off-task comment.

Leadership When the effects of these two leader types were examined, we found that groups with high math leaders discussed more high quality solution attempts ( \(M=3.00, S D\)
\(=.38)\) than groups with low math leaders \((M=1.57, S D=\) .79), \(t(12)=2.97, p<.05\). In terms of learning outcomes, members of groups with high math leaders scored higher on the quiz assessing their understanding of the standard deviation formula ( \(M=.82, S D=.16\) ) than members of groups with low math leaders \((M=.68, S D=.16), t(40)=\) \(2.78, p<.01\). The results of a \(2 x 2\) between-subjects ANOVA (math skill by leader type) with quiz performance as the dependent variable revealed no significant interaction \((F(1,38)<1)\), suggesting that the expertise of the leader benefited both high and low skill students similarly.

Content of Discussions On average, these groups contributed around 180 utterances during the invention discussion. Only about 10 of these utterances were proposals or amendments to proposals for solution methods. Almost half of the comments were clarifications or requests for clarifications about a proposed solution. About 30 were evaluations of suggested approaches. All other categories represented \(10 \%\) or less of the utterances.
Results from this discourse analysis suggest that groups who generated a wider range of solutions, proposed more solutions, made more clarifications of proposed solutions, and made fewer comments about being at impasse. A more interesting observation is that they also engaged in more discussion of task coordination. When explored in the context of leader type, groups with a high math leader made more comments related to task coordination, fewer comments about being at impasse, and devoted less discussion to determination of math expertise. Ongoing analyses are more specifically examining who contributes what to the discussion and when. Analyses suggest that low math students are the ones more likely to make comments about expertise, and also, surprisingly, that they are the ones more likely to contribute evaluations of the proposed solutions. This may account for why evaluative comments do not seem to relate to better performance in this sample. As the discourse analysis deepens and matures, this approach is hoped to generate a better understanding of what features of discussion may be critical for learning from invention, so that these features may be used to engineer the design of effective classroom invention activities.

\section*{Discussion}

The results of this research have shown that groups with members of different backgrounds or expertise may generate a broader range of solution approaches during invention tasks, and that this may benefit understanding of the canonical solution. Group composition in terms of math skill affects when students are able to get the most out of mathematical learning-by-invention activities. Students who worked in mixed groups were better at explaining their understanding of standard deviation on a quiz following the activity than students who worked in more homogeneous groups. Significant effects of group composition were seen in the variety of solution approaches that were considered by groups, particularly higher quality approaches.

Interestingly, it was the mixed groups who generated the widest variety of solution attempts, suggesting that they seem to be in a particularly good position to make the most of invention exercises. This is consistent with several other findings suggesting that diversity in expertise among group members contributes to more adaptive, flexible and creative problem solving (Canham, Wiley, \& Mayer, 2012; Goldenberg \& Wiley, 2011; Wiley \& Jensen, 2005; Wiley \& Jolly, 2003). Additionally, the consideration of a wider variety of solution approaches during the invention phase, including a larger number of higher quality approaches, predicted the uptake of a later lesson about the standard deviation formula and mediated the effects of group composition and diversity on learning.

To further explore the conditions that might enable effective learning from invention, we found that who emerges as the leader of a diverse group matters. Mixed groups with high math leaders discussed more high quality solution attempts as compared to groups with low math leaders. Interestingly, our discourse coding is also suggesting an important role for defining or coordinating the task among group members (c.f. Moreland \(\&\) Levine, 1992). Groups with high math leaders made more comments in relation to task execution which seemed to relate to their productivity. Yet, it is important to recognize that the leaders self-selected in this study and this can introduce many reasons why these particular groups may have been more or less effective. We are currently conducting a follow-up experiment, again in the context of statistics instruction as part of an undergraduate Psychology course, where we will be assigning high math and low math students to be leaders for the small group activity. Experimental assignment is critical for determining whether and how the expertise of the group leader itself may be important for effective learning from invention activities.

The results thus far suggest that generating a wide variety of approaches to solution may be one important factor determining whether invention discussions prepare students for later learning. Yet, in some cases a richer discussion around fewer alternatives may also lead to successful learning-from-invention, especially if the discussion leads to key insights. Alternatively, we have some evidence that a few of the groups seemed to benefit from the visual affordances of the graphical representations they made. It is possible that some specific kinds of solution attempts may be particularly helpful toward preparation for future learning (i.e., more visual ones or more abstract ones; Ainsworth, 2006, Schwartz, 1995).

The continued analysis of the discussion protocols is intended to serve as source of insight on what particular behaviors one may wish to support while students engage in learning-by-invention tasks. Thus far interactions among group members have not been scripted, roles have not been assigned, and students have not been given any specific direction how to engage in the task together. A next step that others have already begun pursuing (Kapur \& Bielaczyc, 2011; Roll, Aleven \& Koedinger, 2009) is to
provide some support to students in order to maximize the benefits of engaging in invention tasks, but not so much support that the benefits of invention over direct instruction are nullified. Indeed, in most of Webb's previous studies showing benefits of peer collaboration on learning in math, the peer interaction was carefully scaffolded which may have allowed for more stable benefits of mixed ability groups to emerge. One goal for the closer analysis of our discussion protocols is to gain an even better understanding of the conditions that facilitate learning by invention, and how we can capitalize on the intriguing possibility that exploration and failure can sometimes reap benefits toward more sophisticated conceptual understanding in mathematics and statistics.

\title{
Dual Processes in Mental State Understanding: Is Theorising Synonymous with Intuitive Thinking and is Simulation Synonymous with Reflective Thinking?
}

\author{

}

\begin{abstract}
In this paper we develop an idea first mooted by Wilkinson, Ball, and Cooper (2010), which is that the dichotomy between theorybased and simulation-based reasoning in the context of mental state understanding is synonymous with the distinction between intuitive and reflective thinking in dual-process accounts of human reasoning (e.g., Evans, 2010). To support this proposal we draw upon a range of concepts and findings deriving from both mainstream reasoning research and from studies of social cognition. We also consider the implications of our proposal for the formulation of an integrative approach to understanding reasoning in all of its many manifestations, whether undertaken for the attainment of socially-oriented goals or for the purposes of learning and discovery.
\end{abstract}

Keywords: Dual Processes, Intuitive thinking, Reflective thinking Simulation Theory, Theory Theory

\section*{Introduction}

The question of how we understand and reason about other people's minds has resulted in considerable debate within psychology and philosophy (e.g., Bach, 2011; Wilkinson, Ball, \& Cooper, 2010). Some researchers propose that such mental state reasoning is achieved through the adoption of tacit and non-tacit "theories" that are typically based around conditional inference rules (e.g., Carruthers, 1996). An example of such a theory might be that if someone fails to achieve something for which they have worked hard then they will feel upset. Other researchers, however, posit that mental state reasoning arises via a process of mental simulation. Such simulation might involve imagining how we would feel in a given situation and assuming that others are sufficiently like us that they will feel the same (e.g., Gordon, 1986). An alternative proposal (Goldman, 2006) is that we take our own beliefs and desires "offline", input the beliefs and desires of the other person, and thence reason as if we had the beliefs and desires of the other person. It is important to note that when we refer to "simulation" in the present paper we adopt a restricted notion that relates solely to the simulation of mental states, whether our own or other people's. We acknowledge that simulation can arise when reasoning in other domains such as design (e.g., see Ball \& Christensen, 2009), but we do not extend our discussion to this issue. Second, we note that the term "simulation" has different meanings to different authors. As explained by Goldman (2006), there is high-level simulation, which refers
to the type of simulation we are discussing in this paper, and also lower-level simulation, which refers to the functioning of mirror neurons when engaged in activities such as imitation. Mirror neurons are neurons that are activated both when we perform an action and when we observe the same action being performed (e.g., Gallese \& Goldman, 1998). Although we acknowledge the evidence for the existence of mirror neurons, we, like others (e.g. Saxe, 2005) are unsure of the explanatory power of this form of simulation.

Recently, theorists have started to move away from polarised views as to whether theorising or simulation is adopted in mental state reasoning and have instead acknowledged that both processes may be at play. This has resulted in a flurry of hybrid approaches appearing in the literature (e.g., Bach, 2011; Mitchell, Currie, \& Ziegler, 2009), which not only propose that both theorising and simulation can occur in mental state reasoning, but which also claim that there are content-based effects that govern the mechanism that is triggered. For example, Mitchell et al. (2009) have argued that we deploy simulation as a "default" process, using theorising in familiar situations. We have recently provided empirical support for a hybrid view in a study that required people to think aloud when reasoning about counterfactual scenarios pertaining to mental states (Wilkinson et al., 2010). Participants adopted both theorising and simulation for these scenarios, with content effects being evident in that more simulation and less theorising arose with scenarios involving "controllable" compared to "uncontrollable" events.

In the present paper we extend an argument first presented by Wilkinson et al. (2010) to the effect that the theorising versus simulation distinction is synonymous with the "intuitive" versus "reflective" distinction as described in contemporary dual-process theories of thinking and reasoning (see Evans, 2010, for an overview). According to the dual-process framework, intuitive thinking is classed as fast, automatic, high capacity, low effort and independent of working memory resources, whereas reflective thinking is classed as slow, controlled, low capacity, high effort and dependent on working memory. We argue here that these characteristics of intuitive and reflective thinking align well with key features of theorising and simulation in contexts associated with mental state understanding. In subsequent sections we support this proposal by drawing on concepts
and findings from contemporary reasoning research and from studies of social cognition. We suggest that conceptualising theorising and simulation in a dual-process manner has the potential to enable researchers to move towards a more compelling account of mental state reasoning that can be subjected to rigorous empirical examination. We conclude the paper by addressing issues that researchers might wish to consider further if they find merit in our proposed dual-process conceptualisation of the processes underpinning mental state understanding.

\section*{Proposed Parallels: Theorising as Intuition; Simulation as Reflection}

Evans (2010) describes multiple distinctions between intuitive and reflective reasoning and we take these distinctions as a foundation for demonstrating how one can arbitrate between theorising and simulation within a dualprocess framework. The first distinction that Evans notes is that intuitive reasoning is fast whereas reflective reasoning is slow. We similarly propose that theorising is a fast process whereas simulation is slower. This in turn is linked to the cognitive effort required for theorising and simulation. Like intuitive reasoning, which Evans proposes involves low cognitive effort, we view theorising as being low effort compared to simulation, which is high effort, much like reflective reasoning. Evans further argues that intuitive reasoning is high capacity and reflective reasoning is low capacity. We contend that the same holds for theorising and simulation, respectively. In addition, for people to engage in theorising they need to have a store of pre-existing theories pertaining to others' mental states, with these theories being drawn upon in an automatic manner when primed by particular contexts. Simulation, however, takes the form of a concurrent and incremental reasoning process (Goldman, 2006), which will require more controlled than automatic processing. Again, this distinction parallels the notion that intuitive reasoning is automatic whereas reflective reasoning is controlled. Evans has made further claims concerning the links between intuitive versus reflective reasoning and working memory. He argues that reflective reasoning is dependent upon working memory resources whereas intuitive reasoning is independent of such resources. We propose that this distinction holds for theorising and simulation too, with simulation being highly dependent upon working memory and executive functioning (e.g., Currie, 1996; Goldman, 2006).

\section*{Empirical Evidence for the Proposed Parallels}

A robust finding in the reasoning literature concerns the phenomenon of "belief bias", which is typically studied in relation to people's abilities at syllogistic inference. Within a standard conclusion-evaluation paradigm participants are presented with two premises that they should assume are true and an associated conclusion. They are then required to determine whether the conclusion follows logically from the premises. Many studies have shown that participants are biased by the conclusion's believability when making
evaluations, rather than reasoning on the basis of the conclusion's validity (e.g., see Stupple, Ball, Evans, \& Kamal-Smith, 2011).

Numerous dual-process accounts have been forwarded as to why belief-bias occurs (see Ball, 2011, for a review). For the purposes of our argument, however, we draw on the "selective processing model" of Evans (e.g., 2000), itself an example of a more general class of dual-process models referred to as "default-interventionist" theories (Evans, 2007). According to the selective processing model of belief bias, intuitive reasoning cues a response that may or may not be overridden by a reflective process. The default, intuitive response is to accept or reject conclusions based solely on their believability. If, however, reflective reasoning is applied then this reasoning is influenced by the conclusion's belief status such that participants will search for confirming models when a conclusion is believable and for disconfirming models when it is unbelievable. Whether a logically correct evaluation ensues for a problem is, therefore, dependent on the interplay between the intuitive and reflective processes, with certain problems (e.g., those with invalid but believable conclusions) being especially difficult because the belief status of the conclusion biases both the default response and the confirmation-oriented reflective response (Stupple et al., 2011).

We propose that in tasks of mental state reasoning people can be similarly biased by their personal beliefs. This is demonstrated by the so-called "curse of knowledge", whereby participants are unable to pass false belief tasks because they cannot inhibit viewing a situation from their own perspective (e.g., Birch \& Bloom, 2007). In such tasks (e.g., Baron-Cohen, Leslie, \& Frith, 1985) participants (typically young children) are introduced to two protagonists in a room, both of whom are aware of a particular state of affairs, such as a marble in a basket. Then one protagonist leaves the room and the remaining protagonist moves the marble to a box. The participant is asked, "Where will the protagonist who left the room look for the marble upon returning?" If the individual is able to reason about another person's beliefs then they should state that the protagonist will look for the marble in the basket. Individuals who fall foul of the curse of knowledge will respond by saying that the protagonist will look in the box (where they themselves know the marble is currently located), demonstrating a form of belief-biased reasoning. We suggest that overcoming this bias, especially when encountering such a situation for the first time, requires the deployment of a controlled process of mental simulation in which the reasoner takes their own beliefs off-line and reasons from the beliefs of the protagonist (e.g., Mitchell et al., 2009). This is equivalent, we propose, to the way that people can engage in reflective reasoning in an effort to overcome belief bias in syllogistic reasoning (Stupple et al., 2011), although, as noted above, even reflective reasoning does not guarantee success since it may itself be biased.

We now return to Evans' (2010) description of the characteristics of intuitive versus reflective reasoning in
order to assess the evidence for the proposed parallels between dual-process views and the theorising/simulation distinction in mental state reasoning. Evans argues that intuitive reasoning is fast whereas reflective reasoning is slow, a view that we propose aligns well with the theorising/simulation distinction. Evidence for our claim comes from Atkinson, Bell, and Feeney (2009), who examined the influence of a speeded-response requirement on how participants reasoned about counterfactual scenarios that were constructed to tap into two robust effects: (1) the "action effect", which is a tendency to regret action more than inaction in the short term (e.g., Kahneman \& Tversky, 1982), with the reverse being the case in the long term (e.g., Gilovich \& Medvec, 1994); and (2) the "temporal order effect" (e.g., Byrne, Segura, Culhane, Tasso, \& Berrocal, 2000), which is the tendency to attribute more negative affect to the person committing the final act in a sequence of actions when a negative outcome occurs. Atkinson et al. (2009) asked participants to reason about the presented scenario, which entailed reading a vignette describing two agents in a negative situation, either in a speeded condition, in which they had to answer as quickly as possible, or in a non-speeded condition, in which they were able to take as long as they wished. Whereas the temporal order effect was unaffected by the speed manipulation, the action effect was disrupted, with the actor selected significantly less in the speeded compared to the non-speeded condition. In relation to the temporal order manipulation we propose that participants uniformly access a "theory" that if a person acts last in a sequence of events leading to a negative outcome then they will feel worse. However, in the case of the action effect, we propose that participants need to run simulations of the mental states of both protagonists to evaluate the interplay between action/inaction and the time that events arose. Such an evaluation process is time-consuming relative to accessing a pre-stored theory, which would explain why the speeded-response requirement only affects the action effect and not the temporal order effect. These findings further demonstrate how a simulation may overturn an initial theory. The fact that the actor was chosen less often in the speeded compared to the non-speeded condition suggests that people held an initial theory that the non-actor would feel more regret, but when afforded the time to run simulations they could overturn this initial response, much as reflective reasoning can overturn an initial belief-biased response in syllogistic inference (Stupple et al., 2011).

The fact that simulation seems to be slower than theorising also speaks to likely discrepancies in the cognitive effort required for these reasoning types. We propose that theorising is low effort, like intuitive reasoning, whereas simulation is high effort, like reflective reasoning. As such, simulation will be dependent on general cognitive resources, including executive functioning and cognitive inhibition (e.g., Currie, 1996; Goldman, 2006) whereas theorising will work independent of such mechanisms. In addition, simulation will be dependent upon working memory whereas theorising will not. Evidence in support of
this claim comes from a study using the "director task" (Lin, Keysar, \& Epley, 2010), where participants are presented with a grid that contains slots that can be seen by both themselves and a director, who is actually a confederate. Some items, however, are only visible to the participant, since they are occluded from the director's view. Participants are instructed what object to move. On critical trials the perspective between director and participant differs so the director may say "move the small mouse" when there are three mice and only the smallest one can be seen by the participant. This requires the participant to engage in simulation by shifting their perspective to that of the director's in order to fulfill the instruction correctly.
Importantly, Lin et al. (2010) found that participants with higher working memory capacities performed better on the director task than those with lower working memory capacities. This provides a link between simulation and working memory that bears strong similarities to the link between reflective reasoning and working memory. For example, De Neys (2006) has shown that individuals with greater working memory resources perform better on belieforiented syllogistic reasoning tasks, and Stanovich, West, and Toplak (2011) have argued that reflective reasoning is dependent upon executive functioning resources. We propose that just as the intuitive/reflective distinction is associated with differential involvement of working memory, so too is the theorising/simulation distinction.
Theorists proposing dual-process accounts of reasoning have also recently begun to draw upon neuroscientific evidence to support their claims. For example, Goel (2003) has presented evidence for "dual pathways" in syllogistic reasoning, with intuitive processes associated with the frontal-temporal pathway and reflective processes associated with the parietal pathway. In a review article, Goel (2007) acknowledges that the question of which neural regions are responsible for particular types of processing is one that has demonstrated differing findings, but that the evidence nevertheless points towards a fractionated system for deductive reasoning rather than a unitary one.
Neuroscientific evidence for theorising and simulation in mental state reasoning is equally complex and has been criticised for failing to provide a clear differentiation between brain regions specialised for such processing (e.g., Apperly, 2008; Wilkinson \& Ball, 2012). Nevertheless, findings are suggestive. For example, Mitchell, Banaji, and Macrae (2005), found that the ventral medial prefrontal cortex was activated when participants made judgements concerning facial expressions. This provides evidence of a partial locus for theory-based reasoning, since an intuitive judgement is all that would be required for this task, with no simulation being necessitated. We believe that our claims for the intuitive/theorising parallels here are strengthened by the observation that this brain region is also known to be activated in syllogistic reasoning tasks when participants provide belief-biased responses (e.g., Goel \& Dolan, 2003).
As for simulation in mental state reasoning, it is admittedly not easy to locate a specific brain region
responsible for such processing. Part of the difficulty originates from the differing conceptualisations of simulation within the literature, with some theorists (e.g., Gallese \& Goldman, 1998) arguing for lower-level simulation (Goldman, 2006). Studies of higher-level simulation in paradigms such as the director task suggest the involvement of a number of brain regions, including the superior dorsal medial prefrontal cortex and the superior/middle temporal sulci extending to the extrastriate body area and the posterior superior temporal sulcus (Dumontheil, Küster, Apperly, \& Blakemore, 2010). Admittedly, the evidence for the localisation of simulation is not clear-cut, but again is suggestive of distinct brain regions being associated with theorising and simulation.

Figure 1: A schematic representation of a hybrid dualprocess model of theorising and simulating.

\section*{Issues Arising from the Proposed Parallelism}

In the previous section we outlined how Evans' (2010) distinction between intuitive and reflective thinking can map onto the concepts of theorising and simulation in mental state reasoning. However, there is still much for theorists to consider if they see benefits in examining such apparent parallels more extensively. In this respect we note that reasoning researchers have now begun to move away from normative accounts of human reasoning towards a descriptivist agenda (e.g., Elqayam \& Evans, 2011). We generally support this approach and suggest that using theorising and simulation within a descriptivist dual-process framework affords an opportunity to develop a rich and innovative programme of empirical and theoretical research. However, several questions need to be borne in mind when pursuing such a project, which we consider below.

A first, critical question is this: exactly how do theorising and simulation function within a dual-process framework? The reasoning literature contains both sequential and parallel dual-process models of phenomena such as belief bias. Sequential models of the default-interventionist variety propose that intuitive reasoning generates a default response
and that reflective reasoning serves either to confirm or override this initial judgement (e.g., Evans, 2006). Parallel models (e.g., Sloman, 2002; Stupple \& Ball, 2008) propose that intuitive and reflective reasoning compete in generating a response. Evans (2009) has also proposed a "hybrid" dualprocess model, which combines sequential and parallel processes. We think it likely that theorising and simulation can operate both sequentially and in parallel such that a hybrid model may capture key subtleties most effectively (see Figure 1). We propose an initial stage of pre-attentive theorising, whereby representational structures such as scripts and schemas are attended to before a decision is made to apply further theorising or simulation. If a theory is insufficient for generating an inferential response then people can switch to first-person or third-person simulation, with the possibility of returning to theorising. A simulation might also override an initial theory-based response. Furthermore, we follow Mitchell et al. (2009) in suggesting that there will be occasions when an appropriate theory is unavailable, such that people will have to engage in simulation to make some kind of inference. Our model therefore operates in a highly content-dependent manner.

Undoubtedly, empirical evidence needs to be provided for the model presented in this paper. In fact, this model grew out of a series of experiments that we conducted, including one reported by Wilkinson et al. (2010), which showed that people simulate more when reasoning about scenarios involving controllable rather than uncontrollable events, with the reverse pattern for theorising. We propose that our model can readily accommodate such evidence for contentdependency in mental-state reasoning. We suggest that more simulation is evoked for controllable events because participants are more readily able to engage in hypothetical thinking and planning in relation to such scenarios, whereas in the case of uncontrollable events participants are likely to engage in the extraction of a theory since there is little more that they are able to do. Wilkinson et al. (2010) also found that participants often switched between theorising and simulation within the same response. This finding aligns well with Figure 1, which can accommodate this process and the inter-dependence of theorising and simulation in that participants may start out theorising and then adopt simulation to develop their answer further. Furthermore, Wilkinson et al. (2010) noted that participants' theory-based responses tended to be much quicker than their simulationbased responses. This is explicable given that the extraction of theories is assumed to arise in a high-capacity but loweffort manner, whereas simulation is assumed to be more involved, requiring a longer and more controlled reasoning process (e.g., Goldman, 2006). We acknowledge, however, that such claims would benefit from corroboration via the deployment of chronometric measures.

A further important issue in relation to theorising and simulation processes within a hybrid model is whether these processes operate independently or whether there are dependencies, with the output of one process determining the likelihood of deploying the other process (see Elqayam,

2009, for a discussion of this issue in the context of dualprocess theories of reasoning). It is too soon to speculate on this matter, although what has been established in our own research using think-aloud techniques is that people are readily inclined to switch between theorising and simulating within the same reasoning task (Wilkinson et al., 2010). This evidence is at least suggestive of a degree of interdependence between the two processes.

We finally turn to the question of what happens in our proposed model when conflict arises between theorising and simulation. For example, imagine a scenario in which a student fails an important assignment and where our inferential goal is to understand what they might be feeling. Using theorising we might infer that the person will be upset, since if someone fails to pass an assessment they are likely to be distraught. However, if we are also presented with the information that the individual spent every evening drinking in the pub during the week prior to the assignment deadline, we may run a simulation of the person's mental state to draw the conclusion that the assignment was not of much importance to them. We propose that when such conflict arises a "type 3" conflict-resolution process comes into play (see Evans, 2009). This process would arise subsequent to processes of theorising and/or simulation, but before the generation of a final response. In this way it would be possible for simulation to override a theory-based decision when conflict occurs between the two processes, much as reflective reasoning can override a belief-oriented response in syllogistic inference tasks (e.g., see Ball, 2011).

\section*{Conclusions}

We have presented arguments for why theory-based reasoning can be viewed as synonymous with intuitive reasoning and simulation-based reasoning can be viewed as synonymous with reflective reasoning within a dual-process framework. This argument was originally advanced by Wilkinson et al. (2010), but we have extended it here so as to provide a more complete and compelling explanation of the parallels between these two hitherto separate conceptual dichotomies. We have additionally considered some of the key questions that need to be addressed by researchers who see value in exploring these suggested parallels further.

Our proposals also resonate with recent calls for greater integration between theorising and simulation accounts of social cognition (Bach, 2011). Bohl and van den Bos argue that the general notion of "theory of mind" is primarily focused on type 2 processing (reflective thinking) rather than type 1 processing (intuitive thinking). We contest this point and instead propose that the traditional distinction between theory-based and simulation-based inferences is best viewed as aligning with the intuitive (type 1) versus reflective (type 2) distinction.

In terms of the development of dual-processes, Evans (2011) has stated that he does not wish to propose that reflective reasoning replaces intuitive reasoning, but rather that the two co-occur in adulthood. This proposal is similar to Mitchell et al.'s (2009) claim that theorising and
simulation operate side-by-side in adulthood. Of course, it is difficult at this point to map out a developmental progression of intuitive and reflective reasoning. Mitchell et al. propose that we start out by simulating and Bach (2011) has suggested that theories may grow out of repeated simulations. These ideas initially seem counterintuitive, since simulation is so dependent upon general cognitive resources (Currie, 1996; Goldman, 2006), which tend not to be well developed in young children. However, the claim is not that children necessarily make correct inferences; indeed false belief studies show that they start out by giving incorrect responses by answering from their own perspective (Mitchell et al., 2009). When it comes to the development of intuitive and reflective reasoning the pattern should, of course, align fully with that for theorising and simulation, with reflective reasoning developing first and intuitive reasoning later, which does seem to capture aspects of the development of expertise. For example, when one first learns to drive a car the process is deliberate and controlled, but after time things become automated. We propose that this represents a shift from deliberate reflection to automatic intuitive reasoning.

We trust that by advancing an account of how theorising and simulation align with intuitive and reflective thinking we have provided inspiration for future empirical work and theoretical development and will enliven future discussion concerning the processes involved in mental state reasoning.

\begin{abstract}
We investigate the effects of explaining anomalies (i.e., observations that conflict with current beliefs) on belief revision, and in particular how explaining contributes to the rejection of incorrect hypotheses, the generation of alternative hypotheses, and the selection of a hypothesis that can account for anomalous observations. Participants learned how to rank students across courses using statistical concepts of deviation, and did so while either explaining sample rankings or writing their thoughts during study. We additionally varied whether or not candidate hypotheses about the basis for ranking were presented to participants prior to learning, and the number of sample rankings that violated intuitive misconceptions about ranking. Measures of learning and coded responses suggest that prompting people to explain can increase the rate at which they entertain both correct and incorrect hypotheses, but that explaining promotes the selection of a hypothesis that can account for anomalous observations.
\end{abstract}

\section*{Introduction}

A critical element of successful learning is the ability to flexibly revise beliefs in light of new data and experience. For example, a mathematics student might form tentative beliefs about how to solve a novel problem, but subsequently revise these beliefs in the face of anomalous data: observations that conflict with working assumptions and therefore signal a need to revise beliefs (Chinn \& Brewer, 1993; Koslowski, 1996). Here we consider how beliefs are revised in light of anomalous observations, and in particular how explaining such observations influences learning.

Generating explanations has been shown to promote learning across a range of tasks and domains, with evidence from experimental studies of category learning (Williams \& Lombrozo, 2010), "self-explaining" in students (e.g., Fonseca \& Chi, 2011), and conceptual development in children (e.g., Siegler, 2002; Wellman \& Liu, 2007). These benefits are likely to derive from multiple sources, including increased engagement and increased accessibility of effective strategies (Siegler, 2002), better metacognitive monitoring (e.g., Chi et al, 1994), and the generation of inferences to fill gaps in understanding (e.g., Chi et al, 2000), among others.

In the present work we build on the Subsumptive Constraints account of explanation developed in prior research (Williams \& Lombrozo, 2010, 2013). According
to this account, explaining a particular observation drives learners to interpret it as an instance of a broad pattern or generalization, and thereby facilitates learning about regularities that apply broadly (Williams \& Lombrozo, 2010; 2013; Williams, Lombrozo \& Rehder, 2013).

To illustrate, consider the findings reported in Williams and Lombrozo (2010). Participants attempted to learn a new classification system involving two categories that could be differentiated by a rule with no exceptions ( \(100 \%\) rule) or an alternative that accounted for most cases, but with two anomalies ( \(75 \%\) rule). Participants who were prompted to explain were significantly more likely to discover the \(100 \%\) rule than those prompted to describe the category members, think aloud, or engage in free study. These findings confirm the prediction that explaining facilitates learning about broad patterns, and also suggest that explaining could make learners especially sensitive to anomalies, as they signal that current beliefs are either false or limited in scope.

Subsequent research, however, suggests a more complicated relationship between explanation and anomalies. Williams and Lombrozo (2013) found that participants prompted to explain favored patterns consistent with prior knowledge, even when such patterns had exceptions (anomalies) that were better explained by alternative patterns. Williams, Lombrozo, and Rehder (2013) found that participants prompted to explain were more likely to overgeneralize broad patterns, effectively ignoring exceptions, even when this resulted in slower and less accurate learning.

Explaining seems to therefore have opposite effects: by encouraging learners to seek broad patterns, explaining can sometimes lead to greater belief revision in light of anomalies, and at other times to the anomalies being effectively dismissed or "explained away" (see also Chinn \& Brewer, 1993; Khemlani \& Johnson-Laird, 2012; Koslowski, 1996). As a first step towards understanding the conditions under which explanation has each effect, Williams, Walker, and Lombrozo (2012) investigated how changing the number of anomalous observations presented interacted with a prompt to explain. We begin by briefly reviewing the results from this study, and additionally present novel analyses concerning participants' coded explanations. We then present a new experiment aimed at differentiating two potential roles for explanation: one in the rejection of current hypotheses in light of anomalies, and another in the generation and selection of new hypotheses.

\section*{Explaining anomalies: Previous findings}

In previous work, we explored the effects of generating explanations for observations that were anomalous with respect to learners' prior beliefs about statistical measures (Williams, Walker, \& Lombrozo, 2012). Participants learned a university's ranking system by studying how pairs of students from different courses had been ranked given the students' grades and the means and standard deviations of their respective courses. The task required learners to compare student grades using concepts analogous to z -scores, and therefore to reject commonly endorsed but non-normative principles for ranking. These non-normative principles included ranking students based on the higher raw score, the greater number of points above the course mean, or closeness to the maximum course score (Schwartz \& Martin, 2004).

A realistic and experimentally useful feature of this task was that participants could encounter ranked student pairs that were either consistent or anomalous with respect to the non-normative principles for ranking. In many ranked student pairs, the student who is a greater number of standard deviations above the mean will also have a higher raw score, be farther from the mean, or closest to the maximum. We call sample rankings that are consistent with all of the identified ranking principles consistent items, and those that are only consistent with the use of \(z\) scores anomalous items because they are anomalous with respect to many participants' prior beliefs (see Fig. 1).

Williams, Walker, and Lombrozo (2012), henceforth WWL12, presented participants with five examples of ranked pairs of students to learn a university's method for ranking students. Participants' study task was either to explain why the higher ranked student was ranked higher, or to write thoughts they had while studying the pair. Of the five example pairs, there was either a single anomaly (and four consistent pairs) or multiple anomalies (four anomalies, one consistent pair). WWL12 found that belief revision was greatest when participants explained and received multiple anomalies. Explaining did not promote belief revision when only a single anomaly was presented,
(a) Sarah got \(85 \%\) in a Sociology class, where the average score was \(79 \%\), the average deviation was \(3 \%\), the minimum score was \(67 \%\), and the maximum score was 90\%.

Tom got \(69 \%\) in a Art History class, where the average score was \(65 \%\), the average deviation was \(8 \%\), the minimum score was \(42 \%\), and the maximum score was \(87 \%\).

Sarah was ranked more highly by the university than Tom.
and multiple anomalies had no effect on learning unless participants explained.

While these findings suggest that explaining may be especially potent for ensuring that learners process anomalies and use them in updating beliefs, there are several reasons why explaining might have this effect.

Explaining anomalies could be improving accuracy by increasing the rejection of the non-normative principles that were inconsistent with the anomalies, or by increasing the generation and selection of the normative principle. Either of these would account for the observed belief revision, and in fact, the effects could be due to a combination of both.

To evaluate these possibilities, we report here the results of coding the written responses that participants provided in the explain and write thoughts conditions. We coded for whether participants mentioned any of the nonnormative principles and whether they identified standard deviation as playing an important role in rankings.

\section*{Verbal Response Coding}

Each of the five written responses participants provided during the study phase of the experiment was coded according to the following criteria: whether a response mentioned a non-normative principle, whether it mentioned the relative-to-deviation principle (i.e., standardized z-scores, whether or not participants used technical terminology to convey the idea), and whether it contained some other response, such as expressions of surprise or confusion, disagreement with the ranking, or mention of other features of the pairs.

Non-Normative Principles The three non-normative principles were incorrect but designed to correspond to intuitive statistical misconceptions. We term the principles (1) raw-score: the higher ranking went to the student with the higher score, irrespective of mean, average deviation, and minimum or maximum score; (2) relative-to-average: the higher ranking went to the student whose score was the farthest above (or least
(b) Sarah got \(85 \%\) in a Sociology class, where the average score was \(79 \%\), the average deviation was \(8 \%\), the minimum score was \(67 \%\), and the maximum score was \(90 \%\).

Tom got 69\% in a Art History class, where the average score was \(65 \%\), the average deviation was \(3 \%\), the minimum score was \(42 \%\), and the maximum score was \(87 \%\).

Tom was ranked more highly by the university than Sarah.

Figure 1: (a) A consistent ranked example for which all four principles predicted the same ranking. (b) An anomalous ranked example constructed by switching the class average deviations of the consistent example from (a). The switch means that the correct relative-to-deviation ranking is now the opposite of what is predicted by the raw-score, relative-to-average, and relative-to-highest-score principles. Emphasis is added for illustration and was not provided to participants.
below) the class's mean score; (3) relative-to-highestscore: the higher ranking went to the student whose score was the closest to the highest score achieved in the class.

Relative-to-Deviation Principle According to this principle, the better student was the one who scored a greater number of standard (average) deviations above the mean (see Schwartz \& Martin, 2004; Belenky \& NokesMalach, 2012). This was calculated as the difference from the mean divided by the average deviation, and is closely related to a normative measure like the \(z\)-score.

\section*{Response Coding Results}

Principles Cited A task (2: explain, write thoughts) x number of anomalies (2: single, multiple) x principle type (non-normative, relative-to-deviation) mixed ANOVA was conducted on the proportion of responses that mentioned each type of principle (see Fig. 2).

This analysis revealed main effects of task, \(F(1,272)=\) 43.98, \(p<0.001, \eta_{\mathrm{p}}^{2}=0.14\), and number of anomalies, \(F(1,272)=37.15, p<0.001, \eta_{\mathrm{p}}^{2}=0.12\). Overall, explaining increased mention of principles, while multiple anomalies led to decreased mention of principles.

There was also a main effect of principle type, \(F(1\), \(272)=49.90, p<0.001, \eta_{\mathrm{p}}^{2}=0.16\), with non-normative principles mentioned more frequently than the relative-todeviation principle. However, this effect was qualified by an interaction between number of anomalies and principle type, \(F(1,272)=40.52, p<0.001, \eta_{\mathrm{p}}^{2}=0.13\). We therefore conducted separate task x number of anomalies ANOVAs for the two principle types.

Non-normative principles were cited more often by participants prompted to explain, \(F(1,272)=19.03, p<\) \(0.001, \eta_{\mathrm{p}}{ }^{2}=0.07\), and less often by those who encountered multiple anomalies, \(F(1,272)=96.49, p<0.001, \eta_{\mathrm{p}}{ }^{2}=\) 0.26 , with no interaction.

The relative-to-deviation principle was also cited more often in the explain condition, \(F(1,272)=13.14, p<\) \(0.001, \eta_{\mathrm{p}}{ }^{2}=0.05\), with no significant effect of the number of anomalies, \(F(1,272)=1.89, p=0.17, \eta_{\mathrm{p}}{ }^{2}=0.01\).

Number of Different Principles Cited A task x number of anomalies ANOVA was performed on the mean number of different principles cited by each participant (see Fig. 3). Participants prompted to explain mentioned a greater number of different principles, \(F(1,272)=16.20\), \(p<0.001, \eta_{\mathrm{p}}^{2}=0.06\), and multiple anomalies resulted in mention of fewer different principles, \(F(1,272)=31.36, p\) \(<0.001, \eta_{\mathrm{p}}{ }^{2}=0.10\). There was also a task x number of anomalies interaction: explaining robustly increased the number of different principles mentioned in the multiple anomalies condition, \(t(125)=3.97, p<0.001, d=0.70\) ), while the effect in the single anomalies condition was not significant, \(t(147)=1.55, p=0.12, d=0.25\).

Figure 2: Data from WWL12: Mean proportion of responses citing either a non-normative principle (upper panel) or the relative-to-deviation principle (lower panel).

Figure 3: Data from WWL12: Mean number of different principles mentioned by each participant.

\section*{Summary and Discussion}

The results of coding responses from WWL12 suggest that the effects of explanation on learning are not principally a consequence of rejecting principles in light of anomalies, at least not in this kind of task. Explaining increased the rate at which participants mentioned the correct relative-to-deviation principle, but also how often participants mentioned non-normative principles, and how many different principles were cited. Instead, it appears that explanation played an important role in the generation of multiple hypotheses and the selection of the correct hypothesis from among them.

We now present a new experiment that aims to better understand the role of explanation in generating the correct hypothesis as opposed to evaluating and selecting the correct hypothesis from among candidates. In order to do so, we replicate the basic design of WWL12 with an additional manipulation: whether or not participants are
presented with a fixed set of candidate hypotheses, including the relative-to-deviation principle, prior to learning.

\section*{Experiment}

Our experiment manipulated whether participants were asked to explicitly consider potential ranking principles before engaging in learning. Specifically, participants in the exposure condition were presented with descriptions of five candidate principles and rated their plausibility. Participants in a no exposure condition completed the task without this initial presentation of candidate hypotheses, effectively replicating WWL12 (see Bonawitz \& Griffiths, 2010, for a similar manipulation).

As in WWL12, we additionally varied whether participants received instructions to explain or to write thoughts, and whether they encountered a single anomaly or multiple anomalies during study.

If the main role of explanation in WWL12 was to facilitate the generation of candidate hypotheses - and therefore of the relative-to-deviation principle - then the exposure manipulation should mimic effects of explanation in the write thoughts condition, and potentially eliminate differences across study conditions. In contrast, if explaining principally or additionally plays a role in the evaluation and selection of the correct hypothesis (i.e., the relative-to-deviation principle, which accounts for all observations), then we should observe effects of explanation even in the exposure condition.

\section*{Methods}

Participants Seven-hundred-and-twenty-seven members of the Amazon Mechanical Turk community participated in exchange for monetary compensation. Four-hundred-and-eighty additional participants were excluded for failing an instructional manipulation check adapted from Oppenheimer et al. (2009) and designed to evaluate whether participants were reading instructions. The number of excluded participants did not differ as a function of condition, all \(p \mathrm{~s}>0.10\).

Materials \& Procedure The materials and procedure mirrored WWL12, except as noted.
Pre-Test. Participants were presented with ten unranked student pairs and judged how likely the university would be to rank one student above another, on a nine point scale ranging from "Definitely student [X]" to "Definitely student [Y]," with a midpoint of "Equally Likely."

Unlike WWL12, six pre- and post-test items pitted the relative-to-deviation principle against a single one of the non-normative principles, with the other two nonnormative principles predicting that the students were equally ranked. Of the ten pairs, two pitted the relative-todeviation principle against the raw-score principle; two against the relative-to-average; and two against the close-to-highest-score. Four pairs were like the anomalous
study pairs in pitting the relative-to-deviation principle against all three non-normative principles.

Pre-Exposure to Principles. In the exposure condition, after the pre-test and before the study phase, participants were shown an example pair of students and told who was ranked higher. This ranking was consistent, similar to the example in Figure 1a. Participants were then presented with five potential rules the university could use to rank students, and asked to judge, on a scale from 1-7, how likely it was that the university used that particular rule. The rules included all four principles discussed above, as well as an additional average-plus-deviation principle \({ }^{1}\), which favored whichever student was the greater number of percentage points above the average plus average deviation.

Study. Each of the five ranked examples was presented onscreen for exactly 90 seconds in a format similar to Figure 1a and 1b. Participants in the explain condition were prompted to explain why the higher-ranked student was ranked more highly, typing their explanation into a text box onscreen. Participants in the write thoughts control condition were told to type their thoughts during study into an equivalent text box.

Post-Test. The post-test was identical to the pre-test, but all student names and grades were changed, with five points added to each grade to generate novel numbers while preserving the way in which the items pitted the principles against each other.

Additional Measures. Additional questions were asked at the end of the experiment (e.g., demographics, sufficient time for task, strategy) but are not discussed here in the interest of space.

\section*{Results}

Learning Pre-test accuracy did not differ significantly as a function of condition (all \(p \mathrm{~s}>0.2\), mean \(=-.90\) ); we subsequently consider the change in pre- to post-test accuracy as our measure of learning.

A task x number of anomalies x exposure ANOVA on the pre- to post- test change in accuracy found main effects of explanation, \(F(1,719)=15.06, p<0.001, \eta_{p}^{2}=\) 0.02 , and number of anomalies, \(F(1,719)=29.59, p<\) \(0.001, \eta_{\mathrm{p}}^{2}=0.04\), with no significant effect of exposure, \(F(1,719)=1.81, p=0.18, \eta_{\mathrm{p}}^{2}<0.01\), nor interactions (see Fig. 4). Participants prompted to explain showed greater learning than those who were not so prompted (whether they observed one or multiple anomalies), and

\footnotetext{
\({ }^{1}\) We thank Daniel Belenky (personal communication) for suggesting this as an additional principle that participants might find compelling and spontaneously employ.
}
participants who saw multiple anomalies learned more as well (whether or not they explained).

Principles Cited To analyze the relative frequencies with which non-normative and normative principles were cited in each response, we conducted a repeated-measures ANOVA with principle type (non-normative principle, relative-to-deviation principle) as a within-subjects factor and task (2), number of anomalies (2), and exposure (2) as between-subjects factors. This analysis revealed a fourway interaction, \(F(1,717)=8.01, p<0.01, \eta_{\mathrm{p}}^{2}=0.01\). We therefore conducted separate task x exposure x principle ANOVAs for the single anomaly and multiple anomalies conditions.

In the single anomaly condition, this analysis revealed that explaining promoted overall mention of principles, \(F(1,448)=13.44, p<0.001, \eta_{\mathrm{p}}^{2}=0.03\), and that nonnormative principles were mentioned more frequently than the relative-to-deviation principle, \(F(1,448)=67.30\), \(p<0.001, \eta_{\mathrm{p}}{ }^{2}=0.13\). There were no other significant effects - in particular, the effect of exposure was not significant, \(F(1,448)<0.01, p=0.99, \eta_{\mathrm{p}}^{2}<0.01\).

In the multiple anomalies condition, there was a task x exposure x principle interaction, \(F(1,269)=5.28, p<\) \(0.05, \eta_{\mathrm{p}}^{2}=0.02\). Participants who explained and were exposed to the hypotheses beforehand were more likely to mention the relative-to-deviation principle over the nonnormative principles, relative to those who explained without exposure. A task x exposure ANOVA for just non-normative principles revealed a main effect of explaining, \(F(1,269)=5.66, p<0.05, \eta_{\mathrm{p}}^{2}=0.02\), and a significant interaction, \(F(1,269)=7.76, p<0.05, \eta_{\mathrm{p}}{ }^{2}=\) 0.03 . For the relative-to-deviation principle, there was only a main effect of explaining. \(F(1,269)=10.03, p<\) \(0.01, \eta_{\mathrm{p}}^{2}=0.04\).

Number of Different Principles Cited The average number of different principles cited was analyzed with a 2 (task) by 2 (number of anomalies) by 2 (exposure) ANOVA, which revealed more principles in the explain condition than the write thoughts condition, \(F(1,712)=\) 26.73, \(p<0.001, \eta_{\mathrm{p}}^{2}=0.04\), with a marginal effect of exposure, \(F(1,712)=2.81, p=0.09, \eta_{\mathrm{p}}^{2}<0.01\). There was also an interaction between task and exposure, \(F(2\), \(712)=4.51, p<0.05, \eta_{\mathrm{p}}{ }^{2}=0.01\) : explanation's boost in number of principles cited was considerably attenuated when participants were exposed to the principles before study. This finding suggests that participants did attend to the exposure task, even though it did not affect learning.

\section*{Relationship Between Coded Responses and Learning} To investigate the relationship between participants' responses to the explain and write thoughts prompts and their learning as reflected on the post-test, we examined correlations and partial correlations between response types and accuracy. The largest contributor to post-test accuracy was the proportion of responses citing the
relative-deviation-principle, \(r(725)=0.60, p<0.001\), followed by the negative effect of the proportion of responses citing the non-normative principles, \(r(725)=-\) \(0.38, p<0.05\). Even conditioning on pre-test accuracy, task, number of anomalies, and exposure, post-test accuracy was positively correlated with citing the

Figure 4: Change in accuracy from pre- to post-test. Non-normative principles

Figure 5: Mention of non-normative principles and the relative-to-deviation principle (per-response).

Figure 6: Number of different principles mentioned by each participant.
relative-to-deviation principle, \(r(640)=0.45, p<0.001\), and negatively correlated with citing non-normative principles, \(r(640)=-0.26, p<0.001\). These findings suggest that coded responses reflected learning, and are at least consistent with the stronger claim that producing the responses was itself a causal factor in driving learning.

\section*{Discussion}

The current study found that participants who were prompted to explain reliably outperformed those in a write thoughts control condition when it came to learning how a university ranked students, a task that required some understanding of population variance or deviation. Although the current data suggest a trend for a larger effect of explanation in the multiple (vs. single) anomaly condition, the interaction was not significant, as it was in WWL12, where explanation facilitated belief revision significantly more when there were multiple anomalies rather than a single anomaly. With respect to one of the main issues that motivated this research - i.e., specifying the conditions under which explaining leads to greater versus less belief revision - our findings are therefore inconclusive.

Nonetheless, the current work provides novel data from participants' coded responses to the explain and write thoughts prompts, which shed light on the role of explanation in rejecting incorrect hypotheses, generating candidate hypotheses, and selecting the correct hypothesis. If it were the case that explaining anomalous observations made learners more likely to reject hypotheses that failed to account for those observations, then we might have expected that prompting participants to explain would lead them to mention non-normative principles less often than participants in the control condition..Instead, we found that participants prompted to explain were more likely to produce non-normative principles, and also more likely to produce a larger number of different principles. This result - found in WWL12 and replicated again here - suggests that explanation instead played a role in the generation and selection of the correct hypothesis concerning ranking.

Our new experiment helped isolate effects of explanation due to hypothesis generation from those of hypothesis selection. We found that "generating" candidate hypotheses for learners did not mimic effects of explanation; explanation improved learning even when candidate hypotheses were provided in both study tasks. This finding suggests that explaining may be playing an important role in the comprehension or selection of the correct hypothesis (see also Siegler, 2002).

\title{
Impulsivity and Overall Similarity Classification
}

\author{

}

\begin{abstract}
It is sometimes argued that implementation of an overall similarity classification is less effortful than implementation of a single-dimension classification. One piece of evidence taken to be in support of this argument is that highly impulsive individuals appear to be more likely to sort on the basis of overall similarity than individuals with low impulsivity (Ward, 1983); presumably, higher impulsivity results in lower effort. In the current article, we identify some limitations in Ward's procedure and, using a more standard measure of impulsivity and a less ambiguous measure of overall similarity classification, re-investigate the relationship between impulsivity and overall similarity classification. Using a match-tostandard procedure, the current experiment finds that overall similarity classification is less prevalent in highly impulsive individuals. The implications of this result, which is opposite to that reported by Ward (1983), are discussed.
\end{abstract}

Keywords: impulsivity; categorization; overall similarity; family resemblance.

In a seminal article, Brooks (1978) argued for two different processes of categorization. In analytic categorization, the participant separates aspects of the stimulus and evaluates their ability to predict category membership. This process of analysis, Brooks assumed, will typically lead to a subset of the stimulus attributes controlling responding. In contrast, nonanalytic categorization is the process of predicting category membership on the basis of overall similarity to known examplesa process that results in all stimulus attributes having some control over responding. Brooks hypothesized that nonanalytic categorization would be more likely to occur where cognitive resources were limited.

Brooks's hypothesis is striking because it assumes that a categorization process that employs all the information in the stimulus (overall similarity) is less effortful than a categorization process that employs a subset of that information (analytic, or "rule-based", categorization). Following Wills, Milton, Longmore, Hester, and Robinson (2013), we describe this as the less-is-more hypothesis-for example, less time spent categorizing objects results in more information from those objects having control over responding (Smith \& Kemler Nelson, 1984). We contrast this with the more-is-more hypothesis-for example, more time spent categorizing objects results in more information from those objects having control over responding (Milton, Longmore, \& Wills, 2008).

The current paper revisits one particular plank in the less-is-more argument; namely, the result reported by

Ward (1983) that highly impulsive individuals are more likely to classify on the basis of overall similarity than individuals with low impulsivity. This result appears to support the less-is-more hypothesis because, presumably, impulsive individuals devote fewer cognitive resources to the categorization task than do reflective individuals.

We had two concerns about Ward's demonstrationthe validity of the measure of impulsivity, and the validity of the measure of overall similarity classification. Below, we outline those concerns, and describe how we addressed them in the current study.

\section*{Impulsivity}

Ward used the Matching Familiar Figures measure of impulsivity (Kagan, 1965), a measure whose validity has been questioned (e.g. Block, Block, \& Harrington, 1974) and which appears to be largely uncorrelated with better validated measures of impulsivity (Helmers, Young, \& Pihl, 1995). In the current study, we employed the Barratt Impulsivity Scale (BIS-11), which is the most widely used measure of impulsivity (Stanford et al., 2009). It has high reliability and good external validity (Patton, Stanford, \& Barratt, 1995). The Barratt Impulsivity Scale is a self-report measure that includes statements such as, "I concentrate easily" and "I am happy-golucky".

\section*{Overall similarity classification}

Ward employed the triad procedure as a measure of the prevalence of overall similarity classification. In this procedure three stimuli, whose relationship to each other is illustrated in Figure 1, are presented simultaneously and participants are asked to decide which two stimuli go together best. Stimuli B and C are similar on both stimulus dimensions, but not identical on either, while stimuli A and B are identical on one stimulus dimension but quite dissimilar on the other. Three responses are possible - an AB response ( A and B go together best), a BC response or an AC response. Time pressure, concurrent load, impulsivity, and instructions to respond impressionistically, all increase BC responses and decrease AB responses (Smith \& Kemler Nelson, 1984; Ward, 1983; Ward, Foley, \& Cole, 1986). AB responding is typically described as "dimensional" responding and BC responding is typically described as "overall similarity" responding, hence leading to the claim that overall similarity (BC) responding increases as cognitive resources

Figure 1: Abstract structure of the triad task. Typically, on half of trials A and B are identical on dimension 1 (Panel b), and on the other half of trials A and B are identical on dimension 2 (Panel a).

\section*{decrease.}

One reason that the triad procedure is ill suited to testing a less-is-more hypothesis is that consistent \(A B\) ("dimensional") responding requires that the participant consider both stimulus dimensions on every trial. This is because the dimension on which A and B are identical varies unpredictably from trial to trial (see Figure 1), and so a consistent AB responder cannot decide in advance of stimulus onset to only attend to one of the stimulus dimensions. Consistent BC responding also requires consideration of both stimulus dimensions on every trial (irrespective of whether one believes that consideration to take the form of an analytic strategy or direct access to similarity relations through holistic "blobs"). Hence both consistent "overall similarity" (BC) responding and consistent "dimensional" (AB) responding requires consideration of all the relevant stimulus information on every trial. It is therefore not the case that overall similarity responding requires consideration of more of the available stimulus information than dimensional responding in the triad task, and hence the triad task is not well suited to testing a less-is-more hypothesis.
In the current study, we employed the match-tostandards procedure, which is perhaps best considered as an interpretatively less ambiguous version of the triad procedure. The procedure was introduced by Regehr and Brooks (1995) as a means of increasing the prevalence of overall similarity classification of novel stimuli, relative to the more commonly employed array sort procedure, in which single-dimension classification dominates (Medin, Wattenmaker, \& Hampson, 1987). In line with the findings of Milton et al. (2008), Regehr and Brooks observed that reaction times were longer for overall similarity classification than single-dimension classification in this procedure, although they did not publish these observations (Brooks, personal communication, 20 October 2009).

In the match-to-standards procedure, participants sequentially free classify each of a series of target stimuli as belonging to one of two categories. The two cate-
gories are represented by two standards-that is, two stimuli that appear on each trial. The two standards differ from each other on all variable stimulus dimensions. For example, in the current study, the two standards are as shown in Figure 2. In the current experiments, there are 10 distinct to-be-classified stimuli, with the abstract structure shown in Table 1. In some respects, the match-to-standards procedure is similar to the triad procedure, because each trial involves deciding which two of the three stimuli go together best (although, unlike the triad task, the option of saying that the two least similar stimuli-the two standards in the match-to-standards procedure - go together is not available). Also, in the match-to-standards procedure, each participant's classification strategy for a particular block is determined over 10 trials (rather than independently for each trial, as in the triad task).

\section*{Experiment}

In summary, the current experiment re-investigates the relationship between impulsivity and overall similarity classification, first reported by Ward (1983), but using improved measures of both impulsivity and of overall similarity classification.

\section*{Method}

Participants and apparatus Thirty-six participants from the University of Exeter took part in the experiment in return for course credit or payment. The stimuli were presented on a 17 -inch CRT monitor, set to a resolution of \(800 \times 600\) pixels and a color depth of 16 -bits per pixel. The participants sat in front of the computer screen at a distance of approximately 50 cms . Responses were made using a standard keyboard.

Stimuli The abstract stimulus structure can be seen in Table 1. The stimulus set consisted of four binaryvalued dimensions (D1-D4) and the stimuli were organized around two prototypes, each representative of the two categories. These prototypes were constructed by
taking all the positive values on the dimensions for one of the stimuli \((1,1,1,1)\) and all of the zero values on the dimensions \((0,0,0,0)\) for the other category. The rest of the stimuli (one-aways) were mild distortions of the two prototypes in that they had three features characteristic of their category and one atypical feature more characteristic of the other category. In total there were 10 stimuli in the set. Sorting the stimuli by overall similarity, as shown in Table 1, maximizes within-group similarities and minimizes between-group similarities. The stimuli were one of the lamp stimulus sets used by Milton and Wills (2004). Each lamp had four variable features; lampshade (with either 5 or 10 dots), width of stand (wide or narrow), color of bar (light or dark blue) and size of base (long or short). See Figure 2 for the prototypes of each category.

Table 1: Abstract stimulus set
\begin{tabular}{cccccccc}
\hline \multicolumn{4}{c}{ Category A } & \multicolumn{4}{c}{ Category B } \\
\hline D1 & D2 & D3 & D4 & D1 & D2 & D3 & D4 \\
\hline 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 \\
1 & 1 & 1 & 0 & 0 & 0 & 0 & 1 \\
1 & 1 & 0 & 1 & 0 & 0 & 1 & 0 \\
1 & 0 & 1 & 1 & 0 & 1 & 0 & 0 \\
0 & 1 & 1 & 1 & 1 & 0 & 0 & 0 \\
\hline
\end{tabular}

Procedure We used the match-to-standards task introduced by Regehr and Brooks (1995), and developed by our lab (Milton \& Wills, 2004; Milton et al., 2008; Wills et al., 2013). Each trial began with a blank screen that was presented for 1000 ms , followed by three lamps in a triangular arrangement. There were two lamps at the top of the screen that depicted the prototypes for category A and B with the to-be-classified lamp presented below the prototypes. Each stimulus array remained on the screen until the participant placed the to-be-classified lamp into either category A (by pressing the ' \(c\) ' key on the keyboard) or category B (by pressing the ' \(m\) ' key). After the participant made a response the next trial began.

There was no feedback; participants were simply instructed at the beginning of the experiment to sort the stimuli in the way they thought most appropriate. At the end of each block, participants were asked to write down the sorting strategy they used before moving onto the next block. Participants were presented with a total of 60 trials, in 6 blocks of 10 trials. In each block, each of the stimuli shown in Table 1 was presented once as the to-be-classified stimulus. The order of presentation within a block was random.

Immediately after the 6 blocks of classifiation, participants' impulsivity was assessed using the Barratt Impulsivity Scale BIS-11 (Stanford \& Barratt, 1995).

Figure 2: Stimulus prototypes

Classification measure Each participant was classified as having produced one of the sort types described below in each of the six blocks of the experiment. These sort types are identical to those used previously by our lab (Milton \& Wills, 2004; Milton et al., 2008; Milton, Wills, \& Hodgson, 2009; Wills et al., 2013).

A uni-dimensional sort is based on a single dimension of the stimulus. It does not matter which dimension is used as the basis of sorting, so long as all of the positive values for the chosen dimension were in one category and all of the zero values for that dimension were in the other category. Additionally, in order to receive this classification, the participant has to describe their sort as being based on a single dimension.

Participants were considered to have produced a oneaway uni-dimensional sort if they described their sorting as being driven by a single dimension but there was a solitary error in their classification. This means that nine of the items were classified on the basis of a single dimension but the other item was placed into the wrong category.
An overall similarity sort, also commonly known as a "family resemblance" sort (Medin et al., 1987), has a structure identical to that shown in Table 1. In order to receive this classification, the participant had to place each of the prototypes, along with their derived one-aways, into separate categories without error. Additionally, they have to describe their strategy as being based either on general similarity or on placing each item into the category with which it had more features in common.

A one-away overall similarity sort is similar to the one-away uni-dimensional sort with the exception that the error occurred in a sort that was otherwise overall similarity.

Any classifications produced by a participant other than those described above were classified as other sorts, even if the description given by the participant fitted one of the sorts described above. The correspondence between the classification produced by a participant and their verbal description of the sort they have produced is very high in this procedure, approximately 0.99 . The verbal descriptions were classified by the authors.

Impulsivity measure Participants were classified as high impulsivity if their score on BIS-11 was greater than
the sample median (64.5), and as low impulsivity otherwise (cf. Martin \& Potts, 2009).

\section*{Results}

For every block, each participant's sorting strategy was classified according to the sort types described above. As in previous studies, one-away uni-dimensional and one-away overall similarity sorts were classified as unidimensional and overall similarity sorts respectively (Milton \& Wills, 2004; Milton et al., 2008; Wills et al., 2013). The total number of sorts for each strategy was calculated and the mean proportions of overall similarity, uni-dimensional and other sorts produced by high impulsivity and low impulsivity participants are shown in Figure 3.

Participants with high impulsivity produced significantly more uni-dimensional sorts than those with low impulsivity, \(t(34)=2.203, p<.05\). Conversely, participants with high impulsivity produced significantly fewer overall similarity sorts than those with low impulsivity, \(t(34)=-2.382, p<.025\). There was no difference in the prevalence of Other sorts, \(t(34)=.206, p=.838\). Correlations of the raw impulsivity scores with the prevalence of unidimensional, overall similarity and other sorts reveal the same ordinal pattern, albeit with slightly higher p-values (unidimensional \(\tau=.22, p=.09\); overall similarity \(\tau=-.20, p=.13\); other, \(\tau=-.06, p=.68\) ).

\section*{Discussion}

Ward (1983) reported that participants with high impulsivity were more likely to classify on the basis of overall similarity than participants with low impulsivity. This is one of a number of results taken to support the idea that overall similarity classification is a low-effort, "fallback" mode of classification that people employ when cognitive resources are limited. However, a close examination of Ward's study reveals that both the measure of impulsivity, and the measure of overall similarity, employed are sub-optimal. The measure of impulsivity (Kagan's Matching Familiar Figures task) is of questionable validity, and does not correlate with other more valid measures of impulsivity. The triad task, employed by Ward as a measure of overall similarity responding, is also interpretatively ambiguous because both consistent overall similarity responding, and consistent dimensional responding, require consideration of both stimulus dimensions on every trial.

In the current study, we employed a more standard measure of impulsivity (the Barratt Impulsivity Scale), and measured overall similarity responding with the match-to-standards task. The match-to-standards task is a variant of the triad procedure that overcomes the interpretive ambiguities in the standard procedure. One of the ways it achieves this is by considering the participants' responses to a series of ten stimuli, rather than
considering the response to each stimulus as an independent data point.

Our refinement of Ward's procedures seems to have led to a reversal of his conclusions. In the current study, high impulsivity is associated with single-dimension responding, whilst low impulsivity is associated with overall similarity responding. Thus, our data seem to support a conclusion opposite to Ward's-overall similarity classification is more requiring of cognitive resources than dimensional responding. Such a conclusion is consistent with previous results employing the match-to-standards procedure. For example, Milton et al. (2008) found that time pressure generally reduces the prevalence of overall similarity responding, Milton et al. (2009) found greater frontal lobe involvement for overall similarity classification than single-dimension classification, and Wills et al. (2013) found that concurrent load, and a small working memory capacity, reduces the prevalence of overall similarity classification, and that instructions to respond meticulously increased overall similarity responding. Milton and Wills (2009) found that overall similarity classification takes longer, and involves more, widely distributed, eye movements than single-dimension classification. Taken together with the results of the current study, a consistent picture is emerging-overall similarity classification is more effortful than single-dimension classification.

One key question, not satisfactorily answered by this study, or by any other published study, is whether the consistent pattern of results emerging from the match-tostandards procedure is specific to that procedure. Perhaps the match-to-standards procedure is the exception, with other procedures pointing consistently to the opposite conclusion? In our view, there is currently insufficient data to answer this question adequately. The triad procedure, at least as typically analysed, is interpretatively ambiguous, but this problem could be overcome with larger samples and more sophisticated model-based analyses (e.g. Thompson, 1994).

Two other procedures that are sometimes taken to support the less-is-more view (that overall similarity classification is lower effort than single-dimension classification) are the Ashby-Maddox procedure (Ashby \& Maddox, 2005) and the criterial-attribute procedure (Kemler Nelson, 1984; Smith \& Shapiro, 1989). As discussed by Wills et al. (2013), these procedures seem likely to be addressing slightly different questions to the one posed here.

The Ashby-Maddox procedure seems, predominately, to be an investigation of the effects of having an easy-toverbalize category structure versus a hard-to-verbalize structure. As single-dimension structures are typically easy to verbalize, and some multi-dimensional structures are not, the two issues are not unrelated. However, recent work by Ashby, Maddox and colleagues sug-

Figure 3: Proportion of other, uni-dimensional and overall similarity sorts, by impulsivity. Error bars represent one standard error
gests that it is verbalizability, rather than dimensionality, that underlies their reported effects, because the effects are still observed when one compares two multidimensional classification problems that differ in verbalizability (Filoteo, Lauritzen, \& Maddox, 2010; Maddox, Pacheco, Reeves, Zhu, \& Schnyer, 2010). There are also an increasing number of studies that suggest that some of the results from the Ashby-Maddox procedure are a consequence of subtle problems with the design or analysis of these studies (Newell, Dunn, \& Kalish, 2010; Newell, Moore, Wills, \& Milton, 2013).

The criterial-attribute procedure, like the AshbyMaddox procedure, seems to be addressing a slightly different question to the one posed here. Specifically, the criterial-attribute procedure may provide evidence that it is effortful to detect the one dimension that permits above-criterion performance in a context where all dimensions individually support at least \(75 \%\) accuracy. Studies using the criterial-attribute procedure (Kemler Nelson, 1984; Smith \& Shapiro, 1989) support the idea that this is effortful, but they are also consistent with the idea that implementing an overall similarity classification is more effortful than implementing a single-dimension classification (Smith, Tracy, \& Murray, 1993). It was the implementation of overall similarity classification that was the topic of the current study.

Why did the current study and Ward's study produce apparently opposite results regarding impulsivity and overall similarity classification? There are a number of possibilities. One possibility, as previously discussed, is that Ward's measure of impulsivity has low validity. If Ward did not measure impulsivity adequately, then contrasting the current result (using a more valid measure) with Ward's findings is largely irrelevant, as Ward's results would not validly concern impulsivity. Another
possibility is that a less ambiguous analysis of the triad task using model-based methods might reveal that high impulsivity was in fact associated with uni-dimensional classification, rather than overall similarity classification, even in the triad task. We are currently investigating this possibility.

One way in which the match-to-standards task differs from other procedures is that the participants' written descriptions of their sorts are combined with the sorts they actually produce in order to classify their behavior. It seems likely that impulsivity affects the content of those written reports. A more critical possibility is that impulsivity might affect the written reports differently to the objective sorts, and hence the results of the current study might have been different if we had only looked at the objective sorts (or only looked at the written reports). However, if impulsivity does affect written reports differently to the objective sorts, then the consequence should be a difference in the prevalence of Other sorts as a function of impulsivity (because Other sorts occur under our classification procedure when the written report and objective sort do not agree). As can be seen in Figure 3, the proportion of Other sorts is low and does not vary by impulsivity. It therefore seems unlikely that our results would have been substantively different if we had considered just the objective sorts or just the written descriptions.

In conclusion, in the current study highly impulsive individuals were more likely to produce singledimension classifications than low-impulsivity individuals (who were more likely to produce overall similarity classifications). The opposite conclusion, suggested by Ward (1983), seems likely to be due to limitations of the procedures employed in that study, although it remains a possibility that both results are valid, but specific to
the procedure employed.

\begin{abstract}
Research on the mental representation of numbers has focused on a horizontally aligned mental number line, but more and more findings have begun to implicate a vertical orientation as well. We investigate the relationship between these two orientations when people generate random numbers. In the horizontal condition, people generated larger numbers when they looked right as opposed to left. In the vertical condition, people generated larger numbers when they looked up as opposed to down. We present two main results based on analyses that compare the two spatial orientations. First, we show that the vertical effect was stronger than the horizontal one. Second, we show a weak correlation between the vertical and the horizontal effect, potentially suggesting a shared underlying mechanism.
\end{abstract}

Keywords: mental number line; SNARC; numerical representation; mathematical cognition; metaphor

\section*{Introduction}

People use numbers for practically everything: counting coins, ordering dinner, making an appointment, filling out tax forms, and more. But how do they represent numbers in the head? Research on numerical representation has focused on the link between numbers and spatial cognition. Neuroimaging studies consistently find that the intraparietal sulcus is implicated in numerical as well as spatial tasks (Hubbard, Piazza, Pinel, \& Dehaene, 2005). And across several neuropathological disorders, deficits in spatial cognition are correlated with deficits in numerical cognition (Zorzi, Priftis \& Umiltà, 2002; Rotzer, Loenneker, Kucian, Martin, Klaver \& von Aster, 2009).

One proposal as to how we represent numbers is the idea of a horizontally oriented mental number line, where smaller numbers are associated with left perceptual space and larger numbers with right perceptual space (at least in Western cultures). Evidence for such a representation comes from the Spatial-Numerical Association of Response Code effect (SNARC), which revealed that people respond faster to relatively larger numbers with their right hand, and faster to relatively smaller numbers with their left hand (Dehaene, Bossini \& Giraux, 1993). This effect has been replicated in over 100 experiments (Wood, Nuerk, Willmes \&, Fischer, 2008), and similar effects have been found with pointing (Fischer, 2003), body movements (Hartmann, Grabherr, \& Last, 2011), handwriting (Perrone, de Hevia, Bricolo, \& Girelli, 2010) and many other methodologies.

While there is much converging evidence for horizontally oriented numerical representations, more and more findings
are emerging that also support the presence of a vertical mental number line. For example, when people are moved upwards by a lifting chair while they generate a "random" sequence of numbers, generated numbers are "higher" than when the chair is moving downwards (Hartmann, Grabherr \& Last, 2011). Similarly, an upwards directed eye movement predicts that the next number in a randomly generated sequence will be "higher" than the preceding number (Loetscher, Bockisch, Nicholls, \& Brugger, 2010). Relatively larger numbers also facilitate upwards directed saccades (Schwarz \& Keus, 2004) and upwards directed spatial attention (Pecher \& Boot, 2011).

Evidence for a vertical representation of number also comes from language processing: When people read sentences that contain the word "more", people are faster to respond with an upwards oriented response button as opposed to a downwards oriented response button (Sell \& Kaschak, 2012). The opposite is true for sentences that contain the word "less". Finally, the classic SNARC paradigm, too, works with vertically oriented response buttons (Ito \& Hatta, 2004; Müller \& Schwarz, 2007; Shaki \& Fischer, 2012), where larger numbers facilitate responses to a high button and smaller numbers to a low button.

The potential existence of two orientations along which numbers are represented naturally leads to the question: What is the relation between the horizontal and vertical mental number line? From the get-go, research on the horizontal number line emphasized the cultural nature of spatial numerical associations, where the orientation of the horizontal axis is thought to stem from a culture's writing direction (Dehaene et al., 1993; Göbel, Shaki, \& Fischer, 2011; for a related perspective focusing on cultural aspects, see Núñez, 2011). As reading and writing are very entrenched behaviors, one could imagine the horizontal mapping to be stronger than the vertical one.

The vertical SNARC effect, on the other hand, has been suggested to come from embodied interactions with the world. Cognitive linguists working on Conceptual Metaphor Theory (e.g., Lakoff, 1987) argue that we build up a mental connection between verticality and quantity because we repeatedly experience a correlation between these two domains in our environment (e.g., when we pour water into a glass, as quantity increases, verticality increases as well). Given that the vertical mapping is also connected to entrenched patterns of language use ("this is a high number", "rents are rising"), one could imagine vertical SNARC effects to be stronger than horizontal ones.

Holmes and Lourenco \((2011,2012)\) explicitly compared the two orientations by pitting them against each other:

When participants had to respond to a top/left and to a bottom/right button, people were quicker to respond to the left button with smaller numbers and to the right button with larger numbers. As this mapping goes against the vertical mental number line but produces a regular horizontal SNARC effect nonetheless, Holmes and Lourenco conclude that the horizontal orientation "trumps" the vertical.

We follow up on the work by Holmes and Lourenco (2011, 2012) by providing another comparison between horizontal and vertical mappings with a different task, namely, a random number generation task. We pursue two main questions: First, we compare the relative strength of the horizontal and the vertical effect. Second, we look to see whether the horizontal and the vertical effect are related to each other across individuals. Thus, rather than pitting the two orientations against each other, we take an individual differences perspective, comparing an individual participant's propensity to align numbers on the vertical axis to her propensity to align numbers horizontally. This approach is inspired by work suggesting considerable individual differences in how numbers are mapped onto space (e.g., Fischer \& Campens, 2008; Fischer, 2008; Beecham, Reeve, \& Wilson, 2009). Moreover, studies on individual difference have been used for a range of different phenomena to investigate the question whether different tasks potentially share the same underlying mechanism (e.g., see Stanovich \& West, 2000). Thus, if the vertical and the horizontal effect are related across individuals, they can be seen as tapping into the same system.

\section*{Experiment}

The task was a random number generation task used by Loetscher et al. (2008) and Hartmann et al. (2011) designed to study spatial numerical associations. Participants called out numbers during rhythmic head movements. In one block, head movements were along the horizontal axis, in another, along the vertical. In line with the horizontal SNARC effect and the previous findings of Loetscher et al. (2008), we expected numbers to be larger when people look towards the right. In line with the vertical SNARC effect, we expected numbers to be larger when people were looking upwards.

\section*{Procedure}

Participants were asked to call out numbers between 1-30 to a beat of 0.5 Hz , played by an electronic metronome (following the procedure of Loetscher et al., 2008). There were three blocks: A horizontal block, vertical block, and straight-ahead block. The order of horizontal vs. vertical block was counter-balanced across participants. The straight block was always last. We asked participants to generate 40 numbers in the straight block and 80 numbers in the vertical and horizontal one. Half the participants started left in the horizontal block and down in the vertical block, and the other half started with the right and up positions.

We built up the procedure in pieces: We first instructed participants to perform the rhythmic head movements to the beat, "as large as possible while still being comfortable". Then, we introduced the random number generation component, participants were told to be "as random as possible" and to avoid counting sequences. We reminded participants that randomness in this context means that each number has equal likelihood, and that each number is independent from the preceding one (see Towse \& Cheshire, 2007). They were also asked not to call out the number while performing the movement but when the head was stationary in the corner positions of each axis. To avoid bias, the experimenter never mentioned numbers or spatial language to describe numbers ("high number", "large number"). Following Loetscher et al. (2008), we asked participants to close their eyes while performing the task.

\section*{Participants}

Sixty-five UC Merced undergraduates (all native speakers of English) participated in the experiment for extra credit in a social sciences course. A total of 6 participants ( \(9 \%\) of the total data) were excluded from the analyses because they were unable to finish the task (frequent self-interruptions, incapability of following the beat even after sustained practice).

\section*{Analysis}

Loetscher et al. (2008) binned numbers into large ( \(>15\) ) and small \((<15)\) numbers, but we took a more direct approach, analyzing all generated numbers as a continuous measure. We performed two separate analyses, one on absolute numbers (whether the average was larger for one position over the other), and another on relative numbers (whether the average difference to the preceding number in the sequence was smaller or larger).

We analyzed the data with mixed models using R ( R Core Team, 2012) and the package lme4 (Bates, Maechler \& Bolker, 2012). Our analysis controlled for the by-participant variability in the response (e.g., some participants might generate overall larger numbers than others), as well as for differential responses to the head turning manipulation \({ }^{1}\).

Because Holmes and Lourenco (2012) had found that it matters whether people are exposed to a vertical or a horizontal block first (ibid. 1049, footnote 4), it was necessary to control for the effect of Block Order. It was necessary to control for the effect of Starting Orientation (left/down vs. right/up) because people tend to have a counting or "runs" strategy (see Towse \& Cheshire, 2007). Such a strategy could create spurious spatial mappings if Starting Orientation were not controlled for. For example, a participant who tended to count upwards and start at the down position might generate numbers that are, on average, higher in the up position than those in the down position.

\footnotetext{
\({ }^{1}\) In other words, the model included both random intercepts and slopes (cf., Barr, Levy, Scheepers \& Tily, 2013). We also tested the interaction of Head Position with the control variables Block
}

Finally, we also controlled for potential long-term changes in each block to see whether the horizontal and vertical effects would become stronger or weaker as the experiment progressed.

\section*{Results}

Compressive scaling Before examining the effect of spatial position, we looked at whether participants' randomly generated numbers would exhibit a small number bias (see Loetscher \& Brugger, 2007). A regression of frequency on number reveals that on average, per each increase of number by 1, frequency decreased by \(8.96(S E=1.78)\) \(\left(\mathrm{F}(1,28)=25.35, \mathrm{p}=0.000025, R^{2}=0.46\right)\). There was no interaction between the small number bias and response orientation (horizontal, vertical, straight) \((\mathrm{F}(2,84)=2.539\), \(\mathrm{p}=0.085\) ). Thus, within each condition (horizontal, vertical, straight), the small number bias was of similar magnitude.

Order effects For absolute numbers, the control variables (Block Order, Starting Orientation, Trial Order) did not interact with Head Position in the horizontal block \(\left(\chi^{2}(3)=1.36, \mathrm{p}=0.71\right)\) or in the vertical block \(\left(\chi^{2}(3)=3.47\right.\), \(\mathrm{p}=0.32\) ). For relative numbers, the control variables also failed to produce any interaction in the horizontal block \(\left(\chi^{2}(3)=3.56, p=0.31\right)\) and in the vertical block \(\left(\chi^{2}(3)=4.78\right.\), \(\mathrm{p}=0.19\) ). This suggests that the effects reported below are relatively independent from these other factors.

Absolute numbers Numbers generated were on average \(0.26(S E=0.24)\) larger when people looked to the right versus to the left, but the effect was not significant \(\left(\chi^{2}(1)=1.2, \mathrm{p}=0.27\right)\). There was, however, a significant effect of vertical position \(\left(\chi^{2}(1)=7.91, \mathrm{p}=0.0049\right)\), with numbers being \(0.67(S E=0.24)\) larger up as opposed to down. To test whether the difference between the two axes is significant, we coded "up" and "right" together and "left" and "down", combining them into a single factor "Position". There was no interaction between "Position" and "Axis Orientation". Thus, for absolute numbers, there is no conclusive evidence for the vertical effect being stronger.

Relative numbers There was a significant effect of horizontal position \(\left(\chi^{2}(1)=4.31, \mathrm{p}=0.038\right.\) ), with numbers being \(+0.52(S E=0.25)\) larger than the preceding number when people looked right versus left, and a significant effect of vertical position \(\left(\chi^{2}(1)=8.13, \mathrm{p}=0.004\right)\), with numbers being \(+1.34(S E=0.46)\) larger than the preceding number in the up position versus the down position (see Fig. 1). An analysis that combined both axis orientations also yielded a significant interaction of Axis Orientation and Position \(\left(\chi^{2}(1)=10.706, p=0.001\right)\), with the vertical effect predicted to be stronger by \(+0.82(S E=0.47)\).

Figure 1: Average relative difference for the horizontal and vertical blocks. Error bars indicate standard errors (taken from the model).

Effect sizes \({ }^{2}\) Standardized effect measures showed stronger effects for the vertical than for the horizontal condition for absolute and relative numbers. This is also reflected in the larger coefficients for the vertical condition in the analyses reported above, as well as the significant interaction between Axis and Position for relative numbers.

Table 1: Effect sizes for absolute and relative numbers by condition.
\begin{tabular}{ll}
\hline Analysis & Cohen's d \\
\hline Horizontal, absolute & 0.17 \\
Vertical, absolute & 0.43 \\
Horizontal, relative & 0.44 \\
Vertical, relative & 0.72 \\
\hline
\end{tabular}

Individual differences We analyzed individual differences by looking at difference scores for right minus left (henceforth "horizontal bias") and for up minus down (henceforth "vertical bias"). For the horizontal condition, \(61.5 \%\) (40 participants) showed a horizontal bias (positive difference score), in line with the SNARC effect for both absolute and relative numbers. Similarly, \(61.5 \%\) of all participants showed a vertical bias for both absolute and relative numbers.

While only \(\sim 15 \%\) ( 10 people) had no horizontal bias and no vertical bias (hence, showing opposite effects of what was predicted by both mappings), about \(38 \%\) ( 25 people) had both a horizontal bias and a vertical bias simultaneously. However, the majority of participants (30 people, \(46 \%\) ) had either one bias or the other. Table 2 summarizes this result:

\footnotetext{
\({ }^{2}\) As there are no standardized effect size measures for mixed models, we chose Cohen's d as shorthand. To calculate this measure, we used a by-participants analysis (averaging over trials).
}

Table 2: Individuals with horizontal or vertical bias.
\begin{tabular}{|c|c|c|c|}
\hline \multirow[b]{4}{*}{Vertical} & \multirow[b]{4}{*}{\[
\begin{aligned}
& \text { yes } \\
& \text { no }
\end{aligned}
\]} & \multicolumn{2}{|l|}{Horizontal} \\
\hline & & & \\
\hline & & 25 & 15 \\
\hline & & 15 & 10 \\
\hline
\end{tabular}

The preceding discussion of individual differences examined propensity to show vertical or horizontal effects categorically (sign of the difference score), yet it is also useful to carefully consider the relative strength of the vertical or horizontal bias per person.

Figure 2: Correlations of horizontal bias ( x -axis) and vertical bias ( y -axis) for (a) absolute numbers and (b) relative numbers. Dashed lines represent correlation without influential points; solid lines with all data.

The solid lines that are shown in Fig. 2 reveal an apparent correlation between the vertical and the horizontal bias. For both absolute numbers and relative numbers, this correlation became significant (absolute: \(\mathrm{t}(63)=2.62, \mathrm{p}=0.011\); relative: \(\mathrm{t}(63)=2.35, \mathrm{p}=0.022\) ). However, visual inspection and influence diagnostics revealed that there were a few individuals with substantial leverage on the data. If data points with large Cook's distance (over 4/(N-k-1)) were excluded, both correlations cease to be significant (absolute: \(\mathrm{t}(57)=0.9, \mathrm{p}=0.37\); relative: \(\mathrm{t}(57)=0.57, \mathrm{p}=0.57\) ).

\section*{Discussion}

Vertical versus horizontal mappings For both absolute and relative numbers, we found stronger effects for the vertical than for the horizontal axis (as indicated by Cohen's d and model coefficients), and for relative numbers, the vertical axis produced significantly stronger results than the horizontal axis.

Why did we find the vertical mapping to be stronger than the horizontal one? And, does this necessarily stand against the results of Holmes and Lourenco \((2011,2012)\) discussed above? We are cautious to conclude that these differences in effect size reflect a straightforward difference in the "strength" or "entrenchment" of the underlying mappings. There are several alternative reasons for why one mapping could lead to stronger or more consistent effects than the other. For example, people often perform smaller vertical head movements than horizontal ones (Glenn \& Vilis, 1992; Pelz, Hayhoe, \& Loeber, 2001), which could have made vertical head movements more salient. People's vertical saccades are also known to be slower and less accurate than their horizontal saccades (Collewijn, Erkelens, \& Steinman, 1988). And research on the vertical-horizontal illusion shows that people generally overestimate vertical extent more than horizontal extent (Finger \& Spelt, 1947; Chapanis \& Mankin, 1967; Prinzmetal \& Gettleman, 1993). Even though the difference in saccades and the verticalhorizontal illusion might be deemed irrelevant given that our task required participants to close their eyes, overall, these results point to fundamental asymmetries between horizontal and vertical space. Thus, it is not impossible that we found vertical effects simply because vertical space is more salient than horizontal space.

This alternative explanation opens up many interesting avenues for future research. As there are considerable interindividual differences in the amount and degree to which individuals move their head (Fuller, 1992; Stahl, 1999), one could correlate each participant's "head movement propensity" with the size of the vertical or horizontal effect. Ideally, one would like to correlate the strength of the head movement with the results of the number generation task on a trial-by-trial basis. The vertical and horizontal biases are predicted to be stronger for relatively larger movements. Moreover, there are also individual differences in the strength of the vertical-horizontal illusion (e.g., Coren \& Porac, 1987). The susceptibility to this illusion could also be correlated with the horizontal or vertical bias. Here, people who have a stronger vertical-horizontal illusion should show stronger vertical effects. If, however, vertical space is more "salient" across the board, it does not fully account for the difference between Holmes and Lourenco \((2011,2012)\) and the present study, because presumably, the same verticalhorizontal asymmetries should be at play.

Here, it is noteworthy that many studies that found vertical effects either invoke random number generation (present study, Loetscher et al., 2010 and Hartmann et al., 2011) or approximate quantity information such as the words "more" or "less" (Sell \& Kaschak, 2012; Pecher \&

Boot, 2011). Moreover, Holmes and Lourenco (2012) found vertical effects only after priming magnitude. This invites the hypothesis that the vertical mapping might be stronger in tasks that invoke a more approximate number system. The small number bias observed in our participants' responses would support this view, as a compressive scaling of the mental number line is associated with the idea of the approximate number system.

However, there are also linguistic reasons to expect that vertical effects are stronger with approximate magnitude representations: We frequently use the words "high" and "low" and "rising" and "falling" to talk about numbers, but we do not use horizontal spatial language the same way. The linguistic vertical metaphors are degree words that underspecify the exact quantity. The underspecification of verbal metaphors might make the vertical mapping particularly amenable for approximate magnitude representations as opposed to exact quantity representations. Finally, if, as cognitive linguists have claimed (Lakoff, 1987), the vertical mapping really comes from embodied interactions with the world, a connection between approximate magnitude and verticality might ultimately have physical origins: The environmental correlation between verticality and quantity often involves uncountable quantities rather than exact numbers, for instance, when pouring liquid into a container, or when creating a pile of pebbles. The horizontal mapping, on the other hand, might be more connected to exact numerical representations because of its connection to writing and symbolic representations of numbers, which are ideal for representing exact sequences (e.g., calendars, numbers on keyboards, rulers).

Absence of order effects The absence of any order effects in the current study is somewhat surprising. That Block Order did not affect the results suggests that whatever mapping is most preferred by a participant is not primed by being exposed to a vertical or a horizontal block first. One could imagine that the vertical or horizontal effects are entirely task dependent, resulting only after a bit of exposure to the up/down or left/right going movements. The absence of an interaction between Trial Order and Head Position suggests that this was not the case. Thus, it appears that participants responded in line with horizontal or vertical SNARC effects from the very beginning of each block. In other words, the spatial numerical associations appear to have been relatively stable.

Individual differences Finally, analyzing the data of separate participants revealed considerable differences between individuals, similar to other studies that have found considerable differences in the way people respond to numerical cognition tasks (Fischer \& Campens, 2008; Fischer, 2008; Beecham, Reeve, \& Wilson, 2009). The most prevalent pattern was that participants either had a horizontal bias or a vertical bias, with a considerable number ( \(\sim 38 \%\) ) having both and only a handful ( \(\sim 15 \%\) )
having neither. There was a weak correlation between a participant's vertical bias and a participant's horizontal bias. This may initially seem to suggest overlapping mechanisms for the vertical and the horizontal mappings. However, closer inspection revealed that this correlation was largely due to a few individuals. Based on the results obtained in the current study, it is clear that more research is needed to determine whether the connection between the vertical and horizontal mapping holds across different tasks.

\section*{Conclusions}

We found that randomly generated numbers were "higher" when people looked upwards and when people looked to the right. We found the vertical effect to be stronger than the horizontal one. There were also considerable interindividual differences: Some people were more easily affected by the vertical manipulation, others, more easily by the horizontal manipulation. Across individuals, there was a weak correlation between the vertical and the horizontal effect. Future research needs to find out under which conditions vertical effects are stronger than horizontal ones, and whether the weak relationship between these two effects holds across different experimental paradigms.

\begin{abstract}
The imitation of successful peers is often heralded as an intelligent shortcut to reduce individual learning costs. Using computer simulations, we demonstrate that this advice can be ill-founded and harmful in a cognitive inference task involving continuous learning. In particular, success-based imitators perform worse than both learners who integrate the learning experience of all group members and isolated learners. We report on sensitivity analyses for this phenomenon and offer explanatory mechanisms.
\end{abstract}

Keywords: group decision making; imitation; social learning; computer simulation

\section*{Introduction}

The results of a recent social learning tournament (Rendell et al., 2010) suggest that it always pays to copy successful others when faced with a choice between individual learning and group learning. Yet, imitation learning is not as prevalent in the biological world as could be expected (Rieucau \& Giraldeau, 2011). Humans, at least, often orient themselves towards successful peers to shorten periods of individual exploration and try to imitate the best group member (GarciaRetamero, Takezawa, \& Gigerenzer, 2009; Garcia-Retamero, Takezawa, Woike, \& Gigerenzer, 2013). Yet, it can be argued that there are situations in which this strategy does not pay off (Denrell, 2005). In this simulation study we want to illustrate one such situation and compare individual learning with several social learning strategies in a sequential cognitive inference task based on the framework used in Garcia-Retamero, Takezawa, and Gigerenzer (2006).

\section*{The learning task and learning strategies}

\section*{The learning task}

We investigated the behavior of virtual decision makers using a paired-comparison task. This is an inference task, in which agents have to decide which of two objects has the higher criterion value. The basis for this inference are the values of a set of dichotomous variables (henceforth called cues) that characterize the two objects. An environment in this study consists of a set of \(N\) objects that are associated with criterion values and \(k\) binary cue values. The agents follow a strictly non-compensatory inference strategy: for each pair
of objects an agent \(i\) looks up cues in an agent-specific order \(O_{i}=\left(o_{1, i}, o_{2, i}, \ldots, o_{k, i}\right)\) until a cue discriminates between the two objects (i.e., until the cue value is different for the two compared objects). In this case the object with the higher cue value (i.e., the value that indicates a higher criterion value) is selected. If none of the cues discriminates, a random decision is made. All agents are given the directions of all cues in each environment. For each cue, this direction is determined to maximize the number of correct decisions assuming that all possible pairs of objects in an environment are known and considered. In this setup, the choice of the cue order alone determines the success or failure of the agent in a given environment. The problem of finding the best cue order has been proven to be computationally intractable when the whole data set is available (Martignon \& Schmitt, 1999). For the case of off-line learning (i.e., for situations in which all cue values for all objects in a decently sized sample are known), a strategy called take-the-best (TTB), which determines the order of cues \(O_{i}\) by ranking them according to their ecological validity, performs well across a variety of problems, especially for generalization tasks (Czerlinski, Gigerenzer, \& Goldstein, 1999; Gigerenzer \& Brighton, 2009). Our study focuses on on-line learning instead: For a learner in an unfamiliar decision setting and without any prior knowledge, learning has to be based on experience on a trial-by-trial basis (Hertwig, Barron, Weber, \& Erev, 2004). The learner has no prior access to information about objects or environment, and full information might be costly and time-consuming if not impossible to obtain.

\section*{Individual learning with the validity algorithm}

In on-line learning situations TTB cannot be easily applied since an agent generally has no basis for accessing or estimating the actual cue validities Todd and Dieckmann (2012) propose a learning mechanism that can be used in this setting, the validity algorithm. The validity algorithm starts out with a random cue order for the first trial and stores the values of two variables for each cue \(i\) : the number of observed discriminations \(d_{i}\) (i.e., the number of observed object pairs with different cue values for the two objects), and the number of correct predictions \(c_{i} \leq d_{i}\) (i.e., the number of observed
object pairs with different cue values, for which the object with positive cue value has a higher criterion value than the object with negative cue value). Both variables are set to zero for all cues at the start. In each learning trial a decision is made using the trial's cue order, and feedback is received on the correctness of this decision. For the first cue in the order that discriminates \(d_{i}\) is incremented by 1 and if the prediction turns out to be correct, \(c_{i}\) is incremented as well. After each trial, cue validities for all cues are estimated as:
\[
\hat{v}_{i}= \begin{cases}\frac{c_{i}}{d_{i}} & d_{i}>0  \tag{1}\\ 0.5 & d_{i}=0\end{cases}
\]

A new cue order is established for the next trial by ranking the validity estimates and adapting the cue order accordingly. Dieckmann and Todd (2004) observe that by using the validity algorithm individual performance can approach the performance that is obtained by using the ecological cue validities from the start (i.e., the performance of individuals that calculate cue validities based on the full sample and order cues according to these validities). Yet, the on-line learning process is likely to be slow and convergence cannot be guaranteed. Group learning has been proposed as a way to speed up this learning process. In this paper, we investigated whether this is in fact the case.

\section*{Group Learning Strategies}

While an isolated individual is often condemned to learn on a personal trial and error basis, humans often find themselves situated in groups that offer ways to overcome this predicament. In the current study we compare the individual performance in the sequential learning task with the performance of members in learning groups using various group learning strategies.

Group members alternate between blocks of individual trials and group exchange phases. After each individual trial, each individual's cue order is updated using the validity algorithm. In the group exchange phase individuals exchange information according to the social rule they have been assigned to. A social cue order is determined, and all individuals adjust their individual cue order. Afterwards each individual's memory is altered in accordance with the new cue order (see below) and the next individual trial block begins.

We implement the following group learning algorithms: 1) imitation, 2) the plurality rule, and 3) the averaging rule.
Imitation An easy way to learn from others is achieved by simply imitating their behavior. If the relevant aspects can be observed or communicated, some individuals can avoid undergoing a longer learning process by copying the result of others. Since it is highly likely that not everyone who is observed is suited to be an adequate model, a degree of specificity is well-advised.

The imitate-the-best rule proceeds by first identifying the individual in the group who achieved the best performance in the preceding trial block. In case of ties, this individual
is randomly chosen among those with the highest number of successes. This individual's cue order is then chosen to be the resulting group cue order and every other individual copies this cue order.

One parameter for this strategy is the number of past observations considered for determining the most successful individual. This parameter has been set to the size of the individual trial block. A trade-off has to be considered here: The longer the time frame, the more observations can be evaluated and the performance measurement might well be more reliable. On the other hand, the more observations are considered the higher the chance that an individual changes the cue order used between the trials, so that older observations may be less relevant or even misleading in regard to evaluating this individual's present cue order.
Plurality The plurality rule in standard choice contexts proceeds by letting individuals vote for their preferred option and the option with the most votes (the plurality of votes) is chosen. A variant of this rule is the ""majority rule"" that implies strictly speaking that there could not be a decision without an absolute majority of votes. So if three alternatives receive \(40 \%, 35 \%\), and \(25 \%\) of the votes, respectively, the plurality rule consistently chooses the first alternative, even if none of the alternatives has obtained more than \(50 \%\) of the votes.

The transfer to ordering cues is straight-forward: For the first and each subsequent rank position (but the last) a vote will be held, where cues whose rank has already been established cannot be voted for. Each individual selects the nonranked cue that comes first in the individual's cue order and the cue with the plurality of votes (or a random cue among those cues tied for the plurality of votes) is ranked at the position that is voted for, until the complete cue order is established. This implies that an individual can vote for the same cue more than once and that the plurality rule uses \(k-1\) voting steps for \(k\) cues.
Averaging One of the principles that underlies evidencebased approaches to management, medicine and education, is the systematic collection and analysis of empirical evidence that can inform practice. Observations are collected in databases and the effectiveness of a treatment is determined via meta-analysis across studies.

A somewhat similar strategy that can be employed by groups in the setting of the simulation is the pooling of evidence across all individuals within the group. To find a cue order, cues are evaluated by using the collected experience of all group members, there is no voting or evaluation of individual solutions. The rule is called averaging rule, because validities of cues are calculated based on average cue information. The average validities \(v_{i}^{a}\) in this case are calculated as
\[
\begin{equation*}

\end{tabular}

The group-based cue order is then constructed by ordering cues in descending order of average validity. The number of individual cue discriminations \(d_{i}\) for all group members is adjusted to the average number of discriminations for this cue in the group (which may be a non-integer number). Note that the same cue order would result from using the ratio of the sum of all discriminations and successful predictions (both denominator and numerator are divided by the same number), but the averaging scales the information back to the level of group members. Averaging individual validities though, would ignore the number of observations that each value is based on and would lead to different results in the general case.

\section*{Memory alteration}

In Dieckmann and Todd (2004), it is assumed that \(c_{i}\) and \(d_{i}\), the number of discriminations and successful discrimination by each cue, are recorded and recalled accurately by individuals. In this simulation we employ a variant that reflects a more realistic, imperfect memory: in fixed intervals, both \(c_{i}\) and \(d_{i}\) are randomly mutated with the constraint that the resulting order of cues has to remain constant. Our variant is therefore likely to perform worse than the original algorithm.

While this memory update is a handicap for individual learning, it is actually a vital step for the group learning algorithms: after each group phase, an individual that replaces his cue order by the newly constructed group-based order faces a problem otherwise: if he retains his old memories unchanged, there will be a high probability that his cue order will change back to the original order when the validity algorithm is employed in individual learning. Only if the first trial after the group learning phase leads to a change in the order of estimated cue validities will the group phase have any effect on the individual.

In the simulations we therefore use the following mechanism for altering an individual's memory: The cue order and the number of discriminations per cue are retained. Only in the case that any \(d_{i}\) is zero, it will be changed to one. The \(c_{i}\) on the other hand are based on percentages drawn from the
uniform distribution \(U(0.5 ; 1)\). A minimum of 0.5 is chosen, as cue directions are known a priori, and the minimum cue validity under this constraint is 0.5 . A set of \(k\) numbers \(r_{i}\) is drawn from this distribution and sorted in descending order \(\left(r_{1}, r_{2}, \ldots, r_{k}\right)\). The number of successes in memory are subsequently calculated as \(c_{i}=r_{i} \cdot d_{i}\). This procedure guarantees that the ordering of cues performed by the validity algorithm will result in the specified cue order.

The retention of all \(d_{i}\) leads to a gradually decreasing probability of switches between cue positions, as more and more observations are needed to change the ratio \(c_{i} / d_{i}\) substantially and the probability to bridge the randomly determined gaps between successive cues is affected accordingly. This property is shared with the original validity algorithm. This memory alteration can be equally applied to group learners and isolated learners, and as a rule it is applied following each group exchange phase (isolated learners are yoked to the randomization schedule of social learners).

\section*{Simulation Setup}

Environments Agents in this simulation have to solve the paired comparison task in environments constructed from data sets. None of the data sets was artificially created or hypothetically derived. All were collected in ecologically meaningful economic contexts. In each environment, agents were confronted with object pairs whose members were randomly selected from the cases in the data sets.

Using a range of empirical environments allows to increase the generalizability of our conclusions. The data sets were chosen for variability, with semantic variance and different types and numbers of cues and cases. Table 1 summarizes the set of ten environments used to generate the inference task. The data sets Forbes 500, Ice Cream (Kadiyala, 1970), and Home Prices were taken from the Statlib collection of data sets \({ }^{1}\). Minimum Wage (Card \& Krueger, 1994) and Stock Prices were taken from the UCLA collection of statistical

}

Figure 1: Simulation structure for a group of 5 simulated individuals

Figure 2: Performance in the base condition: lines depict the average expected accuracy of individual cue orders across individuals and environments for the four simulated learning strategies
data sets \({ }^{2}\), Wildcat Strikes accompanies (Simonoff, 2003) \({ }^{3}\). The Machine Learning Repository at UCI (Asuncion \& Newman, 2007) contributed the CPU Performance data (Ein-Dor \& Feldmesser, 1987), Weisberg (1985) references the Land Rent data. The Professors' Salary data were taken from Rice (1995) \({ }^{4}\), the Software Development data are based on Matson and Huguenard (2007).

Each data set was transformed for use in the simulation. We dichotomized all non-binary cue variables ( \(0 / 1\) ) using the median (for the Land Rent and the Professor Salary data) or the mean of each variable (for the rest of the environments). In some cases, only a subset of the original variables was included as some cue-criterion relationships could not be sensibly interpreted. In two cases the number of original variables was reduced to make their inclusion in the simulation feasible. All transformations and selections were applied before running any of our simulations.

Simulation parameters In our base condition, groups consist of five individuals each. All individuals start with ran-

\footnotetext{

}
dom cue orders. Blocks of individual learning trials are interspaced with phases of group exchange (see Figure 1). There are five trials per individual learning block, and in each trial an individual samples one pair of objects, makes an inference and obtains feedback. Each individual \(j\) stores three pieces of information: the number of successful predictions in the current trial block \(\left(s_{j}\right)\), the number of discriminations that each of the cues in the data set made ( \(d_{i, j}\) for each cue \(i\), i.e., the number of decisions based on this cue) and the number of successful predictions that were based on each cue \(i\left(c_{i, j}\right)\). Only the number of successes is reset at the beginning of each trial block, the other variables are changed by individual learning and the memory alteration procedure described above.

The simulation proceeds for 50 trial blocks and group exchange phases (i.e., for 250 rounds of individual trials). For each of the three social rules - imitation, plurality and \(a v\) eraging - 2,000 groups (10,000 individuals) were simulated for each data set in the base condition, while we simulated 10,000 isolated learners for comparison.

Figure 3: Effect of group size on performance relative to isolated learners after 50 group-exchange phases

\section*{Results}

\section*{Base condition}

Round-wise results for the base condition are presented in Fig. 2. Groups that implement the averaging rule and the plurality rule perform better than isolated learners immediately after the first social learning phase with the averaging rule being the best learning algorithm. On the other hand, groups relying on imitation perform even worse than isolated learners and while their performance increases over time, the distance between imitators and isolated learners actually widens.

The results point out a faulty component of the imitation strategy in this context: groups implementing imitation learning are unable to pick out the truly successful strategies based on sample information. What drives these differences between learning strategies and how robust are these findings? A closer analysis of single environments reveals a stable ordering of the algorithms (for each paired comparison between algorithms: \(p=.002, N=10\), two-sided binomial test), the results do not seem to be due to particular properties of specific data sets. In the following, we examine the sensitivity of the observed pattern regarding group-size.

\section*{The effect of larger groups}

To test the effect of group size we simulated 1000 groups for each group size across all data sets and algorithms. We chose group sizes of two to ten members and in addition 15, 20 and 25 members and averaged results after fifty group exchange phases. Fig. 3 demonstrates the effect of this variation on groups implementing the different learning strategies in terms of the relative difference to the average accuracy of isolated learners: The averaging strategy profits the most from larger group sizes with diminishing marginal returns. For the plurality rule, the addition of new members is beneficial up to about five members, while additional members do neither improve nor decrease the performance. Most strikingly though, the performance of imitators decreases with group size, showing the worst result for 25 members.

\section*{Discussion and Conclusion}

For the plurality rule a group size of two is equivalent to a random choice when the two members disagree, therefore the increase in performance for the first few members is easily explained. The effect of further members has to do with inertia: After each group exchange phase, all individuals start with the social cue order established in that phase. To change the social order in the following social learning phase, a plurality of individuals must have changed their order in the same way. In a larger group, the plurality choice can be considered to be more valid, but it becomes more difficult to change the social order, as each individual learns from different paired comparisons resulting in potentially different changes in individual cue orders. As a plurality of votes is necessary for a change this can lead to inertia.

Imitation learning is yet a special case: With larger group sizes it is more probable to find orders with a successful past track record. Based on the observation that even a random cue order achieves a decent rate of successful comparisons,there is a good chance of finding an individual with perfect or near-to-perfect track record for a block of trials. What creates a first problem, is the fact that the chosen individuals will have learned based on mostly or exclusively successful comparisons, as any failure lowers the success score. The success of individuals could be due to encountering simpler problems in the environment (that can be solved using many cue orders). As candidate solutions are developed by individual learning only, the group will retain strategies that are based on biased samples, on an "under-sampling of failure" (Denrell, 2003). A second problem for imitation strategies is that a suboptimal change in a single individual order combined with an unfortunate distribution of encountered object pairs can be transferred to all group members in one group exchange phase. It is much more difficult to retain learning increments using this strategy.

In this study, we have identified one class of situations, in which imitation learning based on observed success is not only worse than often feasible social learning alternatives, but it is even worse than isolated individual learning. The problems encountered by the learning algorithm are likely to
be endemic in other relevant decision contexts. The inferiority of the learning principle may be difficult to notice, as the performance of imitators increases over trials as for all other strategies, and there might be no other strategies for comparison. Stereotypical causal explanation patterns will assume that something special and unique to the individual must have been responsible for success. This has to be seen in sharp contrast with situations in which the quality of a strategy can be judged using external or logical criteria. The performance of imitation based on mere past success constitutes a lower bound for imitation performance. Concrete evidence for decision makers falling into the trap of taking past success as a proxy for future performance and ignoring sampling and selection processes is given by Offerman and Schotter (2009). In their experiments participants tend to copy the behavior of decision makers that took great risks and were lucky to get the best possible outcome using a risky strategy with a lower expected value than alternative strategies. In an ongoing learning context these problems might well be attenuated and decision makers should eschew the choice of naive benchmarking procedures and mindless imitation of the most successful (Denrell \& Liu, 2012; Pfeffer \& Sutton, 2006), if they want to channel the power of social learning into obtaining the best possible results.

\begin{abstract}
We investigated both subjective and objective differences in viewing non-social versus social scenes. Specifically, we examined four related questions: 1) Do participants prefer non-social or social scenes? 2) Are there differences in subjective exploration of non-social and social scenes? 3) Are there differences in objective exploration of these scenes? 4) Does a non-social trait connection to nature - influence the extent of non-social scene exploration? Experiment 1 found, surprisingly, that participants prefer non-social over social scenes, and correspondingly, they reported exploring these scenes more. Experiment 2 used eyetracking to test the validity of this introspection and confirmed that participants explore non-social scenes more than social scenes. We also discovered that connection to nature selectively modulates exploration of non-social scenes, demonstrating a critical interaction between observer and scene characteristics in the deployment of spatial attention.
\end{abstract}

Keywords: eye-tracking; exploration; attention; individual differences; subjective experience.

\section*{Introduction}

The desire to understand how attention is guided in the real social world has increased the use of eye movement tracking in complex natural environments. Accordingly, there has been a growing interest in the role that social stimuli play in the allocation of human attention and eye movements (for a recent review see Risko, Laidlaw, Freeth, Foulsham, \& Kingstone, 2012). However, this leaves a pertinent question unanswered: what role, if any, do nonsocial stimuli play in the allocation of attention in real world scenes?

Recent evidence indicates that when social and non-social scenes are put in direct competition, there is a distinct preference to look at social scenes, and particularly, at the eyes of the people in the social scenes (Fletcher-Watson, Findlay, Leekam, \& Benson, 2008; Birmingham, Bischof, \& Kingstone, 2008). Given that attention operates largely in
service of an individual's goals and intentions, and that looking behaviour is positively correlated with reward (Sullivan, Johnson, Rothkopf, Ballard, \& Hayhoe, 2012), a straight-forward prediction is that a selection bias for social stimuli over non-social stimuli reflects a subjective preference. However, an alternative possibility is that eye movements towards the social content of scenes (particularly the eyes of the people in the scenes) is being driven by a low-level neural system that is preferentially biased to process biologically relevant information (Laidlaw, Risko, \& Kingstone, 2012). In this case, one's subjective preference of the stimuli is not necessarily driving gaze behaviour. The aim of Experiment 1 was to determine whether subjective preference may be driving attention towards social stimuli.

Participants were asked to subjectively rate their liking for non-social scenes and social scenes. Importantly, previous research has shown that the social scenes used in the present study attract fixations to the eyes of the people in the scenes (Birmingham et al., 2008). We also asked participants to introspect on how much they thought they had explored the social and non-social scenes. We did this to investigate the accuracy of subjective intuition as to how one looks at scenes. Because our past work has shown that there is a marked tendency for participants to fixate onto the eyes of people in the scenes, we predicted that participants would report they had explored social scenes less than non-social scenes.

\section*{Experiment 1}

\section*{Methods}

Participants Sixteen students from the University of British Columbia participated in the 30 -minute experiment in exchange for course credit.

Stimuli Participants viewed a slideshow of 51 unique images at their own pace. Of interest were 6 interior and 6
landscape scenes from Foulsham, Kingstone, and Underwood (2008), as well as 7 social scenes from Birmingham et al. (2008) that have been shown to trigger rapid and sustained eye movements to the eyes of the individuals in the scenes. The social scenes either depicted 1 person alone, or 3 people interacting. Only these scenes were analyzed for the purposes of this study because they were used directly in Experiment 2. \({ }^{1}\) Exploratory eye movements are potentially affected by the saliency distribution of the stimuli (Itti, Koch, \& Niebur, 1998). For example, stimuli with widely distributed salient locations could lead to a distributed eye movement pattern, and stimuli with salient locations concentrated in a small area could lead to a concentrated pattern. For this reason, we ensured that the image areas spanned by the most salient points were matched across image types. \({ }^{2}\)

Questionnaires Participants were asked to rate, on a 5-point Likert-type scale, how much they liked the scenes, and how much they explored the scenes.

Data Analysis A one-way repeated-measures analysis of variance (ANOVA) was used to compare the average preference and exploration ratings of the interior, landscape, and social scenes.

\section*{Results}

There was a main effect of scene type on the average preference ratings, \(F(2,30)=46.94, M S E=8.95, p<.001\). Post-hoc, Bonferonni-corrected t-tests revealed that participants significantly preferred landscapes over interiors, \(t(15)=5.60, p<.001\), and social scenes, \(t(15)=8.59, p<\) .001. See Figure 1.
There was a main effect of scene type on the exploration ratings, \(F(2,30)=12.00, M S E=1.14, p<.001\). Post-hoc, Bonferonni-corrected \(t\)-tests revealed that participants reported greater exploration of the interior and landscape scenes compared to the social scenes (interiors: \(t(15)=3.56\), \(p=.003\); landscapes \(t(15)=4.32, p=.001)\). There were no significant differences in exploration ratings between interiors and landscapes, \(p>.10\). See Figure 2.

\footnotetext{
\({ }^{1}\) The remaining slideshow images were used in different experiments not reported here. They included other social, interior, and landscape scenes from the same stimuli sets, in addition to other scenes from a different stimuli set (Foulsham \& Kingstone, 2010). When all images from the current stimuli set are analyzed, the same results are obtained.
\({ }^{2}\) We computed saliency maps for each scene using the Saliency Toolbox (Walther, 2012) and determined the location of the most salient locations (defined as the set of locations with a saliency value of at least \(50 \%\) of the maximum saliency in the scene). We then calculated the image area spanned by these locations (i.e., their convex hulls). A comparison of all scene types showed that there were no significant differences in the image areas between the scenes.
}

Figure 1: Average ratings of how much participants liked each scene type. Participants significantly rated landscapes highest and social scenes lowest (all \(p\) 's \(<.001\) ). Error bars represent the standard error of the individual means.

Figure 2: Average ratings of how much participants explored each scene type. Participants significantly rated landscapes \((p=.001)\) and interiors \((p=.003)\) above social scenes. Error bars represent the standard error of the individual means.

\section*{Discussion}

In Experiment 1 we found that participants preferred the non-social landscape scenes and interior scenes over the social scenes. Given that our previous work using the current social stimuli has demonstrated a marked looking preference for social versus non-social stimuli, and that this finding has been confirmed by other researchers (FletcherWatson et al. 2008), it was reasonable to predict that this preference in looking behaviour would reflect a subjective preference for social over non-social stimuli. However, in contrast to reward theory, the data appears to support the notion that selection bias towards social stimuli is driven by something other than subjective preference.

In addition, subjects showed the strongest preference towards landscape scenes. This finding supports the idea that people have a unique preference for nature (Grinde \& Patil, 2009; Mayer \& Frantz, 2004; Nisbet, Zelenski, \& Murphy, 2011; Schultz \& Tabanico, 2007).

Consistent with past work indicating that people tend to 'lock' their eyes on people in social scenes, our study found that participants rated their exploration of the non-social scenes to be significantly greater than the social scenes. This finding seems to validate the accuracy of subjective intuition about how one allocates attention. Nevertheless, research has demonstrated that individuals can be very poor at judging whether their eyes have moved or not (e.g., Belopolsky, Kramer, \& Theeuwes, 2008). Even when individuals do realize their eyes have moved, they can be notoriously poor at judging where they may have looked (Foulsham \& Kingstone, 2013). Thus we thought that it was important to objectively confirm the validity of participants’ subjective reports, by testing subjects' exploratory looking behaviour with the same stimuli.

In addition, and in light of our recent work that an individual difference trait in visual curiosity can influence visual exploration (Risko, Anderson, Lanthier \& Kingstone, 2012), we took this opportunity to investigate the intriguing hypothesis that a non-social trait may selectively predict how one looks at non-social content. To test this idea we used the Connectedness to Nature Scale (CNS; Mayer \& Frantz, 2004). Connectedness to nature has been demonstrated to be implicitly part of an individual's identity, that is, how the natural world is included in one's representation of self (Schultz \& Tabanico, 2007).

In a sense, connection to nature can be seen as an antithesis of scales that measure social traits. While scales like the Autism Quotient (AQ) measure one's connection to the social world (Baron-Cohen, Wheelwright, Skinner, Martin, \& Clubley, 2001), the CNS measures one's connection to the non-social world. Thus, if autism spectrum disorders and social skills scores on the AQ are predictive of how people look at social content (Chen \& Yoon, 2011; Freeth, Foulsham, \& Kingstone, 2013), it is plausible that CNS may be predictive of how people look at non-social content.

In Experiment 2, participants performed a free-viewing task of interior, landscape, and social scenes while being eye-tracked, and then completed the CNS. We looked at how exploration may be different across scene types, and whether CNS scores were related to these exploratory eye movements (Risko et al., 2012). Following the results of Experiment 1, we predicted that exploration should be equal for interiors and landscapes, and significantly less in social scenes.

\section*{Experiment 2}

\section*{Methods}

Participants Twenty-three participants from the University of British Columbia were given course credit, or paid \(\$ 5\), to participate in the 30 minute study.

Stimuli The same scenes were used as the ones analyzed in Experiment 1. The scenes were \(1024 \times 768\) pixels, and corresponded to a horizontal visual angle approximately \(42^{\circ}\), and a vertical visual angle approximately \(33^{\circ}\).

Questionnaires Each participant was asked to provide demographic information, and to complete the CNS. The CNS is a 14 -item questionnaire with a 5-point Likert-type scale, used to measure participants' trait levels of feeling emotionally connected to the natural environment (Mayer \& Frantz, 2004). This inventory has acceptable internal reliability ( \(\alpha=.84\); Mayer \& Frantz, 2004).

Apparatus An SR Research Eyelink 1000 eye-tracking system, recorded participants' eye movements at 1000 Hz . Stimuli were presented to participants on a \(23^{\prime \prime}\) monitor. Scenes and eye movements were also presented to the experimenter on an adjacent monitor located in the testing room, relaying real-time feedback on system accuracy.

Procedure Participants were seated 60 cm from the computer monitor, with their heads positioned in a chin rest. Participants were told to view each image as they would normally do. Scenes were presented for 10 s. Participants viewed the images before being asked to complete the questionnaire.

Data Analysis An \(8 \times 8\) grid was created for each image, yielding 64 interest areas that were invisible to participants. Each region subtended approximately \(5.25^{\circ}\) horizontal visual angle, and \(4.13^{\circ}\) vertical visual angle. We quantified participants' exploratory eye movement behaviour using an exploratory index (EI). This index is the ratio between the number of unique regions visited in a scene, and the total number of fixations in that scene (i.e., the number of regions visited with the number of fixations normalized). We believe the EI measure gives a more accurate quantification of exploratory strategy. A raw count of regions visited is easily biased by the total fixations a participant makes: the greater the total number of fixations, the greater number of regions that would be visited simply by chance. This is reflected in the data as a raw count of regions visited correlates highly with the total number of fixations in nonsocial scenes: \(r=.73, p<.001\), and social scenes: \(r=.67, p\) \(<.001\), whereas our EI measure does not, both \(p\) 's \(>.22\). \(^{3}\) By normalizing for the number of fixations, the EI measure assesses how participants spatially allocate their attention given the same constraints (number of fixations).

It is arguable that this EI value misses within-region exploration, and reversing the ratio (number of fixations over regions visited) would better capture exploration.

\footnotetext{
\({ }^{3}\) Using raw counts of regions visited instead of EI also gives us different results. Interiors had the greatest counts, with landscapes in the middle, and social scenes garnering the least. In addition, raw counts did not correlate with CNS in social or non-social scenes.
}

However, this value would be unable to distinguish whether participants are simply repeatedly looking at the same features within a region. Given the size of the regions, it is likely only one attractive feature (e.g., eyes) is contained within it. While it is true that a participant who attends these features more can be said to have "explored" them more, it is inconsistent with our operational definition of exploration. We are interested in exploration in the sense of spatial distribution of attention, not exploration in the sense of focus toward one specific feature.

A repeated-measures ANOVA was conducted between the average EI values of each scene type. Pearson's correlations were conducted separately between the EI mean for non-social scenes and CNS scores, and the EI for social scenes and CNS scores. Pearson correlations were also conducted between CNS scores and other eye movement measures (total fixations and fixation durations), to see if the trait was related uniquely to exploration.

Figure 3: Average exploratory index values of participants viewing social, interior, or landscape scenes. Participant's significantly explored non-social scenes significantly more than social scenes (both \(p\) 's \(<.001\) ). Error bars represent the standard errors of the individual means.

\section*{Results}

There was a main effect of scene type on EI values, \(F(2,44)\) \(=31.67, M S E=0.88, p<.001\). Post-hoc repeated-measure, Bonferonni-corrected, t-tests revealed that participants did not differ in exploring interiors and landscapes, but explored both significantly more than social scenes (interiors: \(t(22)=\) 10.62, \(p<.001\); landscapes: \(t(22)=6.26, p<.001)\). See Figure 3.

The correlations between CNS scores and EI measures are shown in Table 1. The correlation between CNS scores and EI for non-human scenes was significant, \(r=.43, p=.04\). However, CNS scores were not correlated with EI for social scenes, nor for any of the other eye movement measures.

Table 1: Correlations between scores on the Connectedness to Nature Scale (CNS), and EI values, total fixations, and fixation durations in non-social and social scenes. Value bolded indicates \(p<.05\).
\begin{tabular}{lc}
\hline Measure & CNS \\
\hline Non-social: & \\
EI & .43 \\
Fixation count & -.05 \\
Duration & -.03 \\
Social: & \\
EI & .08 \\
Fixation count & -.02 \\
Duration & -.07 \\
\hline
\end{tabular}

\section*{Discussion}

The results of Experiment 2 confirm our findings in Experiment 1. Participants explored the non-social scenes far more than the social scenes, in keeping with the subjective reports in Experiment 1. Equally remarkable, we found that a non-social trait, connectedness to nature, predicted the variation in exploratory eye movements. This power to predict scene exploration was specific to the nonsocial scenes.

\section*{General Discussion}

We began our work by asking the following question: In light of the field's growing interest in social attention, what important role, if any, do non-social stimuli play in the allocation of attention in real world scenes? Our work has provided at least four new insights.

First, in Experiment 1, we found that participants preferred non-social scenes - whether they are outdoor scenes or interior scenes - significantly more than social scenes. This finding suggests that subjective preference and reward mechanisms are not responsible for the preferential bias to look toward social stimuli rather than non-social stimuli.

Second, in Experiment 1 we found that participants provided a subjective report that they explored non-social scenes (both landscapes and interiors) more than social scenes. Despite good reason to question the accuracy of this self-assessment, Experiment 2 found that people did explore non-social scenes far more than social scenes.

This finding in turn revealed that people are in fact accurate at subjectively gauging the extent to which they move their eyes through different scene types.

Finally, in Experiment 2, we discovered that a non-social trait, one's connectedness to nature, was selectively related to exploratory eye-movements in non-social scenes. In other words, non-social traits can selectively influence attention in certain scene types. This finding demonstrates the importance of using non-social scenes in exploring the influence of trait differences on attention. After all, if we
had only used social scenes we would have missed the effect. It is also noteworthy that our work extends the work of Risko et al. (2012) to include a new individual trait related to exploratory eye movement behaviour connectedness to nature.

Yet why was connectedness to nature not related to exploration in social scenes? There are at least three possibilities, all worthy of future investigation. First, it may be that there is an overwhelming pull to attend to human stimuli such that any differences in attention that might be influenced by individual traits are over-ridden. Highly attractive features that capture attention, like eyes and faces, may lead to failure of an exploratory viewing bias. This possibility suggests social EI and non-social EI are not distinct constructs. CNS would be related to both social and non-social EI if not for the overwhelming pull of eyes and faces. Alternatively, human content may produce a viewing strategy itself (e.g., making sense of the scene; Birmingham et al., 2008), and this strategy is prioritized over exploratory behaviour. Such an explanation has important implications for researchers wanting to study individual differences in areas related to attentional exploration, such as inspiration, creativity, and curiosity (Fredrickson \& Anderson, 1999; Kasof, 1997; McCoy \& Evans, 2002; Risko et al., 2012; Schlewitt-Haynes, Earthman, \& Burns, 2002). The third possibility is that the CNS is not related to human connectedness. There may be 'connectedness to human' traits that could be related to human content. As mentioned previously, there is evidence that AQ scores are predictive of how people look at social content (Chen \& Yoon, 2011; Freeth et al., 2013), as well as evidence of other traits like social anxiety related to attention to social stimuli (Mansell, Clark, Ehlers, \& Chen, 1999). This would suggest that social EI and non-social EI are distinct constructs, and that different traits would relate independently to each scene type. Further study will be needed to examine these three possibilities.

In addition to stable characteristics like personality (Risko et al., 2012), our findings raise the possibility that factors like attitudes and feelings may also influence one's eye movements, and thus be embodied in eye movement behaviour. For example, connection to nature relates positively to pro-social and outward looking values, but negatively to inward looking values (Weinstein, Przybylski, \& Ryan, 2009). Might these attitudes be embodied in broadness or narrowness of attentional focus (see Chua, Boland, \& Nisbett, 2005, for a similar hypothesis)? Since the current study was purely correlational, inferences about such a possibility cannot be made. In the future, we hope to investigate the direction of this relationship.

Results from our two experiments combined support the possibility that the bias to look at social stimuli is subserved not by one's subjective preferences for social versus non-social stimuli. If one wishes to maintain that these eye movements to social stimuli are due to reward mechanisms (Sullivan et al., 2012) then one must abandon the assumption that the reward system is related to preference.

However, if that is true, then perhaps the notion of reward itself needs to be reconceptulaized. Perhaps a better account for our results comes from recent evidence of a primitive low-level neural system that automatically drives attention and eye movements toward biologically relevant information, such as the eyes of others (Laidlaw et al., 2012; Levy, Foulsham \& Kingstone 2012).

On a more practical level, our investigation provides an example of the validity of using subjective reports, in addition to measuring objective variables. The fact that the subjective results in Experiment 1 were mirrored by the objective results in Experiment 2 mitigates some of the concerns cognitive scientists may have about doing subjective experience research (for a review, see Kingstone, Smilek, \& Eastwood, 2008). For example, we show that subjective reports are reliable and replicable across individuals. We also show that attentional exploration does not operate below conscious awareness since participants’ subjective reports were consistent with looking behaviour (cf. Nisbett \& Wilson, 1977). Our study gives empirical backing to the validity, and necessity, of using subjective experiences in addition to objective measures (Kingstone et al., 2008).

Overall, our results suggest that the use of non-social stimuli in studying real-world attention should not be overlooked. Non-social stimuli offers participants a chance to avoid the overwhelming pull of social stimuli. As such, factors like individual traits and subjective preferences that affect eye-movement behaviour may be buried when using social stimuli. On a more theoretical level, our study contributes to a burgeoning field that seeks to uncover how psychological aspects of one's identity are intimately linked to the lowest levels of one's underlying physiology (Chua et al., 2005; Dodd et al., 2012; Dodd, Hibbing \& Smith, 2011; Risko et al., 2012). Continuing to identify these subjective aspects will surely lead to interesting and important knowledge about how different individuals uniquely select, perceive, and ultimately act towards different stimuli.

\title{
The invisible hand: Toddlers infer hidden agents when events occur probabilistically
}

\begin{abstract}
This study looked at whether toddlers posit the existence of unobserved causes when events occur probabilistically. Older (18-24 months) and younger (12-17 months) children were introduced to novel events. An experimenter pressed a red handle and a lollipop emerged from a box; she then pressed a green handle and a cake emerged. These events were repeated three times. On the fourth trial, the experimenter switched either the order or relationship between events. In the Deterministic condition, the experimenter pressed the green handle first and the red handle second; in the Probabilistic condition, the red handle produced the cake and the green handle produced the lollipop. On the test trial, the experimenter pressed the red handle and a hand emerged, holding the lollipop. The older toddlers looked longer at the hand in the Deterministic than the Probabilistic condition, suggesting they inferred a hidden cause when the events occurred probabilistically.
\end{abstract}

Keywords: causal learning, determinism, toddlers, lookingtime measures.

\section*{Introduction}

The \(19^{\text {th }}\) century mathematician Pierre Simon-LaPlace speculated that if there were an intellect capable of analyzing all the forces operating in nature "to it nothing would be uncertain; the future, like the past, would be as the present before its eyes." Twentieth century physics has made this view untenable; we now know that our universe is comprised of irreducible uncertainties. Nonetheless, the idea of indeterminate events boggles the imagination. We cannot resist explanation even if our world is resistant to it.

However inaccurate, a belief causal determinism may be advantageous for learning. A deterministic universe provides well-specified conditions under which a learner can infer the existence of hidden variables. If events appear to occur spontaneously, either an unobserved generative cause is present or an inhibitory cause is absent; if events appear to occur stochastically, either an unobserved inhibitory cause is present or a generative cause is absent.

Is a belief in causal determinism an artifact of Enlightenment thought or a fundamental feature of human cognition? Developmental evidence suggests that children resist both spontaneous and stochastic causation well before they receive formal science instruction. By the age of five, preschoolers posit hidden causes to account both for apparently uncaused events (Bullock, Gelman \& Baillargeon, 1982; Chandler \& Lalonde, 1994; Gelman, Coley, \& Gottfried, 1994) and for caused events that occur
some, but not all, of the time (Schulz \& Sommerville, 2006; see also Piaget \& Inhelder, 1975).

However, relatively little is known about the origins of deterministic beliefs earlier in development. The vast majority of studies looking at indeterminate causation in infancy have focused only on the specific case of unexplained motion events (see Gelman \& Gottfried, 1996; Gottfried \& Gelman, 2005; Leslie, 1984; Luo \& Baillargeon, 2005; Luo, Kaufman, \& Baillargeon, 2009; Markson \& Spelke, 2006; Muentener, Bonawitz, Horowtiz, \& Schulz, 2012; Premack, 1990; Saxe, Tenenbaum, \& Carey, 2005; Saxe, Tzelnic, \& Carey, 2007; Spelke, Philllips, \& Woodward, 1995). Thus for instance, if an inanimate object flies over a wall, infants seem to be less surprised if a hand is revealed at the origin of the object's movement than at the terminus of the movement, suggesting that infants posit hidden causes when objects appear to move spontaneously (Saxe et al., 2005; 2007). Recent work has extended these findings beyond motion events: infants infer the presence of agents as causes not only when objects move, but also when they change states spontaneously (i.e., when a box breaks apart or plays music; Muentener \& Carey, 2010).

However, infants' expectation that physical events have causes may not imply any broader commitment to determinism. Are toddlers sensitive to stochastic causal events as well as spontaneous ones? Some suggestive evidence that toddlers ( \(M=18\) months) resist probabilistic causation comes from the finding that toddlers imitate deterministically effective actions more faithfully than they imitate probabilistically effective ones (Schulz, Hooppell, \& Jenkins, 2008). However, we do not know whether toddlers actually posit the existence of unobserved causes when events occur probabilistically. The current study investigates this question. Given that positing unobserved variables might be more complex than differential exploration, we used 18 -months as the bottom of our range to test a group of older toddlers, \(18-24\) months, and we compared their performance to younger children, 12-17 months.

We introduced toddlers to novel causal relationships that were either deterministic (Cause A generated effect A 100\% of the time, and Cause B generated Effect B 100\% of the time) or probabilistic (Cause A generated Effect A 75\% of the time and Effect B \(25 \%\) of the time; Cause B generated Effect B \(75 \%\) of the time and Effect A \(25 \%\) of the time). We hypothesized that if toddlers are causal determinists, then they might infer the existence of an unobserved agent given probabilistic evidence but would have no reason to expect
an unobserved causal agent given deterministic evidence. Following the approach used in previous studies (Muentener \& Carey, 2010; Saxe et al., 2005; 2007) we used a human hand as the candidate causal agent. We predicted that when the hand is revealed, toddlers would look at it longer in the Deterministic condition, when no agent is expected, than the Probabilistic condition, where an unobserved cause might be inferred.

\section*{Methods}

\section*{Participants}

Sixty-four toddlers (mean age: 17.2 months; range: 12.0 to 23.5 months) were recruited at a Children's Museum. We tested both younger (12-17 months) and older (18-24 months) toddlers. There were 16 toddlers in each condition (age group \(\times\) evidence conditions). An additional 23 toddlers were recruited but not included in the final sample due to: experimenter error \((\mathrm{n}=10)\), fussiness \((\mathrm{n}=9)\), or parent interference \((\mathrm{n}=4)\). There were equal number of boys and girls.

\section*{Materials}

Toddlers were introduced to a purple box ( \(37.6 \mathrm{~cm} \times 29.2\) \(\mathrm{cm} . \times 20.3 \mathrm{~cm}\).) with two handles ( 21.6 cm in length). The left handle was red with black stripes. The right handle was green with white spots. See Figure 1. The box was placed in front of a black foam board screen \((117.9 \mathrm{~cm} \times 97.8\) \(\mathrm{cm})\). The experimenter could hide behind the screen and observe the child through pinholes in the screen. Two openings in the screen on either side of the box allowed the experimenter to reach her hands through to manipulate the handles. The box had an opening in the back and the top so that the experimenter could conceal her hand in the box and lift objects out of the box. When a handle was pressed the experimenter lifted either a lollipop ( 9.4 cm in diameter) or a toy cake ( 7.6 cm in height, 7.6 cm in width) out of the box. An MVP player was also used: the red handle was always accompanied by the sound of an ascending scale on a xylophone; the green handle was always accompanied by the sound of a descending scale on a xylophone.

\section*{Procedure}

Toddlers were recruited from a local Children's Museum and tested in a private room located on the museum floor. The child was placed in a high chair approximately 100 cm in front of the box. The child's parent sat to the right of the high chair, out of the child's direct line of sight.

The experimenter pointed to the box and the two handles. See Figure 1. Then she went behind the screen. The experimenter knocked on the center of the box behind the screen and said, "Hi, [child's name]! Watch this box!" She began the Familiarization Trials by putting her hand out of the left hole and waving at the child. She then pressed the red handle and, with her other hand concealed in the box, triggered the ascending scale and lifted the lollipop
out of the box. Pilot work established that to an adult observer, it looked like the handle caused the lollipop to emerge from the box. She held the lollipop up for 2 seconds

\section*{Initial Display}

A box with two handles.

\section*{Familiarization Trials}

When the red handle is pressed, the lollipop pops up; when the green handle is pressed, the cake pops up. This sequence was repeated three times.

Red handle - Lollipop

Green handle - Cake

\section*{Test Trial}

When the hand presses the red handle, the other hand holding the lollipop pops up.

Figure 1: Procedure of the experiment.
and then released the red handle and simultaneously returned the lollipop to the box. She brought her hand back behind the screen. She then put her hand out of the right hole and waved at the child. She pressed the green handle and, with her other hand concealed in the box, triggered the descending scale and lifted the cake out of the box. She held the cake up for 2 seconds and then released the green handle and simultaneously returned the cake to the box. The
experimenter repeated the familiarization trials a total of three times.

On the Switch Trial, the experimenter said, "[child's name], watch!" In the Deterministic condition, she switched the order of events, repeating the events in the Familiarization Trials except that she pressed the green handle first and the cake popped up; she then pressed the red handle and the lollipop popped up. In the Probabilistic condition, the experimenter switched the relationship between events, repeating the events in the Familiarization Trials except that when the experimenter pressed the red handle, the cake popped up; when she pressed the green handle, the lollipop popped up.

On the Test Trial, the experimenter put her hand out of the left hole and waved to the child. She then said "Aha!", pressed the red handle and lifted her hand holding the lollipop all the way out of the box so that both her hand and the lollipop were visible to the child. She remained stationary in this position until the child looked away from the stage for at least 2 consecutive seconds. Note that she ran the familiarization, switch and test trials cohesively without measuring children's looking times to each trial. Most of the children were engaged in the experiment and kept looking all through it. A coder blind to the conditions coded the children's looking times from the beginning of the "Aha!" sound to the start of the 2-second looking away off-line from videotape. The blind coding from videotape corroborated the experimenter's online judgment in all but three cases; three children were dropped from the analysis and replaced due to premature termination of the test trial. A second coder blind to the conditions coded one third of the clips. Inter-coder reliability was \(95.6 \%\).

\section*{Results}

We examined the effect of the condition manipulation on toddlers' looking time to the test trial separately within each age group (12-17 months, 18-24 months; see Figure 2). The 12-17 month olds, looked equally long at the test trial in the Deterministic and Probabilistic conditions (Deterministic mean: 10.5 s ; Probabilistic mean: \(9.8 \mathrm{~s} ; t(30)\) \(=.39, p=.698\) ). However, the \(18-24\) month-olds looked significantly longer at the test trial in the Deterministic condition than the Probabilistic condition (Deterministic mean: 13.7 s ; Probabilistic mean: \(8.2 \mathrm{~s} ; t(30)=2.51, p=\) .018 ). This is consistent with the possibility that children had inferred the presence of an unobserved candidate cause in the Probabilistic condition but not the Deterministic condition.
Note the Switch Trial and the Test Trial were perceptually more similar to each other in the Deterministic condition than the Probabilistic condition. In the Deterministic condition, the only difference between the last event of the Switch Trial and the Test Trial was the presence of the hand; in the Probabilistic condition both the handle pressed and the hand differed. This suggests that the toddlers in the Deterministic condition looked longer at the Test Trial not because it was perceptually more novel but because the
hand was more unexpected in the Deterministic condition than the Probabilistic condition.

Figure 2: Looking times on the deterministic and probabilistic conditions as a function of age. \({ }^{*} p<.02\)

\section*{Discussion}

These results suggest that 18-24 month-olds posit unobserved causes when they observe probabilistic evidence. Toddlers who saw a stochastic relationship between causes and effects appeared to be less surprised that a human hand was involved in the events than toddlers who saw a deterministic relationship. This is consistent with the possibility that toddlers are causal determinists.

However, the current results also leave a number of questions unanswered. Children may assume that artifacts behave deterministically without extending this assumption to the physical world more broadly. Artifacts, including the stimuli used here, may have particularly salient, and familiar, deterministic causal relationships. We do not know to what extent toddlers would infer the presence of unobserved causes to account for naturally occurring probabilistic events. Additionally, we do not know to what extent either adults or children extend a belief in causal determinism beyond the physical world, to psychological and social events. Future research might investigate the extent to which children draw inferences consistent with causal determinism across a broader range of contexts.

Additionally, we do not know why the younger toddlers in our study failed to distinguish the Deterministic and Probabilistic conditions. It is possible that \(12-17\) montholds accept that events can happen stochastically. Alternatively, given that there were only three Familiarization Trials and a single Switch Trial, the distinction between the conditions may have been too subtle for the younger toddlers to detect. Younger toddlers might have failed to learn the causal relationships initially, or failed to detect either the order or relational change. Given more exposure to the target events, even young toddlers and infants might posit unobserved causes to explain probabilistic evidence.

Finally, it would be interesting to know what kinds of unobserved causes children allow as explanations for
probabilistic evidence. Saxe et al. (2005) found that infants failed to treat one object as a cause of another object's motion, although they accepted both a hand and a novel, handless agent puppet as potential candidate causes (Saxe, et al., 2007). Similarly Muentener \& Carey (2010) found that infants accepted a hand but not an object as a candidate cause of another object changing state. Finally, Newman, Keil, Kuhlmeier, and Wynn (2010) found that infants expected that agents (balls with eyes) could add order or structure to a scene but that objects (balls without eyes) could not. In this study, we only tested toddlers' inferences about human agents as candidate causal agents in probabilistic events; it would be interesting to know whether toddlers' inferences about the unobserved causes behind probabilistic events are limited to agents.

What the current study does establish is that even toddlers' causal inferences go well beyond the evidence they observe. Given sparse data for a novel probabilistic causal relationship, toddlers inferred the existence of an unobserved causal agent. To the degree that a belief in causal determinism shapes the inferences even of one-and-a-half-year-olds, they are well equipped for exploration and discovery.

\section*{Acknowledgements}

Warm thanks to the Boston Children's Museum and participating parents and children. Thanks to Anne Kim for help with data collection and to Rachel Magid for help with making the stimuli and coding the data. This research was funded by a National Science Foundation CAREER award to L.S.

\begin{abstract}
This study aimed to explore the relationship between children's sharing behavior and Theory of Mind (ToM) understanding. Seventy-four 2 to 4 years old Chinese children participated in 3 tasks using toys that could be shared with a puppet that was animated by a female experimenter. On each task, the puppet expressed her desire for the items using a series of cues that progressively became more communicative. Children's ToM understanding was assessed with the scale of ToM tasks (Wellman, Fang, Liu, Zhu, \& Liu, 2006). There were two main findings: (1) younger children relied on more explicit communicative cues to share resources with the puppet, while older children shared more spontaneously and (2) children's sharing behavior was positively correlated to their ToM scores, independent of age. Findings suggest that preschoolers' sharing behavior is enhanced by their ToM understanding and explicit communicative cues provided by a social partner.
\end{abstract}

Keywords: preschoolers; sharing behavior; Theory of Mind understanding.

\section*{Introduction}

Sharing is an important aspect of human cooperative activities with roots very early in life. Studies have shown that infants as young as 8 months old show spontaneous offering of food and other objects to parents (e.g., Hay \& Murray, 1982; Hay, 1979; Rheingold, Hay, \& West, 1976). Though sharing emerges early, it appears to be a unique challenge for young children. Sharing resources is a much less frequent activity compared to other cooperative activities in young children, such as empathy-related responding, helping and instrument collaboration (Eisenberg, 2005; Grusec, 1991; Warneken \& Tomasello, 2007, 2009). Toddlers share toys with others rarely, though the rate of sharing increases from 12 to 30 months of age (e.g., Brownell, Svetlova, \& Nichols, 2009; Hay, Castle, Davies, Demetriou, \& Stimson, 1999; Levitt, Weber, Clark, \& McDonnell, 1985). Other work has shown that preschoolers also share little. For example, three- to five-year-old children reserved 10 pieces of food for themselves while sharing only one piece of food with their peers (Birch \& Billman, 1986). Sharing is difficult for children probably because it results in a sacrifice of something valued for the
welfare of someone else. There is evidence suggesting that children share more if there is no sacrifice compared to identical circumstances with sacrifices (Svetlova, Nichols, \& Brownell, 2010; Thompson, Barresi, \& Moore, 1997).

Though numerous studies have been conducted on sharing behavior, it remains difficult to depict the development of sharing, partially because many studies do not control the circumstances under which sharing was observed. For example, we do not know whether early social acts of offering items to others are primarily otheroriented unless we control for the social partner's behavior. In these cases, infants may just be seeking attention or reaction from the social partner, or may be complying with the request of others. Previous studies have shown that 2-year-old children shared food with an adult only when the adult actively communicated directly about what she wanted (Brownell et al., 2009), or reached toward the child with palm up while alternating gaze between the child and the food (Dunfield, Kuhlmeier, O’Connell, \& Kelley, 2011). Therefore, it is unclear to what extend children's "sharing" acts are truly sharing behavior with the intention to benefit others if the recipient's behavior is not controlled. By systematically manipulating the social partner's behavior, we might get a comprehensive understanding of the development of other-oriented resource sharing (see also Brownell, Iesue, Nichols, \& Svetlova, 2012). Therefore, the first goal of the present study was to examine how the social partner's communication supports young children's sharing. To do this, we systematically manipulated the expressive cues provided by the partner in the sharing task such that the partner made her needs progressively more explicit with a fixed sequence of cues. We then aimed to see at what point children would share.

Another unaddressed question is how we explain the development of sharing in children. Current theories have proposed various underlying mechanisms of sharing, such as the basic imitative tendencies toward people (Grusec, 2006; Hay \& Cook, 2007; Rheingold, 1982), the ability to differentiate self's and other's internal states (e.g., Moore, 2007), the sympathetic ability to relate self's emotions and feelings to other's (e.g., Eisenberg, 2007; Zahn-Waxler \& Radke-Yarrow, 1990), the understanding of ownership
(Brownell et al., 2012), and an innate biological preposition for empathy and altruism in infants (Tomasello, 2008; Warneken \& Tomasello, 2009b; Zahn-Waxler, Robinson, \& Emde, 1992). These different theoretical perspectives emphasize the social-cognitive and motivational components of early pro-social responding at different levels. Yet they agree, to different extents, that the origins of altruistic pro-social behavior are based on universal norms of fairness and reciprocity in combination with our understanding of other people's needs or wants (e.g., Fehr \& Fischbacher, 2004). This 'understanding of others' needs and wants' can be manifested in the Theory of Mind (ToM) understanding, which refers to the ability to attribute mental states - beliefs, intents, desires, pretending, knowledge, etc. - to oneself and others and to understand that others have beliefs, desires and intentions that are different from one's own (Premack \& Woodruff, 1978). From this perspective, is it possible that ToM understanding has an impact on prosocial behavior?

ToM understanding and pro-social behavior are both undergoing significant developmental changes during the preschool years (Benenson, Pascoe, \& Radmore, 2007; Blake \& Rand, 2010; Fehr, Bernhard, \& Rockenbach, 2008; Rochat et al., 2009; Wellman et al., 2006; Wellman \& Liu, 2004). Evidence suggests that these two abilities may share the same underlying neural processes (McCabe, Houser, Ryan, Smith, \& Trouard, 2001). That is, studies using functional magnetic resonance imaging (fMRI) found that as adult participants behaved cooperatively in a trust game, brain areas related to ToM (medial prefrontal cortex) were activated (McCabe et al., 2001). Moreover, previous studies have shown that preschoolers' ToM negatively predicted aggressive or disruptive behavior for boys and positively predicted pro-social behavior for girls after controlling for age (Walker, 2005). In addition, ToM has been suggested to be a facilitator of fairness-related behavior (Sally \& Hill, 2006), such as higher proposed offers in the Ultimatum Game (Takagishi, Kameshima, Schug, Koizumi, \& Yamagishi, 2010). These studies suggest that children with more advanced ability of understanding others' mental states may need less explicit supports from the social partner in interpreting his/her desires or needs, thus may be more likely to perform pro-social behavior. The second aim of the present study is to test this hypothesis in preschoolers.

\section*{Methods}

\section*{Participants}

Seventy-four Chinese children from two kindergartens in Beijing, China participated in the study. Both kindergartens largely served children of university staff and faculty in urban Beijing. There were twenty-five 2-year-olds ( \(M=\) 28.86 months, \(S D=3.16\), range: \(24.46-34.43\) months; 14 girls), twenty-five 3-year-olds ( \(M=39.49\) months, \(S D=\) 2.21, range: \(34.92-42.69\) months; 12 girls), and twentyfour 4-year-olds ( \(M=47.30\) months, \(S D=2.51\), range:
43.02 - 51.08 months; 14 girls). An additional 3-year-old boy was excluded from the study due to experimenter error.

\section*{Materials and Procedure}

Each child participated in both the sharing task and the Theory of Mind task in a quiet separate room adjacent to the child's classroom. Testing was conducted by a female experimenter ( E ) performing a hand puppet (a brown bear) named "Maomao" along with the help of a female assistant (AE). The session began with a warm-up and familiarization period during which Maomao (animated by E) and AE played with the child for several minutes to ensure that the child was comfortable approaching and interacting with both of them. The order of the sharing tasks and the theory of mind tasks were counterbalanced. All the sessions were video recorded.

Sharing Tasks. Three sharing tasks were administered with order counterbalanced across participants. Each task featured different items to be shared: there were 2 stickers in the 'sticker' task, 2 toy watermelons and 2 knives in the 'watermelon' task, 4 colorful beads and 2 strings in the 'bead' task. Therefore, there were 12 items in total across these three sharing tasks. These items were shown to be equally liked by children in a pilot study. Children thus had multiple opportunities to share different types of toys. This aimed to provide a relatively comprehensive measurement of sharing behavior. During the test, Maomao sat across a child-sized table from the child, and AE sat to one side of the table, at a 90-degree angle to the child and the puppet. After a short familiarization, AE brought out toys, and showed the child and the puppet how to play with these toys. AE then left the room, asking the child, "Could you please take care of these toys when I am gone? I'll be back soon. You can play with them by yourself, or with your new friend Maomao. Thanks, bye!" She then left the room. After AE left, Maomao provided three progressively more explicit cues about her needs and desires. The cues were presented in three phases: (1) Commenting phase: when the child was exploring toys, Maomao positively commented on the toys, such as "these are so beautiful!" She then repeated this 2 times, pausing for about 10 seconds between each. (2) Desiring phase: Maomao expressed her desires for these toys, such as "I like these toys! I want to play with them" in the same manner as the first phase. (3) Requesting phase: Maomao made an explicit request by asking the child for these toys, such as "would you please give me some to play with" in the same manner as the other phases. If the child shared at any point, Maomao discontinued the cues, thanked the child, and played with the toy(s) for about 10 seconds, and then signaled AE that the task ended by knocking the table. If the child did not share in the final phase, E signaled AE in the same way. AE then came back and moved on to a second sharing task with new toys.

Scale of Theory of Mind Tasks. These tasks were modeled after the Chinese version of the five core ToM
understanding tasks (Wellman et al., 2006; Wellman \& Liu, 2004). A small toy figure with Chinese visages and dark hair, whose name was Feifei, served as the target protagonist for the tasks. Although formats and general ideas were not different from the tasks used by Wellman and his colleagues (2006), task materials were modified in several places so that they were familiar and appropriate for our sample.

Diverse Desires: The participant was presented with pictures of an apple and a pear, and was asked to pick one that \(\mathrm{s} / \mathrm{he}\) liked better. Then \(\mathrm{s} /\) he was told that Feifei likes X better where X was always the opposite of the child's answer. The subsequent question for the child was which one Feifei would choose if she was hungry.

Diverse Beliefs: The participant was presented with pictures of a schoolbag and a drawer along with a picture of a car, and was told that Feifei was looking for her car. Then the child was asked to choose where (schoolbag vs. drawer) \(\mathrm{s} /\) he believed the car was. The experimenter (E) then stated that Feifei thinks the car is in X , where again X was always the opposite of the child's answer. The subsequent target question asked of the child was where Feifei was going to search for her car.

Knowledge Access: the participant saw a box with a fork inside. E then told the child that Feifei had never opened this box before. The target question was whether Feifei knew what was inside the box.

Contents False Belief: E presented the participant with a box with pictures of cookies on it. E then asked the child what \(\mathrm{s} / \mathrm{he}\) thought was inside the box. She then showed the child that it was actually a small pencil inside. After showing the child the real contents of the box, she told the child that Feifei had never opened this box. The target question was what Feifei thought was inside the box.

Real-Apparent Emotion: the participant saw a sheet of paper with three faces on it - a happy, a neutral, and a sad face. After ensuring that the child understands these emotional expressions, E told the child a story about a boy expecting a toy gun as his birthday gift, but actually getting a boring book. But he did not want to behave impolitely, so he decided to hide his feelings. The child was then asked how this boy really felt and how he tried to appear to others by pointing to the pictures with faces.

\section*{Coding and Scoring}

Each child received a score of sharing from 0-3 for each task, corresponding to the phase during which sharing occurred: \(0=\) did not share at all; \(1=\) shared in the requesting phase; \(2=\) shared in the desiring phase; \(3=\) shared in the commenting phase. Higher scores thus indicated quicker sharing with less explicit cues from the recipient. Scores were averaged over the three tasks to create an average sharing score for each child. In addition, the number of items shared by each child in all three sharing tasks ( \(0-12\) items in total) was also coded.

Children got a score of 1 for each ToM understanding task they passed. Thus, the range for ToM scores was 0-5.

The first author coded all of the videos, and another coder blind to the research goal rated \(25 \%\) of these videos. Cohen's kappa was computed to measure inter-rater reliability. Values for Cohen's kappa were 1.00 for the number of items shared in the sharing tasks as well as scores in the TOM task, and were 0.98 for the sharing score.

\section*{Results}

Preliminary analysis using the sharing score and the number of items shared by children showed that there were no significant main effects of task order or sex, nor was there an interaction between task order and sex. Therefore, the following analyses were conducted by collapsing the data across these factors.

\section*{Age Differences in Sharing and ToM}

An ANOVA test was conducted with the average sharing score as the dependent variable and age as the independent variable. Results showed that older children shared more spontaneously than did younger children, \(F(2,71)=6.38, p\) \(=.003\), partial \(\eta^{2}=.15\) (see Table 1 for means and standard deviations). Bonferroni corrected post-hoc tests showed that 4-year-old children had significantly higher sharing scores than 2 - and 3 -year-olds, \(p=.006, .011\), respectively, yet there was no significant difference between children of the two younger groups, \(p=1.00\).

Another ANOVA test was conducted with the total number of items shared as the dependent variable. Interestingly, no significant age effect was found, \(F(2,71)\) \(=1.36, p=.26\), partial \(\eta^{2}=.04\) (see Table 1).

Table 1: Means (Standard Deviations in Parentheses) for Primary Measures as a Function of Age
\begin{tabular}{lllc}
\hline Measure & 2 years & 3 years & 4 years \\
\hline \begin{tabular}{l} 
Sharing \\
Average sharing \\
score (0-3)
\end{tabular} & \(1.73(0.84)\) & \(1.77(0.79)\) & \(2.40(0.52)\) \\
\begin{tabular}{l} 
Total number of \\
items shared (0--
\end{tabular} & \(4.32(2.70)\) & \(3.96(1.79)\) & \(4.92(1.41)\) \\
\(\quad 12)\) & & & \\
\begin{tabular}{l} 
ToM
\end{tabular} & & & \\
\(\quad\) Total ToM & \(1.52(0.77)\) & \(2.16(0.80)\) & \(2.88(1.03)\) \\
Diverse Desires & \(0.92(0.28)\) & \(0.96(0.20)\) & \(0.96(0.20)\) \\
\begin{tabular}{l} 
Diverse Beliefs
\end{tabular} & \(0.20(0.51)\) & \(0.76(0.44)\) & \(0.83(0.38)\) \\
\begin{tabular}{l} 
Knowledge Access \\
Contents False \\
\(\quad\) Belief
\end{tabular} & \(0.08(0.28)\) & \(0.40(0.50)\) & \(0.67(0.48)\) \\
\begin{tabular}{l} 
Real-Apparent \\
Emotion
\end{tabular} & \(0.00(0.00)\) & \(0.00(0.00)\) & \(0.08(0.28)\) \\
\hline
\end{tabular}

In addition, children's total ToM score also increased significantly with age, \(F(2,71)=14.73, p<.001\), partial \(\eta^{2}\) \(=.29\). More specifically, the age effect was significant in children's score on the task of Diverse Beliefs \([F(2,71)=\) 3.33, \(p=.04\), partial \(\eta^{2}=.09\) ], the task of Knowledge Access \(\left[F(2,71)=11.41, p<.001\right.\), partial \(\left.\eta^{2}=.24\right]\), the
task of Contents False Belief \([F(2,71)=9.09, p<.001\), partial \(\left.\eta^{2}=.20\right]\), but not on the task of Diverse Desires [ \(F(2\), 71) \(=.24, p=.79\), partial \(\eta^{2}=.01\) ] or the task of RealApparent Emotion \(\left[F(2,71)=2.18, p=.12\right.\), partial \(\eta^{2}\) \(=.06]\), as shown in Table 1.

\section*{Associations between Sharing and ToM}

Since significant age effects were found in both scores of sharing and ToM understanding tasks, Pearson partial correlational analyses were conducted to investigate whether sharing was associated with ToM understanding after controlling for age. Results showed that the total score of ToM, Diverse Beliefs and Knowledge Access were both positively correlated to children's sharing scores and the number of items shared with age being controlled for, \(r\) ' \(s\) ranged . \(26-.36\), \(p\) 's \(<.05\) (for details, see Table 2). However, the scores of Diverse Desires and Real-Apparent Emotion did not correlate significantly to sharing.

To further examine the effect of ToM understanding on children's sharing behavior, we conducted a series of multiple regression analyses. We first regressed age on the sharing score and found that age had a significant effect on the sharing score ( \(\beta=.30, p=.01\) ), but the model only explained \(8.7 \%\) of the variance in the sharing score, \(F(1,72)\) \(=6.87, p=.01\). This age effect became non-significant \((\beta\) \(=.06, p=.65\) ) as the total ToM score was added as another independent variable. The effect of ToM was significant ( \(\beta\) \(=.42, p=.002\) ), and increased the variance accounted by \(11.8 \%, F_{\text {change }}(1,71)=10.55, p=.002\). After adding ToM as the predictor, the full model explained \(20.5 \%\) of the variance in sharing score, \(F(2,71)=9.17, p<.001\).

Table 2: The relationships between ToM and sharing after controlling for age ( \(N=74\) )
\begin{tabular}{lll}
\hline & \begin{tabular}{l} 
Average \\
sharing score
\end{tabular} & \begin{tabular}{l} 
Total number of \\
items shared
\end{tabular} \\
\hline Total ToM & \(0.36^{* *}\) & \(0.34^{* *}\) \\
Diverse Desires & 0.04 & 0.19 \\
Diverse Beliefs & \(0.29^{*}\) & \(0.22^{+}\) \\
Knowledge Access & \(0.26^{*}\) & \(0.28^{*}\) \\
Contents False Belief & 0.14 & 0.11 \\
Real-Apparent & 0.09 & 0.03 \\
\(\quad\) Emotion & & \\
\hline \multicolumn{1}{l}{ Note \({ }^{+} p<.10,{ }^{*} p<.05,{ }^{* *} p<.01\)} &
\end{tabular}

Similarly, we conducted another regression analysis with the total number of items shared as the dependent variable. Results showed that age alone had no significant effect on the number of items shared ( \(\beta=.07, p=.54\) ), and the model only explained \(0.5 \%\) of the variance in the number of shared items, \(F(1,72)=.38, p=.54\). After adding ToM as the independent variable, the full model explained \(12.3 \%\) of the variance in the number of items shared, \(F(2,71)=4.98, p\) \(=.01\). The effect of ToM was significant ( \(\beta=.42, p=.003\) ), and increased the variance accounted by \(11.8 \%, F_{\text {change }}(1\), \(71)=9.54, p=.003\). The results of the above regression
analyses indicate that preschoolers' performance on the ToM tasks, rather than age, was responsible for both the average sharing score and the number of items shared over three sharing tasks.

\section*{Discussion}

First, consistent with our hypothesis, we found that 4-year-old children needed less communicative cues to share than 2- and 3-year-old children did. Four-year-old children generally shared when the partner was just commenting on the toys, whereas the majority of the other two younger groups of children shared when the partner verbally requested the items. This result suggests that older children might need less scaffolding from a social partner to perform sharing behavior (Brownell, Iesue, et al., 2012; Brownell et al., 2009; Svetlova et al., 2010). It also implies that older children might have a more robust intention to benefit others as they shared spontaneously and quickly with a partner who had no toys, while younger children might only share under pressure or to comply with another's request (e.g., Hay, Caplan, Castle, \& Stimson, 1991). Our results thus add new evidence to previous findings that toddlers need more explicit cues to perform sharing and helping behavior (Brownell et al., 2009, 2012; Svetlova et al., 2010).

Interestingly, we found that even though 2 - and 3 -yearold children needed more communicative support in order to perform sharing behavior (their sharing scores were lower), once they shared, they shared as many objects with the social partner as older children did. Blake and Rand (2010) also found that even though 6-year-old children were more likely to donate stickers than 3-year-old children did, once they shared, they gave the same amount of stickers at all ages. These results imply that children may engage in two separate decisions when interacting with a social partner: (a) whether to share and (b) how much to share. As proposed by Blake and Rand (2010), the different developmental trajectories of these two choices may imply different processes involved in those two different phases of sharing behavior. More studies are required to identify these differential underlying processes.

More importantly, we found that children's Theory of Mind understanding correlated to their sharing behavior, independent of age. The regression analyses showed that ToM was a significant predictor of how spontaneously and quickly children shared, as well as how many items children shared, whereas age did not predict these sharing measures. These results suggest that ToM understanding might be a potential underlying mechanism of children's age-related increase in sharing.

This finding is consistent with and extends previous research demonstrating associations between theory of mind ability and pro-social behavior. For example, prior studies have shown that theory of mind ability correlates to prosocial behavior (e.g., Sally \& Hill, 2006; Walker, 2005), and there is evidence suggesting that these two abilities may share the same underlying neural processes (McCabe et al., 2001). Furthermore, studies of nonhuman primates have
found that chimpanzees, which do not have as well of a developed theory of mind as compared to humans, are rational maximizers in that they make unfair offers and accept unfair offers in the Ultimatum Game (Jensen, Call, \& Tomasello, 2007). Likewise, children who had more advanced theory of mind abilities proposed more fair offers in the Ultimatum Game than children with less advanced theory of mind (Takagishi et al., 2010). These results suggest that fairness-related behavior is related to the ability to infer the mental states and intentions of others. Our findings thus further support this hypothesis by showing that more advanced theory of mind ability was positively associated with children's spontaneous sharing and the amount of items shared with others.

In sum, the present study showed that sharing behavior may be more likely to occur when the partner makes his/her needs, desires and emotions more apparent, thus reducing the need for complex inferences about others' internal states, especially for young children whose ability to infer others' psychological states are immature. For older children who have more advanced ToM understanding, the requirement of the provision of ostensive cues from the recipient may not be necessary, thus they shared more spontaneously, more quickly and shared more items.

\begin{abstract}
The analogy of space to human cognition has a longstanding tradition. Our study aims to elaborate on the validity of this analogy for search in memory. Using the search of associative memory framework (SAM) we show that people are able to dynamically recruit independent memory representations in the recall of country names. By instructing participants to use specific recall cues we also show that despite a strong effect on the retrieval sequence, total recall from memory remains unaffected. Whereas these findings strongly support a higher dimensionality to memory than often assumed, the simultaneous finding of severe retrieval time costs for non-default representations suggests that the use of particular retrieval structures may be adaptive. In sum, our results support local-to-global memory search strategies similar to foraging strategies in space, but further suggest that memory is not constrained to one local representation, but may indeed support many.
\end{abstract}

Keywords: Free recall; verbal fluency task; memory representation; Search of Associative Memory (SAM).

\section*{Introduction}

Memory has long been considered to represent a highdimensional landscape over which we search for information. The recent proliferation of semantic space models, which acquire semantic similarity of words based on statistical processing of text corpora implicitly characterizes memory as embodying such a representation. This idea is not new. In his "Principles of Psychology" William James wrote "We make search in memory ... just as we rummage our house for a lost object" (1890, p. 654), suggesting that search in memory is comparable to search in space. But how comparable is it? Research on spatial imagery and cognitive maps suggests that mental operations share much in common with the way we move around the physical world (e.g. Kosslyn, Ball, and Reiser, 1978). Almost all models of long-term memory incorporate a dimension of similarity (inverse of distance) in order to explain priming and serial position effects (e.g. Anderson, \& Pirolli, 1984; Brown, Neath, \& Chater, 2007). Shepherd's account of
distance in mental representations (Shepard, \& Metzler, 1971), as well as models of categorization (e.g. Nosofsky, 1988), suggests a similar conceptual landscape, in which similar items reside near one another and less similar items reside further apart.

Underlying these approaches is an implicit assumption, one that is highlighted by James. If searching memory is like rummaging our house for a lost object, is there just one house (i.e., representation) or are there many? Could an item be in more than one representation, and if so, does one representation facilitate memory search better than another? If memories reside in multiple representations, this presents a problem for many existing models of knowledge representation-that is, especially those that produce but one representation. Moreover, multiple representations would exemplify a feature of memory that clearly separates memory from space: outside of wormholes, the only way to get from one point in space to another is to travel the distance between them. Memory, on the other hand, may have no such constraints.

Before we describe how we investigated the possibility of multiple memory representations, we first describe some of the previous research that has highlighted the relationship between memory and space.

\section*{Memory and Space}

Following this analogy between space and memory, Hills and colleagues recently put forth a model wherein free recall from memory produces patterns that can be predicted by a classical theorem of optimal foraging theory, the marginal value theorem (Hills, Jones, Todd, 2012). This theory describes optimal switching between explorative and exploitative search in response to a patchy resource environments. Further supporting the notion that internal search may be similar to external search in space, Hills, Todd, and Goldstone (2008) found that priming search in space primes search in a lexical search task, suggesting that a shared cognitive process may search in both domains.

Drawing from the search of associative memory framework (SAM), Hills and colleagues' model expresses search as an alternation between local and global memory search. In local search, sequential items are retrieved based on similarity to the last recalled item together with a position invariant context cue. In global search, this context cue is used exclusively. Interpreting the network of similarities as a landscape of distances, local search is spatially confined with nearer items in memory being more likely to be retrieved. Global search, on the other hand, is independent of this landscape allowing for jumps across the landscape that may utilize an alternative representation-much as wormholes do in science fiction. These aspects of local and global search capture the different search modes typical of exploration/exploitation trade-offs found in patch foraging models. However, they appear to break with the spatial analogy to the degree that the search process can escape the confines of one representation by switching to another.

Recently, Abbott et al. (2012) proposed a slightly different model to explain the findings of Hills and colleagues with a stronger focus on the underlying representation. Their theoretical approach expresses the patterns of free recall as a random walk through a single partly connected graph (see Steyvers, \& Tenenbaum, 2005). Their full random walk model also incorporates local-to-global transitions. However, compared to Hills et al. the switches between subsequent cues a) are random and thus independent of local retrieval success, except in the case of allowing more time for a global jump to occur and, more importantly b) do not imply any change of representation but rather a reset to the start point of search (similar to the executive search process model used to describe search for anagrams in Hills, Todd, \& Goldstone, 2010). Additionally, the simulation results of Abbotts et al. also indicated that apparent optimal retrieval patterns were possible without local-to-global transitions. Together, this work provides only weak support for multiple representations and the presence of context-based local-to-global transitions in memory.

\section*{Present Study}

Overall, the spatial analogy for memory and memory search has been successful, but existing theoretical approaches offer alternative hypotheses. Moreover, all of the previously described approaches have assumed that there is only one representation of memory that allows for local search. To investigate the potential for multiple representations in memory, we had people search their memory for country names. Friedman and Dewinstanley (2007) showed descriptively that at least three independent factors predict country retrieval: geographic distance to the previously recalled country, phonetic similarity to previously recalled countries and characteristics of the particular country itself (e.g. their frequency in the news). The availability of these multiple
objectively determinable cues within a single recall category suggest the potential for multiple representations, and allow us to address the following questions within a computational framework.

First, we want to assess if these three cues are used and how and in what form they are integrated in the retrieval of countries. Is the default local search representation (similarity-based) best characterized by space (e.g., Euclidean distance) or some other representation? Further, are the local search cues integrated dynamically with the global cue (item-based). To address this, we collected uninstructed recall data where people where simply asked to name all the countries they can think of. Our second question addresses more specifically the question of multiple representations: Specifically, how does a voluntary change of retrieval cues influence recall? Assuming a unitary underlying representation, changing the retrieval cues should harm retrieval with respect to response times, number of retrieved items, or both. Provided representations are independently accessible, retrieval sequences should reflect changes in the representation, and may further reflect differences in the accessibility of information with a representation. To this end we ran two instructed conditions in which participants where asked to base their recall on the letters of the alphabet or on geographical neighbors.

\section*{Method}

Participants We collected data from 71 students at the University of Basel. The sample had an average age of 24.7 and \(71 \%\) of the participants were female. Participation in the study was rewarded either by course credit or a fixed payment of 7 Swiss francs. Additionally the participants received 0.25 Swiss francs for every recalled country.

Procedure Participants were seated in front of a computer. First, each participant's typing speed was assessed. Next, they received the instructions to the country fluency task. In the control condition participants were asked to type all the countries they can think of, but were not given direction with regard to how to retrieve countries. In the alphabet condition participants were instructed to proceed by the letters of the alphabet. In the neighbor condition participants were asked to always first attempt to recall a neighboring country (with a shared border) before recalling a country from elsewhere. In both the alphabet and the neighbor condition participants were also instructed that whenever there were unable to recall a country by the first letter or a neighbor they could recall any other country.
Scoring All country entries were checked for spelling and validity. Only the 193 current members of the United Nations as well as Kosovo, Taiwan, Vatican City and Palestine were accepted as valid countries. Some synonyms were accepted, for example "Holland" for Netherlands. As approximations for the spatial
representations (i.e., retrieval structures) we implemented three measures: Distance, calculated as shortest Euclidian distance between the borders; Neighbor, indicating if two countries shared a border; and Geodesic distance, determined by shortest number of border crossing required to move from one country to the other. All information used for the spatial representations were based on the CIA World DataBank II. To measure phonetic representation, three further retrieval structures were implemented: Levenshtein distance, which indicates the number of orthographic edits; Initial letter, indicating if consecutive items share the same first letter; and Phonetic similarity following Friedmann and deWinstanley (2007), with phonetic similarity indicating the same letter in the first or the last three positions of two countries. To estimate the frequency we took two measures: Google, indicating the log number of hits for a country generated by a Google search, and News, indicating the log number of mentions in the weekly newspaper Die Zeit, which is widely read in all German speaking countries.
Modeling The model framework we used to simulate the search process is based on SAM (Raaijmaakers \& Shiffrin, 1981). The foundational assumption of the model is that recall is achieved by probing retrieval structures in memory with a specific cue set, that is, the memory probe. With \(I\) representing a possible target item for recovery in the search space, the probability of retrieving \(I\) is computed as the product of the individual retrieval strengths for \(I\) across a probe set of \(M\) cues, with \(S(Q, I)\) representing the semantic similarity between cue \(Q\) and item \(I\). This is incorporated into an overall probability of retrieval for item \(I\) via the ratio rule:
\[
P\left(I_{i} \mid Q_{1}, Q_{2}, \ldots, Q_{M}\right)=\frac{\prod_{j=1}^{M} S\left(Q_{j}, I_{i}\right)^{\beta_{j}}}{\sum_{k=1}^{N} \prod_{j=1}^{M} S\left(Q_{j}, I_{k}\right)^{\beta_{j}}}
\]
where \(N\) represents the total number of items available in the category for retrieval and \(\beta\) represents the saliency (or attention weight) assigned to a given cue.

Every search cue generates a retrieval strength \(S(Q, I)\) for each item based on the items similarity to the last item, e.g. in terms of Euclidian distance, or the item's own qualities, e.g. frequency in the newspapers or the Eigenvector of similarity-based cues. Using a maximum likelihood method, we fit \(\beta \mathrm{s}\) to each participant's data, using the participant's individually generated sequence of items. This produced a log-likelihood fit, which was penalized based on the number of free parameters via the Bayesian information criterion. Results are presented as the median improvement in the Bayesian information
criterion relative to a random model specifying that all remaining items in the search space are equally likely to be retrieved, with greater values of BIC indicating a better fit.

We examined various static and dynamic models, using spatial, phonetic and frequency cues. In our terminology, static models rely on the same set of cues over the entire retrieval interval. Dynamic models on the other hand allow for a switching between cues. In SAM similarity-based cues are dropped when a threshold of retrieval failures is reached. This we modeled using an additional threshold parameter on the retrieval strengths of similarity-based local cues.

\section*{Results}

\section*{Which cues are used?}

As a first step in the analyses the predictive power of individual cues \({ }^{1}\) was tested in a single cue version of our retrieval model. Figure 1 shows the BIC advantage over the random model for the unconstrained as well as the Alphabet and Neighbor condition. The results indicate that not all retrieval structures are equally predictive in the uninstructed (control) condition. Spatial representations seem clearly to be the dominating cue in this condition. Next to spatial information, only frequency of mentions in the news had predictive power. In contrast to the results of Friedmann and deWinstanley

Figure 1: Median of differences in BIC between the random model and single cue retrieval models.

\footnotetext{
\({ }^{1}\) The eigenvectors of the similarity-based cue representations were dropped from the analyses as none were predictive.
}
(2007) when our participants were not instructed to use any particular cue they do not seem to rely on any phonetic cue. The overall pattern changes substantially in the instructed conditions. When instructed to recall by the letters of the alphabet, the Phonetic and Initial cue models fit very well, whereas the individual spatial models do not exceed chance level. On the other hand, the fit in the Neighbor condition is best fit by the spatial models. Thus, people appear to have changed their retrieval behavior in both conditions.

\section*{Are cues integrated dynamically or statically?}

Contrary to the expectation that all cue classes - spatial, phonetic and frequency - contribute to the fits, the single cue data indicates that only two of three classes of cues are used in the individual conditions. We further asked how the cues are integrated and if the type of integration holds over the conditions and the particular cues used in these conditions. We compared two models: static, with both cue classes are used over the entire retrieval interval, and dynamic \({ }^{2}\), using the similarity-based cue together with the context cue or, when the similarity-based cue falls below a fitted threshold, the context cue alone.

Figure 2 illustrates the results for these models. In line with the single cue models the models combining News with spatial cues fit the data of uninstructed and Neighbor condition best and provide a poor fit for the Alphabet condition. The Alphabet condition was best fit by phonetic information combined with frequency in the news. In regard to the state of integration the models also show a clear pattern. Irrespective of the condition, the dynamic models provide a better fit to the data than the static integration models.

\section*{Does cue use affect performance?}

The analyses thus far show a) that cues can be voluntarily changed and b) that this however has no effect on the dynamic integration of local information with global frequency information. But did the controlled choice of a particular retrieval impact memory accessibility? Figure 3 shows the results for number of countries retrieved. An analysis of variance reveals that the slight advantage in the Neighbor condition is not greater than we would expect by chance ( \(\mathrm{F}_{2,68}=.73, \mathrm{p}=.48\) ). Thus, the overall accessibility in terms of number of countries was not dependent on using a particular cue. Item response times on the other hand reveal a substantial detriment when countries where retrieved by the letters of the alphabet. The median retrieval time in the alphabet condition (mdn

\footnotetext{
\({ }^{2}\) The dynamic search model described in the text corresponds to the search models in Hills, Jones and Todd (2012). An alternative version of the model was also tested, that uses the similarity-based cue when above threshold and the contextbased cue when below threshold. However, the results were indistinguishable.
}
\(=7.7 \mathrm{~s}\) ) was about five times higher than the retrieval times in the uninstructed ( \(\mathrm{mdn}=1.4 \mathrm{~s}\) ) and neighbor condition ( \(\mathrm{mdn}=1.5 \mathrm{~s}\) ). Consequently, participants in the Alphabet condition also keep on searching for a much longer period than in the other two conditions. This is likely due to participants feeling that they could not go back to previous letters. Clearly, however, not all alphabet-based responses are slow. About \(21 \%\) of the response times in the alphabet condition fall below the medians of the other two conditions. Thus in a number of cases Alphabetic retrieval was faster than in the uninstructed and Neighbor condition.

\section*{Discussion}

In this study we were interested in the utilization and integration of multiple cues in retrieval from memory. By having participants retrieve all the countries they know under three different instructions we were able to show that dynamic search models as proposed by Hills and colleagues (Hills, Jones, Todd, 2012; Hills, \& Pachur, 2012) provide the best account for the data in all conditions. Further, the data clearly demonstrated that people are able to deliberately change the cues they are using (see Gronlund \& Shiffrin, 1986). This however had no impact on how these cues were combined with a global representation of frequency. Finally, our data

Figure 2: Median of differences in BIC between the random model and different cue integration models for the three conditions. All similarity-based cues are combined with the News cue. Dashed lines represent the best single cue model in the three datasets.

A

B

Figure 3: Number of items retrieved (A) and bean plots of item level response times in seconds corrected for typing speed (B) in the three condtions. Error bars represent standard error of the mean. Shapes in the right hand plot represent the density, the solid red line the median.
shows that changing the cue is not necessarily harmful to the recall performance - the same performance level was reached in terms of total items retrieved, despite dramatic costs in overall retrieval times.

What do our results mean with respect to our initial question whether memory is one or many representations? Clearly, people are able to change the cues they are using and our results further suggest that they may access alternative representations However, these changes can come with costs. These costs can be interpreted as the result of different distances within a given representation. Thus, a wrong cue or retrieval structure might mean traveling greater or lesser distances in memory. Under this interpretation two speculations can be made. The comparable performance in terms of number of retrieved items would disappear under time pressure and, in the present case, the overall retrieval success is potentially a result of a relaxed retrieval failure threshold. It remains striking that the same overall performance was reached in our three conditions, as recognition data indicates that people have potentially about twice as many countries stored in their memory (Friedman \& deWinstanley, 2007).

Moreover, in every case, models using frequency in the news alone for stretches of the retrieval interval performed much better despite being penalized by the extra threshold parameter. This, there appears to be at least one alternative representation allowing for nonspatial movement in memory space. Combined with evidence for dynamic switching, this breaks with the spatial analogy by allowing for travel through memory via multiple representations.

Both, the successful switch of representations under specific instructions and the independent use of frequency are difficult to explain within the model that is based on a unitary representation or space as proposed by Abbot et al. (2012) and others. Our results seem to be much better explained by frameworks allowing for the variable integration of multiple cues. The SAM-based memory search model developed by Hills and colleagues is but one model affording this possibility. Other models such as multi-trace memory models (e.g. MINERVA; Hintzman, 1986) or the recently proposed context maintenance and retrieval model (CMR; Polyn, Norman, \& Kahana, 2008) are also in principle capable of utilizing multiple cues to varying degrees over time. However, in modeling and most experimental work the possibility of entirely switching between representations has been rather neglected. In our eyes this possibility should receive more attention in future research.

Assuming that our current findings are not constrained to the recruitment of a spatial versus a phonetic or alphabetic local search representation leads to the question of what is the right retrieval strategy to use. Clearly, our data shows that, without instructions, alphabetic and phonetic retrieval strategies receive little support. The data also suggests that this is done for a good reason, as response times tend to be on average larger when using phonetic cues. On the other hand, a substantial number of alphabet retrievals were at least as fast as retrievals based on spatial information. A savvy memory forager could potentially exploit this fact by adaptively switching between retrieval cues - that is, by taking dimensional short-cuts through memory space. In principle, this is no different from the short-cuts made
available by global transitions to frequency. But, cognitively, it represents the capacity to jump between local representations, or landscapes, in much the same way that children might enter an alternate universe by passing through a mirror.

\begin{abstract}
Quantitative analyses and the analyses of a questionnaire were conducted to examine the relations between participants' communicative activities and their interactional attitudes in conversations both in their native and second languages. The two categories of conversations revealed different gaze patterns that reflected the differences in difficulties they had with communication and grounding patterns. The participants were less conscious of their own gazes in conversation in their second language than those in their native language probably because of the difficulties and mental pressure they felt.
\end{abstract}

Keywords: Second language conversation; Language expertise; Utterance; Gaze; Grounding; Communication

\section*{Introduction}

As modern society has become more global, the importance of conversations in a second language has been increasing more than ever before. People are traveling around the world either on business or for pleasure due to progress in transportation systems and advanced Internet technologies that connect areas that have different linguistic backgrounds. Organizations are increasingly forming teams with members whose mother tongues are not the same, and sometimes co-workers and collaborators from different countries are connected via the Internet. Second language conversations are commonly observed in daily life, and the expertise of conversational participants often ranges from low to high. An urgent issue today is to support mutual understanding in these conversations.

Language use is a form of joint action that is carried out by groups of people who act in coordination. Their joint action involves not only verbal but also non-verbal activities to achieve a common "grounding" process, i.e., to form the basis of mutual understanding (Clark \& Brennan 1991, Clark 1996). There have been quantitative studies that have reported that eye gazes play an important role in monitoring understanding by communication partners of the content of conversation and contributions made to the performance of collaborative tasks (Boyle, Anderson, \& Newlands 1994, Clark \& Krych 2004).

Grounding is also an important process in second languages. There have been studies that have regarded "nativeness" as "expertise" and compared the grounding process between differing levels of language expertise (Kasper 2004, Hosoda 2006). Hosoda reported that participants' disfluencies or linguistic errors were usually not treated as problems with interactions, but they were oriented to differences in linguistic expertise by repair (a) when one speaker invited the other's repair, and (b) when mutual understanding was jeopardized unless one party repaired the other. Eye gazes and facial expressions play an important role in monitoring both partners' understanding in the repair process. These studies have, however, been qualitative and there have been few quantitative analyses of the relation between the grounding process and non-verbal activities in second language conversations.

Veinott et al. (1999) found that non-native speaker pairs benefited from video in route guiding tasks in the field of computer supported collaborative work (CSCW), whereas native speaker pairs did not. They argued that this was
because video helped the non-native pairs to negotiate a common ground whereas it did not do so for the native pairs. Their study revealed that video images of the conversation partners helped them to establish mutual understanding in their second language conversations, although it was still not clear which element in the video information contributed to establishing the common ground.

Previous research has suggested some differences in conversational features between a mother tongue and a second language. The duration as a percentage when other participants are observing the speaker in English as a second language is longer than that in Japanese as a mother tongue (Kabashima, Nishida, Jokinen, Yamamoto 2012; Yamasaki, Furukawa, Nishida, Jokinen, Yamamoto 2012). Even though these results are consistent with Hosoda's observations and suggest an interesting feature of second language communications, it is still not clear how this feature interacts with other communicative features.
The main aim of this study was to examine the relations between participants' communicative activities and their interactional attitudes in conversations both in their native and second languages. We conducted quantitative analyses to study the differences in communicative behaviors in second and native language conversations. We also analyzed a questionnaire to examine the interactional attitudes of the participants. We integrated the results of the two analyses to examine the differences in communication processes in native and second language conversations.

\section*{Data Collection}

We collected data in a mother tongue and in a second language from conversations by the same interlocutors.

\section*{Participants}

A total of twenty-four university students ( 14 females and 10 males: eight groups) between the ages of 18 and 24 participated in the experiment, and each conversational group consisted of three participants who did not know another. They were Japanese university students who had acquired Japanese as their mother tongue and had learned English as a second language. Their communication levels in English were measured based on the Test of English for International Communication (TOEIC). We recruited participants to cover wide range of expertise in English. Their scores ranged from 450 to 890 , and the average was 591 ( 990 being the highest score that could be attained). Each participant was ranked into three degrees of expertise according to the order of his/her English expertise based on the TOEIC score within the group.

\section*{Experimental Setup}

Three participants sat in a triangular formation around one table. Each participant sat in the same position for all four trials. The three participants sat 1.5 m apart. Three sets of NAC EMR-9 eye trackers and headsets with microphones were used to record the eye gazes and voices of all three participants (Figure 1). The viewing angle of the EMR-9
was \(62^{\circ}\) and the sampling rate was 60 fps . The participants talked about two types of predetermined themes in English as a second language and in Japanese as their mother tongue (e.g., each group participated in four conversations).

Figure 1: Experimental Setup

\section*{Procedure}

The conversational topic was assigned before each trial and there were two types of themes. The first was freeflowing in which they chatted naturally on foods they liked or disliked. The second was goal-oriented in which they collaboratively decided what to take with them on trips to uninhabited islands or mountains. We randomly arranged the order of the topics of conversation to cancel out the effect of order. We also randomly arranged the order of the languages used in the conversations.

The eye trackers were calibrated and participants started to converse after instructions on the experiment were explained. Each group had conversations of four different topics on free-flowing and goal-oriented themes in Japanese and in English. Each conversation lasted for 6 min .

The participants filled in a questionnaire after each conversation. Consequently, the subjects in each group participated in four conversations and filled out four questionnaires. We then analyzed the data from the free flowing conversations in Japanese and in English. The total numbers of utterances were 1858 in English and 2059 in Japanese, and gaze events were 2360 in English and 2727 in Japanese, respectively.

\section*{Annotations}

One of the authors manually annotated the time spans for utterances and gazes at other participants to integrate the utterance and eye gaze data. The eye gaze data of two participants were not recorded because of trouble they had with the equipment, and they were excluded from the analyses. We used the EUDICO Linguistic Annotator (ELAN) developed by the Max Planck Institute (Fig.2) as the annotation tool.

\section*{Questionnaire}

We asked the participants to fill in the questionnaire to analyze their interactional attitudes in each conversation. The questionnaire consisted of 29 items and each of them was ranked on a Likert scale from one to seven. Each
question was categorized into communicational features such as participants' gazing activities, their feelings toward other participants, their interest in the topic of conversation, their conversational skills in English, and their evaluation of the conversation content. The progress of the trials can affect the familiarity. We conducted ANOVA on the values obtained from questions on evaluating their familiarity to other participants to check if there are any differences in the values among the trials. The results did not revealed significant differences on the evaluation of familiarity with the progress of trials. The results suggest that, in this experiment, familiarity to other participants were not affected by the progress of the trial.

Figure 2: Annotation Screen Shot

\section*{Analyses}

We used two methods in the analyses; the first involved quantitative analysis of communicative activities such as utterances and gazes, and the second involved analyzing a questionnaire on the participants' interactional attitudes. The correlations between the quantitative data and the values obtained from evaluating the questionnaire were also analyzed to study the relations between the participants' communicative activities and their interactional attitudes in conversations both in their native and second language.

\section*{Analysis 1: Utterances and Gazes}

First, we compared the total duration of the utterances between the Japanese and English language conversations to check the difficulty in communicating in the second language. The total duration of the utterances was expected to be longer in Japanese than in English. A paired \(t\)-test indicated a significant difference between conversations in Japanese as a native language and those in English as a second language ( \(\mathrm{t}=4.848, \mathrm{p}<.01\), Japanese: \(a v .=110222\) \(\mathrm{msec}, S D=39178 \mathrm{msec}\); English \(a v .=79185 \mathrm{msec}, S D=\) 6347). They talked more in conversations in their native language than in those in their second language.

Gazing activities during utterances were also compared between conversations in Japanese and those in English. We compared (1) how long the speaker was observed by other participants (ratio being observed), and (2) how long the speaker observed other participants (ratio observing).

The average for the ratio being observed is defined as:

Average of Ratio Being Observed \(=\frac{\sum_{i=1}^{n} D P O S(i)}{\sum_{i=1}^{n} D(i)} \times 100(\%)\)
Here, \(D(i)\) is the duration of the \(i\)-th utterance and \(\operatorname{DPOS}(i)\) is the duration when other participants are observing the speaker in the \(i\)-th utterance.

The average for ratio observing is defined as:
\[
\text { Average of Ratio Observing }=\frac{\sum_{i=1}^{n} D S O P(i)}{\sum_{i=1}^{n} D(i)} \times 100(\%)
\]

Here, \(\operatorname{DSOP}(i)\) is the duration when the speaker is observing other participants in the \(i\)-th utterance.

Previous research has suggested that the speaker is observed more in their second language conversations than in those in their native language, and that the difference in second language expertise affects the communication style (Kabashima, Nishida, Jokinen, Yamamoto 2012; Yamasaki, Furukawa, Nishida, Jokinen, \& Yamamoto 2012). These predictions are consistent with observations of the repair process in second language conversations (Hosoda 2006).

Under the hypotheses that the speakers were observed more in conversations in their second language than in their native language and that language expertise affected gazing activities, we conducted \(2 \times 3\) ANOVA with the language difference being within subject factors and with expertise rank in English being between subject factors. The results revealed significant main effect both on language differences \(\left(\mathrm{F}_{(1,19)}=24.823, \mathrm{p}<.01\right)\) and on the expertise ranking in the second language ( \(\mathrm{F}_{(2,19)}=3.625, \mathrm{p}<.05\) ), and no interactions were observed. Fisher's LSD test indicated significant differences between the 1st and 3rd ranks ( \(\mathrm{p}<.05\) ).

The average and the SD values of the ratio being observed for each rank are listed in the table below.
\begin{tabular}{|l|l|r|r|r|}
\hline Expertise Rank & Condition & \multicolumn{1}{l|}{ av. } & No. of the samples & \multicolumn{1}{l|}{ SD } \\
\hline 1 & Native Language & 73.33 & 7 participants & 11.299 \\
\hline & Second language & 82.77 & 7 participants & 3.946 \\
\hline 2 & Native Language & 78.77 & 7 participants & 8.257 \\
\hline & Second language & 85.09 & 7 participants & 1.764 \\
\hline 3 & Native Language & 81.29 & 8 participants & 2.663 \\
\hline & Second language & 88.48 & 8 participants & 3.151 \\
\hline
\end{tabular}

Table 1: Average values for ratio being observed
The results indicate that the speakers were observed more in conversations in their second language than in those in their native language, and speakers with low levels of expertise in their second language tended to be observed more than speakers with high levels of expertise.

\section*{Analysis 2: Comparison of Values from Questionnaire}

The values from evaluating each item on the questionnaire were compared for Japanese and English to examine the differences in the participants' interactional attitudes in conversations in their native and second languages. The results suggest they had greater difficulty
and were more stressed in their second language conversations as we had predicted. The items that exhibited significant differences in the t-test \({ }^{1}\) were in the following table. Here a single asterisk * in the tables denotes \(p<.05\) and a double asterisk \({ }^{* *}\) denotes \(p<.01\), respectively.

\section*{Evaluation of Expertise:}

The participants evaluated their expertise and their partners' expertise higher in their native language conversations as follows.
- Evaluate your speaking expertise.
\begin{tabular}{|l|r|c|c|c|c|}
\hline & \(N\) & \(a v\). & \(S D\) & \(d f\) & \(t\) \\
\hline Japanese & 24 & 4.63 & 1.245 & 23 & \multirow{2}{*}{\(6.323^{* *}\)} \\
\hline English & 24 & 2.67 & 1.404 & 23 & \\
\hline
\end{tabular}
- Evaluate your partner's English speaking expertise.
- Toward higher ranked partners
\begin{tabular}{|c|c|c|c|c|c|}
\hline & \(N\) & \(a v\). & \(S D\) & \(d f\) & \(t\) \\
\hline Japanese & 24 & 5.63 & 0.97 & 23 & \multirow{2}{*}{\(3.760^{* *}\)} \\
\hline English & 24 & 4.54 & 1.615 & 23 & \\
\hline
\end{tabular}

\section*{- Toward lower ranked partners}
\begin{tabular}{|c|c|c|c|c|c|}
\hline & \(N\) & \(a v\). & \(S D\) & \(d f\) & \(t\) \\
\hline Japanese & 24 & 5.29 & 1.083 & 23 & \multirow{2}{*}{\(3.680^{* *}\)} \\
\hline English & 24 & 4.21 & 1.532 & 23 & \\
\hline
\end{tabular}
- Do you think he/she could understand your discourse?
- Toward higher ranked partners
\begin{tabular}{|c|c|c|c|c|c|}
\hline & \(N\) & \(a v\). & \(S D\) & \(d f\) & \(t\) \\
\hline Japanese & 24 & 5.67 & 1.239 & 23 & \multirow{2}{*}{\(2.220^{* *}\)} \\
\hline English & 24 & 5.17 & 1.308 & 23 & \\
\hline
\end{tabular}
- Toward lower ranked partners
\begin{tabular}{|c|c|c|c|c|c|}
\hline & \(N\) & \(a v\). & \(S D\) & \(d f\) & \(t\) \\
\hline Japanese & 24 & 5.83 & 1.239 & 23 & \multirow{2}{*}{\(3.423^{* *}\)} \\
\hline English & 24 & 5.08 & 1.176 & 23 & \\
\hline
\end{tabular}

\section*{Feelings toward Partners:}

The participants were more nervous and felt more pressure from their partners in their second language conversations. They felt their partners concentrated more in second language conversations. These results suggest the participant felt more stress in second language conversations.
- Did you get nervous when you spoke?
- Did you get nervous when you spoke?
\begin{tabular}{|c|c|c|c|c|c|}
\hline & \(N\) & \(a v\). & \(S D\) & \(d f\) & \(t\) \\
\hline Japanese & 24 & 2.50 & 1.504 & 23 & \multirow{2}{*}{\(5.249^{* *}\)} \\
\hline English & 24 & 4.33 & 1.606 & 23 &
\end{tabular}
- Do you think your partner got nervous when he/she spoke?
- Toward higher ranked partners

\footnotetext{
\({ }^{1}\) There were only 24 participants and it is not clear if these values were normally distributed. However, exactly the same list of items also revealed significant differences in Wilcoxon's signed rank test, and the results can be considered to be sufficiently stable.

\hline English & 24 & 4.13 & 1.191 & 23 & \\
\hline
\end{tabular}
- Did you enjoy the conversation?
\begin{tabular}{|c|c|c|c|c|c|}
\hline & \(N\) & \(a v\). & \(S D\) & \(d f\) & \(t\) \\
\hline Japanese & 24 & 5.33 & .963 & 23 & \multirow{2}{*}{\(2.077^{*}\)} \\
\hline English & 24 & 4.83 & 1.167 & 23 & \\
\hline
\end{tabular}
- Did you think that you could talk as you usually do?
\begin{tabular}{|c|c|c|c|c|c|}
\hline & \(N\) & \(a v\). & \(S D\) & \(d f\) & \(t\) \\
\hline Japanese & 24 & 5.46 & 1.179 & 23 & \multirow{2}{*}{\(5.438^{* *}\)} \\
\hline English & 24 & 3.21 & 1.641 & 23 & \\
\hline
\end{tabular}

\section*{Analysis 3: Correlations between Gazing Activities and Values from Questionnaire}

These results indicate that the participants gazing activities and interactional attitudes differed in conversations in their native and second languages, as had been predicted. We conducted Spearman's correlation analysis on their gazing activities and their interactional attitudes that were contained in the questionnaire data. The items that exhibited significant correlation are shown with the correlation values (Spearman's \(\rho\) ) in the following tables. A single asterisk * denotes \(p<.05\) and a double asterisk denotes \(p<.01\) on the tables.

\section*{Consciousness of Gazing Activities:}

The values obtained from evaluating gazing activities had high correlations with gaze durations in Japanese conversations although they did not in English conversations. These results indicate that the participants were conscious of their gazing activities in conversations in their native language, whereas they were not in their second language.

Japanese:
\begin{tabular}{|l|c|}
\hline Ratio Observing & \(\rho\) \\
\hline \hline <-> Did you watch his/her face as a whole? & \(.511^{*}\) \\
\hline <-> Did you watch his/her eyes? & \(.588^{* *}\) \\
\hline
\end{tabular}

\section*{Analysis 4: Correlations of Items on Questionnaire}

There were several interesting differences in the results from Spearman's correlation analysis of the items in the questionnaire for the Japanese and English conversations as listed below.

\section*{Difference in Interactional Attitudes}

The speakers' evaluations of their ability to concentrate were correlated with their evaluations of gazing at the listeners' upper body, face, and eyes in English, but only with their evaluations of gazing at the listener's eyes in Japanese. This suggest that speakers were paying attention to wider areas of their partners' body when they concentrated during second language conversations, whereas they were only paying attention to the eyes of their partners in native language conversations. .

English:
\begin{tabular}{|l|r|}
\hline Did you concentrate on your utterances? & \(\rho\) \\
\hline \hline \begin{tabular}{l} 
<-> Did you watch the listener's upper body as \\
a whole?
\end{tabular} & \(.485^{*}\) \\
\hline <-> Did you watch his/her face as a whole? & \(.537^{* *}\) \\
\hline <-> Did you watch his/her eyes? & \(.605^{* *}\) \\
\hline
\end{tabular}

Japanese:
\begin{tabular}{|l|c|}
\hline Did you concentrate on your utterances? & \(\rho\) \\
\hline \hline\(->\) Did you watch his/her eyes? & \(.417^{*}\) \\
\hline
\end{tabular}

\section*{Feelings toward Other Participants}

The participants evaluations of their understanding of their partners' discourse were correlated with those of their positive feelings toward their partners in English conversations, whereas there were no such correlations in Japanese conversations. The participants tended to have positive feelings toward their partners when they could understand what their partners said in second language conversations, but just understanding their partners' discourse was not enough for the participants to have positive feelings toward their partners in native language conversations.

English:
\begin{tabular}{|l|l|c|}
\hline \begin{tabular}{l} 
Do you think you could understand his/her \\
discourse?
\end{tabular} & \(\rho\) \\
\hline \hline \begin{tabular}{l} 
<-> Did you have a sense \\
of closeness to your \\
partner?
\end{tabular} & \begin{tabular}{l} 
Toward higher \\
ranked partners:
\end{tabular} & \(.639^{* *}\) \\
\cline { 2 - 3 } & \begin{tabular}{l} 
Toward lower \\
ranked partners:
\end{tabular} & \(.549^{* *}\) \\
\hline \multirow{3}{*}{\begin{tabular}{l} 
<-> Did you become \\
interested in him/her?
\end{tabular}} & \begin{tabular}{l} 
Toward higher \\
ranked partners:
\end{tabular} & \(.523^{* *}\) \\
\cline { 2 - 3 } & \begin{tabular}{l} 
Toward lower \\
ranked partners:
\end{tabular} & \(.532^{* *}\) \\
\hline
\end{tabular}

The participants' evaluations of pressure from their partners had a correlation with their evaluations of their own nervousness when they spoke in English conversations but not in Japanese conversations. This suggested that pressure from their partners led directly to the speakers' nervousness in second language conversations, but not in native language conversations.

English:
\begin{tabular}{|l|l|c|}
\hline \multicolumn{2}{|c|}{ Did you feel pressure from them? } & \(\rho\) \\
\hline \hline \multirow{3}{*}{\begin{tabular}{l} 
<-> Did you get nervous \\
when you spoke?
\end{tabular}} & \begin{tabular}{l} 
Toward higher \\
ranked partners:
\end{tabular} & \(.419^{*}\) \\
\cline { 2 - 3 } & \begin{tabular}{l} 
Toward lower \\
ranked partners:
\end{tabular} & \(.460^{*}\) \\
\hline
\end{tabular}

\section*{Discussion}

Thus far, we have compared the utterances, gazes, and interactional attitudes of participants in native and second language conversations. Quantitative analyses were conducted on utterance and gaze data in Analysis 1. The shorter total duration in English conversations suggested difficulties the participants had in their second language conversations. Preliminary analysis using one-fourth of this corpus denoted that the average number of filled pauses and percentage of turn-hold after pause were more than double in English in comparison with those in Japanese (Yamasaki, Furukawa, Nishida, Jokinen, Yamamoto 2012). These results also suggested difficulties the participants had in their second language conversations.

The speakers were observed by listeners more in their second language conversations than in their native language
conversations. The speakers with lower levels of linguistic expertise were gazed more than those with higher levels of linguistic expertise in their second language conversations. These results are consistent with observations by Hosoda (Hosoda 2006), and they indicate that such gazing patterns represent one of the interactional features unique to second language conversations. The listeners made more use of visual information from the speaker to help further understanding in conversations in their second language than that in their native language, and it is likely that speakers with low levels of expertise need more gazes from their partner to help their repair process in grounding activities in second language conversations.
A comparison of the values obtained from the questionnaire also revealed difficulties the participants had in their second language conversations in Analysis 2. They evaluated their linguistic expertise to be lower in their second language conversations and they felt more pressure from their partners, and were more nervous. They were not able to conduct conversations as they usually did, and the conversations did not warm up as much as those in their native language.

The difficulties in second language conversations seemed to have affected their management of conversational activities. The results obtained from correlation analysis in Analysis 3 of the participants' gazes and their self evaluations of their own gazes indicated that the participants were not conscious of their gazing activities in conversations in their second language, whereas they were in their native language. This suggests that difficulties in second language communication made the participants concentrate too much on managing conversations to be conscious of their own communicative activities.

Analysis of correlation in the items on the questionnaire in Analysis 4 revealed differing interactional attitudes in native and second language conversations. The speakers seemed to make use of visual cues from wider areas of the listeners' upper bodies when they concentrated more on their second language conversations than those in their native language where they only made use of visual cues from the listeners' eyes.
Another interesting finding from Analysis 4 was that understanding what a conversation partner said was likely to lead to positive evaluation of the partner in conversations in the second language whereas no such tendencies were observed in conversations in the native language. This suggests that understanding the partners' utterances is already considered to be an achievement in second language conversations whereas just understanding what the partners say is not enough to have positive feelings toward them.

\section*{Conclusion}

We examined the relations between participants' communicative activities and their interactional attitudes both in native and second language conversations. Quantitative analyses and analyses of a questionnaire revealed that the participants had more difficulties in their
second language conversations than those in their native language, and they demonstrated different interactional attitudes in the two categories of conversations. .

Speakers were observed more by listeners in conversations in their second language than those in their native language, and speakers with lower levels of expertise were observed more in second language conversations which probably reflected more frequent repair processes.

The participants were less conscious of their gazing activities in conversations in their second language than those in their native language probably because of the difficulties and pressures they felt in their second language conversations. We trust these findings will contribute further to supporting second language communications and second language learning.

\begin{abstract}
Yeates, Jones, Wills, Aitken, McLaren and McLaren (2012) devised a serial reaction time (SRT) task that provided evidence for human learning without awareness. Adapting the SRT paradigm usually employed to investigate implicit learning, participants responded to two simple white circle fills on either side of a screen. Instead of these following a sequence that participants were unaware of (e.g. Willingham, Nissen \& Bullemer, 1989) this task involved a separate stimulus, which was sometimes predictive of one of the circle fills. A square in the center of the screen would fill with one of eight colors before each circle fill: one of these colors predicted a right circle fill and the other a left on \(80 \%\) of trials on which those colors occurred. When pressing the key that followed the consistent response trained with these two colors, participants were both faster and more accurate than when responding to either the inconsistent response or control colors. Participants demonstrated a lack of contingency awareness, performing at chance in identifying the predictive colors and on a suitably sensitive prediction task. On reanalyzing this result, this paper shows that it was confounded with a sequential artifact produced by the experimental design itself. Pilot studies demonstrated weak learning of color contingencies when the artifact was removed, thus we sought to improve learning by both increasing the amount of training and placing the predictive color cue on the circle fills. Without the sequential artifact, we can produce the same result, although we concede the effect is less robust than we first indicated. Thus, we are able to reiterate our original conclusion: that this task can demonstrate learning of color contingencies in the absence of awareness and can be used to investigate implicit learning in humans.
\end{abstract}

Keywords: Associative learning; implicit learning; SRT task

\section*{Introduction}

At the \(34^{\text {th }}\) Annual Conference of the Cognitive Science Society Yeates, Jones, Wills, Aitken, McLaren and McLaren (2012) presented a novel serial reaction time (SRT) task, arguing that it produced convincing evidence for implicit learning in humans. The current paper tempers these claims, by first pointing to a subtle artifact in the experimental design, and then running experiments in which this artifact has been removed.

The criticisms leveled at research exploring implicit learning are extensive and well documented (e.g. Lovibond and Shanks, 2002; Mitchell, De Houwer and Lovibond, 2009; Shanks and Lovibond, 2002; Shanks \& St. John, 1994). One enduring research paradigm, however, that
remains popular is the SRT task. These studies typically require participants to perform a task in which they respond quickly and accurately to stimuli presented to them in a fastpaced series. In the version developed to investigate implicit learning by Willingham, Nissen and Bullemer (1989), unknown to participants these stimuli are presented in a particular sequence. Faster performance on these sequences, compared to participants who had been trained on random control sequences, provided Willingham et al. (1989) with evidence of learning in the absence of the ability to verbally report or explicitly predict those sequences.

Yeates et al. (2012) aimed to devise a paradigm with which one could both demonstrate implicit learning and investigate implicit processes. Reasoning from a dualprocess account of human learning, with both Cognitive (conscious, controlled, rule-based and symbolic) and Associative (automatic, statistical) systems (McLaren, Green and Mackintosh, 1994) assumed to be available, led Yeates et al. (2012) to develop an experimental design that attempted to circumnavigate rule-based, conscious processing of the stimuli. The intention of the study was to provide an experimental setting in which associative processing would be encouraged to underpin learning of relationships present in the SRT task.

To this end, a two-choice SRT task based on Jones and McLaren's (2009) and Aitken's (1996) previous work was devised. Participants were required to respond with two different, spatially compatible key presses to a white circle fill: either on the left or right hand side of the screen. On each trial, prior to the circle fill, a square (outlined in white in the center of the screen) would fill with one of eight colors; which participants were told functioned as a simple, central fixation to optimize their performance and avoid bias to either of the circle locations. They were therefore instructed to attend to the square but not told of its true value, which was (on certain trials) as a predictor of which circle would fill. Hence, this SRT task did not train participants to predict their next response from the sequence of previous responses; it used a separate stimulus to predict at which location the response stimuli would next occur.

A within-subject control was employed, so that only two of the eight possible colors correlated with one of the response stimuli locations. The other six colors occurred with equal likelihood before a right or left circle fill and therefore bore no predictive relation to the response
participants were making. The two predictive colors were themselves only partially ( \(80 \%\), following Posner \& Synder, 1975) predictive of a right or left circle fill. Hence one color would predict a right circle fill \(80 \%\) of the time and a left circle fill \(20 \%\) of the time. The other predictive color would precede a left circle fill \(80 \%\) and a right circle fill \(20 \%\) of the time. The prediction rate over the experiment works out at \(57.5 \%\), thus conscious detection of the presence of contingencies within the experiment would be very difficult. In conjunction with the rapid pace of the task, which involved short inter-trial intervals (ITIs: 250 msecs between response and square color fill, 250-500 msecs between square color fill and circle fill) and responses from participants ( \(M=298.4\) msecs, \(S D=27.7\) ), it is a design that does not encourage nor benefit participants to try and "work it out".

Two of the non-predictive colors were presented alongside the predictive colors in experimental blocks, which made up half of the 20 total blocks in the experiment and were alternated with control blocks (containing the remaining four control colors), the order of which was counterbalanced across participants. To avoid issues due to the sequence of lefts and rights, we designed the experiment so that each control block comprised the same sequence of circle fills as the experimental block it preceded/followed (dependent on counterbalancing). Thus, when comparing the difference between experimental predictive color performance with control performance, we could be confident this was not the product of the sequence of responses performed.

The final design feature of the paradigm employed to encourage participants away from attempting to consciously discover underlying relationships between the stimuli was to prohibit repetitions of the same color on consecutive trials. If participants were exposed to random sequences, we hypothesized that consecutive trials that involved repetitions of the same, predictive color would increase the salience of that color being particularly related to one circle fill, and thus one response. Thus, the experience of randomly being presented with a string such as: red-right-red-right-redright...etc. was prohibited.

This, however, introduced the artifact this paper is concerned with, as the consequence of introducing such a restriction on the trial sequences increased the number of alternations between right and left responses and decreased the number of repeating response trials in our experiment. For example, in an experimental block if you have just received the color that predicts a right response, you have a four in five chance of a right circle fill and thus a right response. Following this trial, on the next trial you can only be presented with: one of the two non-predictive colors (which are equally likely to be a right or a left); or the color that predicts left ( \(80 \%\) of the time). Therefore, you have a (roughly) two in five chance of another right trial and a three in five chance of a left trial. The confound occurs in that such alternations are more likely to occur on predictive trials that follow the contingency within the experiment, and least likely to occur on the \(20 \%\) of predictive color trials that
don't follow the trained contingency, and are equally likely on control trials. This, rather worryingly, neatly explains our original findings, if we assume that people either naturally prefer to alternate responses, or learn to do so. The result would be better performance on consistent predictive color trials, worse performance on the inconsistent predictive color trials, and intermediate performance on control color trials.

We sought to investigate this possible confound, with both a re-analysis of the original data and further experiments to ascertain the extent to which our previous claims - that we had demonstrated implicit learning using a novel, neat and robust paradigm - would survive when removing this potential artifact. The exact nature of the sequential artifact itself is interesting as, if indeed the observed results of the original experiment were concerned not with the relationship between color and circle but the statistical regularity of alternations versus repeats, was this learnt or is it simply a behavioral preference?

\section*{Original Experiment}

The full details of the experiment can be found in Yeates et al. (2012). A brief description of the method follows here, with the further analyses run on the original data, which corrects the original analysis by including a comparison between control and experimental blocks to investigate sequential effects.

\section*{Method}

Participants. The study involved 32 participants from the University of Exeter who each performed a two-choice serial reaction time over one session lasting roughly an hour.

Materials. The experiment involved the on-screen presentation of two white circle outlines and a white square outline, all 1.9 cm in width. The square was presented in the center of the screen, with the circles 2.2 cm either side to the right and left. The stimuli were one of eight possible colors: red, green, blue, yellow, pink, orange, brown and teal; that appeared within the square outline. The circle outlines would only fill white.

Design. Half of the colors were presented in experimental blocks and the other half in control blocks. There were 10 of each type of block, which alternated throughout the experiment and comprised of 120 trials each. In each block, each of the four colors were equally likely to occur. In control blocks, half of the time a color would precede a right circle fill and half the time a left circle fill. In experimental blocks two of the colors acted as controls, with the same number of right and left circle fills after these two colors. One of the two predictive colors in an experimental block preceded a right circle fill on 24 out of 30 trials, with the other color preceding a left circle fill on \(80 \%\) of trials. Therefore we classified trials as: Predictive-Consistent (the 24 of 30 trials that followed the predictive relationship); Predictive-Inconsistent (the 6 of 30 trials where the circle fill following a color was not the target trained circle fill);

Experimental Non-Predictive (control color trials in experimental blocks); and Control Non-Predictive (control color trials in control blocks). The same color could not occur on consecutive trials. All blocks involved an equal number of right and left circle fills, and control block right and left circle fill sequences followed the same sequence of right and left circle fills as the experimental block adjacent to it (either preceding or following depending on the counterbalancing).

Procedure. On each trial the square would fill with one of eight possible colors and, after a variable interval of between 250 and 500 msecs one of the two circles would fill in white. This was the cue for participants to respond with spatially compatible keys of either " \(x\) " or " \(>\) " on a standard QWERTY keyboard for the left and right circle, respectively. A 250 msec ITI followed, during which the circle and square outlines were again presented on screen. Errors were signaled with a beep and each block was followed by a 30 sec break.

Participants were instructed to fixate on the colored square to avoid a bias toward either of the circle flashes, and were told that the experiment was concerned with responding quickly to simple stimuli. No mention was made of the predictive nature of the colors, or of any relationships in the experiment to learn about. A verbal interview and prediction task followed the experiment. The structured interview aimed to assess knowledge of the experimental contingencies and asked participants to describe anything that they had noticed and to identify two colors that may have been predictive. The prediction task involved the same stimuli as in the previous experimental and control blocks, with two blocks of 16 trials each - one with experimental and one with control colors. These colors were randomly presented an equal amount of times to participants within the square in the center of the screen. Instead of this stimulus preceding a circle fill that prompted a response, the display remained the same until participants made a prediction about where they thought the circle would have filled in the experiment using the same response keys (" \(x\) " or " \(>\) "). Participants were informed that pressing either of the response keys would not be considered an error and no feedback was given.

\section*{Results}

In the original paper, Yeates et al. (2012) analyzed both reaction times (RTs) and error rates across the four Trial Types mentioned previously. An analysis of variance (ANOVA) was conducted comparing Trial Types across Blocks. We found a significant effect of Trial Type in both RTs and errors, both following the same ordinal pattern with slower and less accurate responding to PredictiveInconsistent, followed by Experimental Non-Predictive and Control Non-Predictive colors, with Predictive-Consistent colors resulting in faster and more accurate responding.

To ascertain whether these results were due to learning of the contingencies present between predictive colors and responding across the experiment, here we report the results of a corrected ANOVA with Block Type as a two level
within-subject variable enabling us to compare experimental and control blocks. We categorized Trial Types in experimental blocks as before (Predictive-Consistent, Predictive-Inconsistent and Experimental Non-Predictive). However, in the corresponding control block that is paired with the experimental block (dependent on participant counterbalancing, either the block preceding or following the experimental block) we did not collapse all trials into Control Non-Predictive. Instead, each of the 120 trials in each control block were labeled with the same Trial Type as the corresponding trial from the paired experimental block. As a brief illustration: if the first trial of the first experimental block was a Predictive-Consistent trial, we would give the first trial of the first control block a Predictive-Consistent dummy label. Thus, instead of collapsing all control block trials to compare for general sequential effects, we can assign them these dummy labels. This will enable us to examine whether the sequential artifact of more alternations than repeats was what produced the pattern of results previously reported. If the control block pattern of responding across the three dummy Trial Types follows the experimental pattern, then we have evidence that sequential effects may have produced any differences in responding rather than learning about color contingencies.

ANOVAs comparing both RT and errors across Block, Block Type and the three level Trial Type revealed a significant effect of Trial Type in both RTs, \(F(2,62)=23.6\), \(p<.001\), and errors, \(F(2,62)=5.67, p=.006\). There was no significant effect of Block Type in either RTs, \(F(1,31)=\) \(1.55, p=.2\), nor errors, \(F(1,31)=.908, p=.3\). However, it is the interaction between Trial Type and Block Type that we are interested in, which was not significant in either RTs, \(F(2,62)=1.11, p=.3\), nor errors, \(F(2,62)=.166, p=.8\). This is due to both experimental and control Block Types following the same pattern, as is seen clearly in Figures 1 and 2. Thus, we found no difference in the observed pattern of responding to Trial Types between Block Types.

Figure 1. Mean RT for each Trial Type for experimental (solid bars) and control (open bars) Block Types.

Figure 2. Mean \% error for each Trial Type for experimental (solid bars) and control (open bars) Block Types.

\section*{Discussion}

The absence of a difference between the Block Types, and the lack of a significant Block Type by Trial Type interaction demonstrates quite clearly that the sequential artifact could have produced most of, if not the entire effect of Trial Type. Given this, it becomes vital to demonstrate that color learning can be obtained without the presence of this sequential artifact if the paradigm is to be of any use. The next experiment does just this.

\section*{Experiment 1}

In pilot work for this experiment, 16 participants formed two groups: eight participants who received the same, constrained sequences as in the original experiment (i.e. a color would never repeat) and eight who were trained on random sequences with no constraint (i.e. color repeats were permitted). Training lasted sixteen blocks (half experimental and half control), as the final four blocks were altered to act as test. In these the same colors were used as in the training, except contingencies were all set to the same, equal probability (50\%) of preceding either circle fill. This introduced a section of the experiment free from trained contingencies, meaning results could be compared across colors when matched. The results of this pilot study encouraged us to develop a design that encouraged more learning, as without the sequential artifact the Trial Type effect began to emerge at test in RTs and across training in errors for the group without the sequential artifact, but very weakly.

In an attempt to develop the original procedure to encourage learning whilst maintaining the original design elements, we first decided to increase the length of training. Instead of extending the experiment, which lasts around one hour, we chose to remove the control blocks and replace them with experimental blocks. Without the constraint on color repetitions and with the introduction of a set of test
blocks, possible sequential confounds should be avoided. Thus, control blocks for comparative purposes become surplus to the task's requirements, hence 15 blocks of experimental, training blocks preceded five blocks of test. This gave us one and one half times the amount of training in the original experiment. The training followed the form of the earlier described experimental blocks, so the experiment now contained only four possible colors in total, two Predictive and two Non-Predictive.

To further increase the possibility of learning, we ensured that participants were attending to the cue (the color of the square fill) when both processing and performing their response. When the circle fill occurs during the experiment, the colored square cue is still on screen and remains there until a response is made. However, attention will have shifted from the center of the screen and the color filled square onto the circle that has filled. Thus, if participants were attending to the circle fill when making their response the contingency between color and response would be strengthened if the color was represented in the location of the response cue itself. Consequently the circle in this version of the experiment did not fill white, but the color of the square color cue preceding it.

\section*{Method}

Participants. 16 University of Exeter undergraduate students ( 4 male, 12 female) aged between 18 and 24 ( \(M=19.25\) ) participated in the experiment for course credit.

Materials. As detailed in the original experiment, but with two differences. Firstly, the color of the circle fills was no longer white but the circle would fill with the color of the preceding square fill. Secondly, the blocks in training were exclusively experimental blocks. The experiment therefore consisted of only four colors in total (two Predictive and two Non-Predictive), presented across 15 training blocks and in 5 test blocks. The sequences were constructed randomly with no color repeat constraint.

Design and Procedure. The experiment again comprised of 20 blocks of 120 trials. All blocks were made up of a sequence of rights and lefts constructed as previously described, with the constraint that no color could follow itself on consecutive trials. The first 15 blocks acted as training, involving the same four colors in each Block Type as detailed in the original experiment. The final five blocks were test blocks involving the same four colors in each. For these blocks all colors were equally likely to be followed by a right or left circle fill. The procedure was as detailed in the aforementioned original experiment.

\section*{Results}

The data for both RTs and error rates were analyzed as in the original experiment, however, the variable of Block Type was no longer needed as all blocks involved the same four colors, two Predictive (split into Consistent and Inconsistent) and two Non-Predictive. Thus Trial Type and Block were the variables of interest in our ANOVAs. The results for RTs can be seen in Figure 3 and errors in Figure 4.

Figure 3. Average RT in msecs for each Trial Type over training (top panel) and test (bottom panel).

Training data demonstrated a significant effect of Trial Type in RTs, \(F(2,30)=11.23, p<.001\), and errors, \(F(2,30)=\) \(9.68, p=.001\). Predictive-Consistent trials are responded to more quickly and accurately than Non-Predictive trials, and these more quickly and accurately again than PredictiveInconsistent trials, which can be seen in both the top panels of Figures 3 and 4. This is further expressed by significant planned contrasts between Predictive-Consistent and Predictive-Inconsistent trials in both RTs, \(F(1,15)=18.98, p\) \(=.001\), and errors, \(F(1,15)=14.44, p=.002\) showing that participants responded faster and more accurately to trials that followed those contingencies they were trained on than those trials that were not consistent with these trained contingencies. Both lower RTs and fewer errors were present in Predictive-Consistent trials opposed to NonPredictive trials as well, shown in the planned contrast between the two in RTs, \(F(1,15)=5.65, p=.03\), and with a non-significant trend in same direction for errors, \(F(1,15)=\) \(1.24, p=.3\).

At test the RT data demonstrate no significant main effect of Trial Type, \(F(2,30)=.86, p=.4\), yet follow the same ordinal pattern as in training. The error data at test also show no significant main effect of Trial Type, \(F(2,30)=\) \(.077 p=.9\), with Predictive-Consistent trials resulting in faster and more accurate responding than PredictiveInconsistent trials. However, this is not entirely the pattern observed in training, as the control Non-Predictive stimuli produce more errors at test.

Figure 4. Mean \% errors for each Trial Type over training (top panel) and test (bottom panel).

The structured questionnaire revealed that twelve of the sixteen participants indicated surprise that the experiment did indeed involve color contingencies. This is further supported by the colors identified by participants as predictive. Given two choices each to name the two colors, participants selected the correct color on 16 out of the total 32 responses (exactly what one would expect by chance). They were asked also which of these two colors predicted which circle fill, which resulted in 9 accurate responses out of 32 (again this is close to the 8 expected by chance).

The prediction task itself involved two blocks of 16 trials, with all four colors occurring equally in each block resulting in eight trials where participants could predict Color 1 (which predicted the right circle fill) and eight trials for Color 2 (which predicted the left circle fill), see Figure 5. Of these 16 trials involving the Predictive Colors we can expect 8 correct responses by chance, which is near to the observed mean correct responses of 8.25 . This is not significantly different from chance and, when taking the colors separately, is not the result of learning about one color alone with mean correct responses of 3.94 and 4.31 for Color 1 and 2, respectively.

\section*{Discussion}

The results in training clearly demonstrate a pattern that provides evidence that learning about the contingencies between color and response has occurred. This is further supported the ordinal pattern in RTs and errors at test, which lessens the possibility that the effect is due to a speedaccuracy tradeoff.

Figure 5. The number of correct responses participants gave for Predictive Color 1 (filled bars) and Predictive Color 2 (open bars).

The structured interview responses and prediction task results provide evidence that this learning occurred outside of awareness, as not only were most participants surprised to learn that contingencies were present, they could not identify these colors, what the colors predicted, or use them to predict the correct, trained response above the level expected by chance.

Thus, we would conclude that across training we clearly demonstrated learning, in the absence of awareness, of color-response contingencies similar to those we believed to have found in our original paper's claim (Yeates et al., 2012). Furthermore, we have demonstrated that this effect somewhat remains when transferred to a test phase. The lack of significance may be attributed to extinction of the trained contingencies. Indeed when considering the first two blocks of test the ordinal pattern of RTs and errors are the same as during training and a post-hoc contrast test demonstrates a significant difference between PredictiveConsistent and Predictive-Inconsistent trials, \(F(2,15)=\) 13.23, \(p<.01\).

\section*{General Discussion}

We can conclude, as in the original paper, that this paradigm can still be used to demonstrate implicit learning in humans. However, this effect is clearly not as robust or easily obtained as we first imagined. When increasing the number of training trials and placing the predictive cue (color) on the response stimuli to ensure participants attended to them while processing or executing their responses we obtained effects comparable to those we previously reported.

We concede that whilst the prediction task demonstrates little evidence of conscious awareness that the result could be made more convincing if we could produce a non-null result (Z. Dienes, personal communication, 3 August 2012). A comparison between participants trained under intentional
instructions or indeed a Bayesian analysis (for which we would require an 'aware' prior from participants with explicit knowledge) of these data could strengthen our claims regarding the implicit nature of this learning.

It is not the intention of this paper to be entirely concerned with methodological issues. Our original paper suggested this paradigm as a method for studying implicit learning in humans and thus a refinement of the paradigm is of importance to the research questions that it enables us to investigate. We proposed that the process by which this occurs is associative in nature and aimed to produce variants of the task to investigate this behaviorally, alongside associative, computational modeling. It remains our intention to do so and we encourage the use of this paradigm in its re-designed form. We also accept that the prediction test in this version of the design is not maximally sensitive, as the test block (during which no contingencies are in play) separates training from this test of awareness. We intend to run other experiments using this paradigm without a test phase to address this issue.

\title{
Linguistic Variability and Adaptation in Quantifier Meanings
}

\author{

\begin{abstract}
People's representations of most and arguably all linguistic and non-linguistic categories are probabilistic. However, in linguistic theory, quantifier meanings have traditionally been defined set-theoretically in terms of categorical evaluation functions. In 4 "adaptation" experiments, we provide evidence for the alternative hypothesis that quantifiers are represented as probability distributions over scales (e.g., Zadeh, 1965). We manipulate exposure to different distributions of "some" and "many" and find that listeners adapt to those distributions, as predicted. Our results suggest that the interpretation of quantifiers is best modeled as a process involving rich, probabilistic representations.
\end{abstract}

Keywords: Quantifiers; Semantics; Language processing; Adaptation; Generalization

\section*{Introduction}

In linguistic theory, quantifier meanings have traditionally been defined set-theoretically in terms of categorical evaluation functions (Barwise \& Cooper, 1981) yielding either truth or falsity of a sentence containing a quantifier. Quantifiers are understood as relations between sets:
some \((A, B)\) is true iff \(\|A\| \cap\|B\| \neq \varnothing\)
\(\operatorname{many}(\mathrm{A}, \mathrm{B})\) is true iff \(\|\mathrm{A}\| \cap\|\mathrm{B}\|>n\), where \(n\) is some large number

For example, the sentence Some candies are green is true just in case the intersection of the candies and the green things is not empty. Similarly, Many candies are green is true just in case the cardinality of the intersection of the candies and the green things is larger than some contextual norm \(n\). This points to a notable feature of some quantifiers: they exhibit both vagueness and context-dependence (Solt, 2009).

A class of alternative views tries to incorporate this feature by representing quantifiers probabilistically. For example, fuzzy logic (Zadeh, 1965) approaches to meaning consider quantifiers such as "some" as probability distributions over scales (e.g., Moxey \& Sanford, 1993). Probabilistic quantifier semantics are at the heart of recent models of both syllogistic reasoning (Chater \& Oaksford, 1999) and scalar implicature (Goodman \& Stuhlmüller, 2013). Here we provide further evidence that quantifiers are indeed interpreted in a probabilistic, graded manner. The novel empirical contribution lies in addressing the adaptability of these distributions to variable language environments.

The probabilistic view on quantifier meaning is illustrated in Figure 1a: "some" and "many" form graded distributions over a contextually determined scale. \({ }^{1}\) Previous work

\footnotetext{
\({ }^{1}\) For example, it is not as plausible to quantify 18 out of 1000 as "many" as to quantify 18 out of 20 .
}

Figure 1: Illustration of across speakers variability in meanings of quantifiers.
has implicitly assumed that these distributions are invariant across linguistic environments, in that the distribution corresponding to, for example, "some" is stationary across different dialects, speakers, genres, and so on.

However, variability in language use is the norm. Speakers differ in their realization of phonemes (cf. Allen, Miller, \& DeSteno, 2003), lexical preferences (e.g., couch vs. sofa), as well as syntactic preferences (e.g., some speakers use passives more often than others, Weiner \& Labov, 1983). Such linguistic variability is a challenge for comprehenders that must be overcome to achieve successful communication. One solution for dealing with variable linguistic environments is to track and adapt to the joint statistics of linguistic categories (e.g. phonemes, words, syntactic structures) and contextual cues, including the speaker.

A powerful way to test whether listeners adapt to the statistics of the input is to determine whether categorization functions shift with exposure. If listeners adapt to new environments in which the statistics diverge from their prior beliefs, this would suggest that linguistic representations are sensitive to and adapt to such sources of variability. This reasoning has been successfully applied to phonetic categories (e.g., Clayards, Tanenhaus, Aslin, \& Jacobs, 2008; Vroomen, Linden, Gelder, \& Bertelson, 2007; Kraljic \& Samuel, 2006), prosodic categories (Kurumada, Brown, \& Tanenhaus, 2012), and syntactic categories (Fine, Jaeger, Farmer, \& Qian, underreview; Kamide, 2012).

Here we ask whether listeners' representations of the quantifiers "some" and "many" are probabilistic and sensitive to environmental variability. Figure 1 b depicts hypothetical some and many distributions over cardinalities for two speakers whose use of the quantifiers differs.

In four adaptation experiments, we provide evidence that quantifiers are represented as probability distributions. More-

Figure 2: Procedure for Experiment 1. Top panel illustrates an exposure phase trial. Bottom panel illustrates a test phase trial.
over, we present evidence that listeners' interpretations of quantifiers rapidly adapt to the statistics of the local linguistic environment represented by a novel speaker. Furthermore, we provide evidence suggesting that listeners' adaptation might be taking place across multiple levels (or types) of representations. We argue that the rapid adaptation that we observe involves both speaker-specific and quantity level representations enabling transfer of adaptation across visual object types.

\section*{Experiment 1}

Behavioral evidence strongly suggests that listeners dynamically adapt to the phonetic and syntactic variability in their language environment (Vroomen et al., 2007; Bertelson, Vroomen, \& Gelder, 2003; Kamide, 2012; Fine et al., underreview). But do such adaptive processes also occur at the level of meaning? We addressed this question in an experiment by investigating whether listeners adapt their interpretations of the two English quantifiers "some" and "many" based on experience with a speaker who uses these quantifiers in a way that deviates from the listener's prior expectations.

Our experimental logic followed that of previous adaptation experiments (e.g., Bertelson et al., 2003). The experiment employed a by-2 between-participant design. One group of participants was exposed to a novel speaker's use of the word "some" (some-biased group). Another group of participants was exposed to a novel speaker's use of "many" (many-biased group). Participants in both groups were then tested on how they interpreted that speaker's utterances.

\section*{Participants}

80 participants were recruited over Amazon's crowd-sourcing service Mechanical Turk. All participants were self-reported native speakers of English. Each experimental session took about 15 minutes and participants were paid \(\$ 2\).

\section*{Procedure and Materials}

Figure 2 illustrates the materials and procedure for this experiment. The experiment proceeded in two phases, the exposure
phase and the test phase.
In the exposure phase, participants watched videos as in the top panel of Figure 2. The video showed a bowl of 25 candies in the bottom right of the screen. The bowl always contained a mixture of green and blue candies, but the number and spatial configuration of the candies differed between trials. Importantly, the video showed a speaker describing the scene in a single sentence. The videos played automatically at the start of the trial and the scene - the candy bowl remained visible even when the video had finished playing (as shown in Figure 2, top). Two different speakers were employed between participants to ensure that effects were not due to a particular speaker.

The exposure phase consisted of 10 critical and 10 filler trials. In critical trials the speaker produced the sentence Some of the candies are green (some-biased group) or Many of the candies are green (many-biased group). On a critical trial, the bowl always contained 13 green candies and 12 blue candies. This scene was identified as the Most Ambiguous Quantity (MAQ) scene in a preceding norming study in which participants rated how well descriptions containing different quantifiers matched scenes sampled from a continuum of quantities.

The remaining 10 trials in the exposure phase were filler trials. On a filler trial, participants observed the speaker correctly describing a scene with no green candies in it as None of the candies are green ( 5 trials) and a scene with no blue candies in it as All of the candies are green ( 5 trials). The purpose of the filler trials was two-fold. First, it made our manipulation less obvious. Second, including clearly true descriptions of unambiguous scenes encouraged participants to believe that the speaker was indeed intending to accurately describe the scene. The order of the critical and the filler trials was randomized.

Following the exposure phase, participants entered the test phase. The test phase was intended to assess participants' beliefs about the speaker's use of both "some" and "many". On test trials, participants saw a candy scene in the center of the display and two identical still images of the speaker from the exposure phase on either side of the scene (see Figure 2, bottom).

The two images of the speaker were paired with one of the two alternative descriptions Some of the candies are green and Many of the candies are green each. The participants' were asked to rate how likely they thought the speaker would be to describe the scene using each of the alternative descriptions. They performed this task by distributing a total of 100 points across the two alternatives (the first and the second slider bars; see Figure 2, bottom panel) and a third alternative - namely "Other" - to reflect how much they thought that neither of the two alternatives fit the scene (the third slider bar). As in the exposure phase, scenes always consisted of a bowl of 25 candies with differing numbers of green candies. To assess participants' beliefs about the speaker's use of "some" and "many", we sampled scenes from the entire scale. Specifically, scenes contained one of
\(\{1,3,6,9,11,12,13,14,15,17,20,23\}\) green candies out of 25 candies. Over 39 test trials, participants rated each scene 3 times. Different instances of the same scenes differed in the spatial configuration of the blue and green candies. The order of the scenes and the mapping from alternative descriptions to slider bars were randomized and counterbalanced.

To ensure that participants were attending to the task, we placed catch trials after about every six trials. On some of these trials, a gray cross appeared at a random location in the scene. Before the next trial began, participants were asked if they had seen a gray cross in the previous scene.

\section*{Data Analysis}

We did not analyze the "Other" responses. The top row in Figure 3a shows the distribution of "some" and "many" in the test phase separately for the two groups of participants. The distributions were obtained by averaging participants ratings for the different scenes along the scale. We first averaged across the three instances of each scene within a speaker and then averaged those ratings across speakers (separately for each point on the scale). Those average ratings were then fit with a generalized linear model with cubic splines, which gave us the continuous curve for each of the two alternative descriptions shown in Figure 3a, top row. Participants in the some-biased group adapted in the opposite (and predicted) direction from participants in the many-biased group. That is, the distributions for participants in the some-biased group were updated such that they were more likely to rate a wider range of scenes as more likely with respect to the "Some" description. Such high ratings of the "Some" description came at the expense of the alternative description. Similarly, the distributions for participants in the many-biased group reflected that these participants were more likely to rate the "Many" description as more likely at the expense of the alternative description.

In order to quantify the shift in interpretations between the two groups of participants, we derived two measures. First, for each participant, we estimated the MAQ as the point where the two curves were closest to each other (excluding the extremes of the scene continuum).

Similar in logic to the phonetic adaptation experiments, we reasoned that participants in the many-biased group would come to interpret a "many" as applying to a wider range of scenes (and hence quantities). Because participants had to share a total of 100 points between the alternatives, this adaptation in favor of "many" would be at the expense of "some" ratings. Therefore, the MAQ scene should shift to the lower end of the continuum of set sizes compared to 13 (the MAQ scene from the norming study). In contrast, for participants in the some-biased group, if they were to adapt to the statistics of the speaker during the exposure phase, they should rate a wider range of scenes more likely to be described using the quantifier "some." These high ratings for "some" would come at the expense of "many." Therefore, the MAQ should shift to the higher end of the continuum of set sizes compared to the MAQ scene from the norming experiment.

To ensure that our findings were not just an artifact of the way the analysis was conducted, we performed a separate set of analyses by computing the Area Under the Curve (AUC) for each of the two alternative descriptions. That is, again, we first fit a generalized linear model with cubic splines for each participant. Then we computed the AUC for each alternative description (by summing up the area under the fitted curve) and subtracted the AUC for the "Some" curve from the "Many" curve.

We reasoned that if participants adapted their quantifier interpretations in the predicted direction, then the AUC difference should be smaller (or negative) for participants in the many-biased group and larger (or positive) in the some-biased group.

All analyses were conducted using the R statistics software package (R Development Core Team, 2005).

\section*{Results}

Middle row in Figure 3a presents the results for MAQ analysis. As predicted, for each speaker, the MAQ values were significantly smaller for the many-biased group than for the some-biased group ( \(p<10^{-6}\) ).

Bottom row in Figure 3c shows re-evaluation of the same data using the AUC analysis. As predicted, for both speakers, the AUC difference for the many-biased group and the somebiased group grew in opposite directions ( \(p<10^{-6}\) ).

These results suggest that listeners indeed track the joint statistics of quantities, speakers, and the quantifiers in their environment, and rapidly adapt their interpretations in response to the new input.

\section*{Experiment 2}

One limitation of Experiment 1 is that effects might be speaker and/or scene specific. Experiments 2 and 3 were designed to test the hypothesis that the updating was more general. Experiment 2 examined adaptation when the emphasis is shifted away from the specific speaker by changing the instructions and by removing the speaker's face from the test phase trials. Experiment 3 used different objects in the test phase - Xs and Os instead of candies of different colors.

\section*{Participants}

Participants were 80 Mechanical Turk workers. All participants were self-reported native speakers of English. Each experimental session took about 15 minutes, and participants were paid \(\$ 1.5\).

\section*{Procedure and Materials}

The experimental stimuli were identical to those of Exp. 1.
The procedure was identical to that of Exp. 1 with the exception of the test trials. Unlike the previous experiment, participants did not see a cue to the speaker's identity. Instead, they saw only the two sentences providing the two alternative descriptions for the scene located at the center. The participants' task was to rate how likely that they thought that \(a\)
\begin{tabular}{lllll}

\hline
\end{tabular}

Table 1: Summary of the experimental designs. VS: visual stimuli. LS: linguistic stimuli.
speaker would describe the scene with each of the alternative descriptions. They again distributed a total of 100 points across the two alternative descriptions and choice of "Other."

As in Exp. 1, 40 participants were assigned to each of the some-biased and many-biased groups. For each group, of the 40 participants, 20 were assigned to each of the speakers in the videos.

A summary of the procedures used in the different experiments is provided in Table 1.

\section*{Results}

We excluded one of the participants from the analysis because they never adjusted the sliders on the test trials. Top row in Figure \(3 b\) plots the mean ratings by participants in each of the two groups. Participants adapted their interpretations of the quantifiers in accordance with the speaker-provided statistics, though less so than in Exp. 1.

We performed the same MAQ and AUC analysis as for Exp. 1. Middle row in Figure 3b illustrates that the MAQ for participants in the many-biased group was significantly smaller than the MAQ for participants in the some-biased group. This was true for both speakers ( \(p<0.01\) ). The AUC analysis, bottom row in Figure 3b, also revealed significant adaptation ( \(p<0.01\) ).

The results from Exp. 2 suggest that the adaptation observed in Exp. 1 is not a simple speaker-specific adaptation effect and suggest instead that listeners' adaptation to the statistics of the linguistic environment might occur at multiple levels of representations. Adaptation was stronger in Exp. 1 where a cue to the speaker was provided in the test phase. However, the fact that we also observe adaptation in Exp. 2 (when no such cue is available) suggests that this adaptation was to some extent generalized across speakers.

\section*{Experiment 3a}

It is nevertheless possible that the adaptation effects found in Exps. 1 and 2 is object-specific, i.e. quantifier interpretations are only updated for quantities of candies. Exp. 3a tested this by replacing the candy scenes in the test phase trials with scenes containing letters ( Xs and Os ).

\section*{Participants}

We recruited 40 participants over Mechanical Turk who were self-reported native speakers of English. Each experimental session took about 15 minutes. Participants were paid \(\$ 1.5\).

\section*{Materials and Procedure}

The test stimuli differed from the previous experiments. On each test trial we presented 25 letters, each of which was either an X or an O . The letters in each scene were scattered within a circle (but there was no visible boundary). The descriptions that participants rated were Some of the letters are Xs and Many of the letters are Xs. Number of Xs in a scene could be any of the values that the number of green candies could be in a scene from Exps. 1 and 2. Participants' task was again to rate (by distributing 100 points) how likely that they thought a speaker would describe the scene with each of the alternative descriptions and the third choice of "Other."

The stimuli in the exposure phase were identical to Exp. 1 and 2 but speaker identity was not varied between participants. Half of the participants were assigned to the somebiased group and half to the many-biased group.

In order to establish that transfer occurred between the candy and the letter scenes, we included a pre-exposure test phase. The aim of these pre-exposure test trials was to measure participants' prior interpretations of quantifiers in candy scene descriptions and compare them to quantifiers in letter descriptions following exposure to candy scenes. That is, we analyzed participants' responses to descriptions of letter scenes in the post-exposure test trials and responses to descriptions of candy scenes in the pre-exposure test trials together to measure whether participants' interpretations changed with exposure.

\section*{Data Analysis}

For each participant in the MAQ analysis, we determined the MAQ for the pre- and post-exposure test responses separately. Then we subtracted the pre-exposure MAQ from the post-exposure MAQ. A positive difference is expected for the some-biased group and a negative one for the many-biased group.

For the AUC analysis, we first calculated the AUC difference on pre-exposure test trials for each participant. Then we calculated the AUC difference on post-exposure test trials. The pre-exposure AUC difference was then subtracted from the post-exposure AUC difference. The expected patterns of results was the same as in the previous experiments.

\section*{Results}

Top row in Figure 3c illustrates the group mean ratings for the post-exposure test trials. Participants' ratings in the some-

Figure 3: Each column shows data for experiment (e.g., left-most column is Experiment 1, right-most column is Experiment \(3 b)\). The vertical lines in the density panels at the top denote the MAQ scene (scene 13) determined based upon a preceding norming study. \(\mathrm{MB}=\) Many-biased, \(\mathrm{SB}=\) Some-biased.
biased group and the many-biased group did not differ before exposure. However, following the adaptation trials, participants' responses reflect that they adapted in the predicted directions:

The MAQ difference analysis in middle row in Figure 3c shows that indeed participants in the some-biased group rated "Some" descriptions as more likely across the whole continuum of scenes, whereas participants in the many-biased group favored "Many" descriptions at the expense of the alternative descriptions \((p<0.01)\). The difference in AUC difference analysis in Figure 3c, bottom row, reaffirmed our findings ( \(p<0.01\) ).

The results from Exp. 3 suggest that participants' quantifier interpretations did not adapt candy-specifically - instead, quantifier adaptation transferred to a different visual environment. That is, the quantity level representation itself adapted.

\section*{Experiment 3b}

To establish that the results we obtained in Exp. 3 were not due merely to the additional pre-exposure test trials, we re-ran Exp. 2 with pre-exposure test trials. The pre- and post-exposure test trials were identical and contained candy scenes.

We recruited 120 participants over Mechanical Turk who were self-reported native speakers of English. Each experimental session took about 15 minutes, and participants were paid \(\$ 1.5\).

60 participants were assigned to each of the the somebiased group and the many-biased group. 30 participants in each group were assigned to each of the speakers.

Top row in Figure 3d shows the mean post-exposure test trial responses (responses did not differ on pre-exposure test trials between groups). Following adaptation trials, there is a clear effect of group in the predicted direction, replicating the results from Exp. 2.

Middle row in Figure 3d shows the results of the MAQ difference analysis. The qualitative patterns of our results reflects the predicted pattern, such that the MAQ difference was positive in the some-biased group and negative in the manybiased group. This difference was significant ( \(p<0.01\) ). In the difference in AUC difference analysis (Figure 3d, bottom row) the participants adapted to the speakers in the predicted directions ( \(p<10^{-4}\) ).

We thus replicated the results from Exp. 2, again indicating that listeners' adaptation of quantifier meanings is broad. It also confirms that the inclusion of pre-exposure test trials
is most likely not the reason for the transfer effect found in Exp. 3.

\section*{Discussion}

Our results indicate that semantic representations can be adapted to new linguistic environments. At least in situations like the ones investigated here, this adaptation seems to be rapid, requiring only very limited exposure. Our observation that adaptation can be transferred across multiple linguistic and visual environments suggest that these adaptations are not limited to the specific nature of the scale, although it remains to be seen how such adaptation generalizes to scales of different ranges. Our experiments support probabilistic theories of quantifier meaning over set-theoretic ones. Our results are also compatible with a soft version of set-theoretic representations under which there are core logical representations that are enriched with probabilistic expectations about the use of quantifiers with different set sizes.

In this paper, we addressed the question of whether and how listeners adapt to speakers' use of the quantifiers "some" and "many." A recently emerging literature in other domains of language processing has provided evidence that listeners can rapidly adapt to speaker-specific variability in their language environment. Most of this line of work has focused on adaptation to phonological variability across speakers (e.g., Kraljic \& Samuel, 2006; Clayards et al., 2008; Vroomen et al., 2007). To our knowledge, our work is the first to extend the logic of language adaptation experiments to semantic representations.

Future experimental work should address whether listeners can adapt to multiple speakers' quantifier use statistics simultaneously. While the relative magnitude of the shift in interpretations of "some" and "many" between Experiments 1 and 2 might be taken to provide preliminary evidence that listeners maintain both speaker-specific and speaker-general representations and that both of these are affected by recent experience with a specific speaker, future work is required to address more directly the nature of representations that are adapted by recent exposure. For example, it is possible that listeners maintain hierarchically structured representations over speakers, groups of speakers (based on their similarity), and so on (cf. modeling of phonetic adaptation; Kleinschmidt \& Jaeger, 2011). Future research will also need to address how much of the adaptation comes from base-rate effects (e.g., changes in the prior probabilities of quantifiers) and how much of it comes from adaptation of the meaning of each quantifier (e.g., changes in the likelihood functions of quantifiers). In pursuing these questions, we believe it will be necessary to take a two-pronged approach, combining behavioral paradigms like the one introduced here with computational models that provide clear quantifiable predictions about how listeners adapt previous experience with other linguistic environments based on recent experience with a specific linguistic environment.

\begin{abstract}
Two category-learning experiments were conducted to examine the role of category structure and learning regime in category learning. We particularly focused on effects of these factors on selective attention, which was measured by eyetracking methods. Results show that even though supervision was weaker than in previous studies, attention optimization and cost of attention were observed during category learning (Experiment 1). Moreover, there were faster learning and stronger attention optimization when statistically denser categories were learned (Experiment 2). At the same time, there were weaker costs of selective attention when learning denser categories than when learning sparser categories. Results are discussed in relation to theories of category learning.
\end{abstract}

Keywords: category learning, cost of selective attention, category structure, eye tracking

\section*{Introduction}

Selective attention is one of the key components in category learning (Kruschke, 1992; Nosofsky, 1986; Shepard, Hovland, \& Jenkins, 1961). The ability to selectively attend to category-relevant dimensions aids the learner to ignore category-irrelevant information and makes learning more efficient. For example, when learning how to distinguish Siberian Huskies from Alaskan Malamutes, which look very similar, the color of the eyes is one of the relevant features one should look for (most Huskies have blue eyes and Malamutes have brown eyes). Therefore, learning to focus on the color of the eyes while ignoring other irrelevant features (e.g. color of the fur or markings) would aid learning the two categories. Selective attention could be captured in category learning tasks that involve eye-tracking as attention optimization, where looking to categoryrelevant information increases and looking to irrelevant information decreases (Hoffman \& Rehder, 2010).

However, optimizing one's attention to the current category-relevant dimension may result in learning to ignore the category-irrelevant dimension, which results in learned inattention to the irrelevant dimension (Kruschke \& Blair, 2000). Therefore, if a new to-be-learned category has a category-relevant dimension that was previously irrelevant, learning may become more difficult, which represents a cost of selective attention. For example, when learning to distinguish meerkats from prairie dogs, which again look
very similar, the shape of the ears is one of the good dimensions to look. However, if one has previously learned how to distinguish Huskies from Malamutes, where eyes were attended and ears were ignored, learning to attend to the once-ignored ears would be hindered.

The close link between attention optimization and the cost of selective attention has been demonstrated in previous research (e.g., Hoffman \& Rehder, 2010). In their study, participants were given either a supervised classification task (e.g. classifying a stimulus into category A or B) or a supervised inference task (e.g. inferring the missing feature of a stimulus that belongs to a certain category) and their eye movements were recorded. Since the classification task (e.g. focusing on the color of the eyes to classify Huskies and Malamutes) required attention optimization to the relevant dimension, results showed cost of selective attention when learning a new category. On the other hand, since the inference task (e.g. figuring out whether a Malamute has blue eyes or brown eyes) does not require attention optimization, the cost did not occur when learning the next category. Therefore, the study showed that (a) the characteristics of the task affect allocation of attention and (b) when attention optimization occurred, the cost of selective attention also followed.

Although attention may be affected by the characteristics of the task (i.e., classification vs. inference) it can also be affected by category structure. Categories that have multiple correlated dimensions (or statistically dense categories) may be learned without selective attention, whereas categories that have few relevant dimensions (or statistically sparse categories) may require selective attention (Kloos \& Sloutsky, 2008; Sloutsky, 2010). For example, when learning the category dog, many dimensions are relevant (e.g. nose, fur, four-legs, etc.) and therefore it is relatively easy to learn. However, when learning abstract concepts such as friction, very few dimensions are relevant among many irrelevant dimensions (e.g. a car trying to stop at the red light and a person trying to open a jar both shows friction). Therefore, to learn a sparse category one has to "selectively attend" to the relevant dimension among many other irrelevant dimensions.

Finally, the deployment of selective attention may be also affected by learning regime. Since supervised learning provides information about the relevant dimension, it is more likely to recruit selective attention than unsupervised
learning (Kloos \& Sloutsky, 2008). Kloos \& Sloutsky (2008) showed that sparse categories could largely benefit from supervision, while it could sometimes hinder dense categories. Since selective attention filters irrelevant information and allocate attention to the relevant on information (Kruschke, 2001; Mackintosh, 1975), trying to attend to multiple correlated information (i.e. dense categories) could be harder than attending to a few.

In the current study, we examined the effects of category structure on selective attention in the course of category learning. In all experiments, a supervised category learning task was used while the participants' eye movements were recorded. Moreover, cost of attention and attention optimization were observed to infer the attentional mechanism in category learning.

Figure 1. Description of the stimuli structure and experimental design. (a) stimuli used in Experiment 1 sparse category, (b) experimental design of Experiment1, and (c) stimuli used in Experiment 2 - dense category (note that ' R ' represents the location of the relevant dimension in each exemplar which was not visible to the participants)

\section*{Experiment 1}

Experiment 1 examined the cost of attention when an extradimensional shift occurred between two sparse categories with supervision. As shown in previous studies, extradimensional shift maximizes cost of attention, therefore making it easy to observe the attentional dynamics during category learning (Hall, 1991; Hoffman \& Rehder, 2010).

\section*{Methods}

Participants Thirty-three adults with normal or corrected to normal vision participated in the experiment for course credit. An additional 8 participants were excluded from the analysis due to not exceeding the learning criterion (see Procedure).
Stimuli Flower-like artificial categories were used in the experiment (see Figure 1a). Each exemplar had a gray hexagon in the middle with six colored shapes on every side. Among the six colored shapes, five changed their color/shape in a binary fashion, whereas one was constant, serving as a category relevant dimension. Therefore, there were 32 unique stimuli for each category with two categories having the relevant feature on the right-bottom side of the hexagon (i.e., category A: purple triangle, category B : blue semi-circle) and two categories having the relevant feature on the left side of the hexagon (i.e., category C: yellow pentagon, category D : orange square). Therefore, the relationship between A or B and C or D was an extra-dimensional shift.
Procedure The experiment had 2 phases and in each phase there were 4 blocks. Within each block there were 8 learning trails followed by 4 test trials. After the first 4 blocks (Phase 1), unknown to the participants, the category had an extra-dimensional shift (see Figure 1b). Therefore if the first half of the blocks were presented with category A, the second half of the blocks were presented with category \(C\) in the learning trials. In the learning trials, exemplars were presented for 1.5 seconds, one at a time in the middle of the screen. At the beginning of each block, participants were told that they would see flowers that have one common feature they had to find, which served as a supervision signal.

In the test trials two category exemplars were presented side by side until the participant made a response. One exemplar was a novel exemplar from the category that was used in the learning trials. The other exemplar was a new category where the relevant feature was in the same dimension as the learned category but had a different feature (e.g. Cat A and Cat B in Figure 1a). Participants were told to choose the exemplar that they thought was a member of the category they saw in the learning trials by pressing a left or right response button. When the response was made, the stimuli disappear without any feedback. Also before each learning and test trial, a fixation point (i.e. red cross) was presented on a random-dot background, and the participants were told to look at the fixation to proceed with the experiment. Moreover, a Tobii T60 eye tracker was used to
collect eye gaze with the sampling rate of 60 Hz during the whole experiment.

\section*{Results}

Before analyzing the data, participants who did not learn the first category were excluded. To be considered as a learner one had to have 3 correct responses out of 4 test trials in the last block of Phase 1 (i.e. block 4). To determine whether a cost was incurred, accuracy, reaction time, and eye gaze data were analyzed by block. Especially by comparing the blocks before and after the unknown category switch (i.e. block 4 vs. block 5).

The overall accuracy for the test blocks was \(.90, S D=.21\) (Phase 1: \(M=.92, S D=.18\), Phase 2: \(M=.87, S D=.23\) ), with all test trials being significantly higher than chance performance, \(p<.001\) (see Figure 2a). Results of a \(2 \times 4\) (Phase \(\times\) Block) within-subjects ANOVA conducted on accuracy scores at test showed a main effect for Block, \(F(2.3,73.61)=8.14, p<.001\), indicating that accuracy differed by block, but there was no significant main effect for Phase or a interactions ( \(p s>.05\) ). Moreover, a significant cost of attention was demonstrated between the last block of learning phase 1 (block 4) and the first block of learning phase 2 (block 5) by a significant decrease in accuracy from block 4 to block \(5, t(32)=5.07, p<.001\).

Before analyzing the reaction time (RT), all incorrect responses were excluded, and for each individual the median RT for each block were used in the analysis. The mean reaction time for all test blocks was \(1160 \mathrm{~ms}, S D=\) 892 ms (Phase 1: \(M=1199 \mathrm{~ms}, S D=922 \mathrm{~ms}\), Phase 2: \(M=\) \(1121 \mathrm{~ms}, S D=863 \mathrm{~ms}\) ) (see Figure 2b). A \(2 \times 4\) (Phase \(\times\) Block) within-subjects ANOVA conducted on RT showed a main effect for Block, \(F(1.77,54.91)=9.58, p<.001\), but there was no significant main effect for Phase or a interaction ( \(p s>.05\) ). Statistical difference between block 4 and block 5 were also found, \(t(32)=2.78, p<.005\), demonstrating a cost of attention.

Eye gaze data were also analyzed for each block by calculating the weighted proportion of looking to the relevant spatial dimension. This value was calculated by taking looking time (fixation) to the relevant features divided by looking time (fixation) to the irrelevant and relevant features combined. However, since there was greater spatial area for irrelevant features ( 5 shapes) than the relevant features ( 1 shape), looking time to the relevant features was multiplied by five to equate the spatial area. Therefore, .50 in the analysis represents an equal amount of looking to the relevant and irrelevant features at a given block. Fixations were calculated by using an I-DT algorithm with a minimum duration threshold of 100 ms and a dispersion threshold of \(1^{\circ}\) of visual angle (Salvucci \& Goldberg, 2000).

The overall weighted proportion of looking to the relevant dimension was for all test blocks was \(.63, S D=.30\) (Phase 1: \(M=.63, S D=.30\), Phase 2: \(M=.64, S D=.31\) ). All blocks except the first blocks in each phase (i.e. block1 and block 5) showed a significantly higher proportion of looking
to the relevant spatial dimension (paired t -test, \(p s<.05\) ). A \(2 \times 4\) (Phase \(\times\) Block) within-subjects ANOVA only showed a main effect for Block, \(F(2.68,80.37)=5.59, p\) <.001. Moreover, a marginal drop was demonstrated after block 4, which indicated a cost of attention, \(t(30)=1.83, p\) \(=.07\) (see Figure 2c).
In sum, both behavioral and eye gaze patterns indicated a cost of attention for participants who learned the first category. Both phases showed an evidence of attention optimization (i.e. increased accuracy, decreased RT, and increased looking time to the relevant dimension). The indication of attention optimization followed by a cost of attention was evident even though supervision was not provided as strong as in previous studies. (Note that explicit feedback was given after every trial in Hoffman \& Rehder (2010)).
(a) Accuracy at Test

(b) Reaction time at Test

(c) Looking time during Learning

Figure 2. Results from Experiment 1. (a) accuracy at Test, (b) reaction time at Test, and (c) looking time during Learning. The proportion of looking to the relevant dimension are weighted values in that the dotted line at .5 indicate chance level of equally looking to the relevant and irrelevant dimensions. Note that all error bars represent +/one standard error.

\section*{Experiment 2}

Experiment 2 examined the cost of attention when an extradimensional shift occurred between two dense categories with supervision.

\section*{Methods}

Participants Forty-two adults with normal or corrected to normal vision participated in the experiment. In addition, one participant was excluded from the analysis due to not exceeding the learning criterion.
Stimuli \& Procedure The stimuli and procedure were identical to Experiment 1 except that dense categories were used. In contrast to sparse categories, dense categories had two category-relevant spatial dimensions instead of one (see Figure 1c). For category A and B, in addition to the bottomright relevant dimension, the upper-left location had a constant shape/color as the bottom-right location had. For category C and D , in addition to the left location, the upperright location had a constant shape/color identical as the left location.

\section*{Results}

The overall accuracy for the test blocks was \(.98, S D=.11\) (Phase 1: \(M=.97, S D=.12\), Phase 2: \(M=.98, S D=.11\) ), with all test trials being significantly higher than chance performance, \(p<.001\) (see Figure 3a). A \(2 \times 4\) (Phase \(\times\) Block) within-subjects ANOVA did not show any main effect or interactions ( \(p s>.05\) ). Moreover, there was no significant difference between block 4 and block 5, indicating the absence of cost.

The mean reaction time for all test blocks was 838 ms , \(S D=528 \mathrm{~ms}\) (Phase 1: \(M=860 \mathrm{~ms}, S D=385 \mathrm{~ms}\), Phase 2: \(M=838 \mathrm{~ms}, S D=528 \mathrm{~ms}\) ) (see Figure 3b). A \(2 \times 4\) (Phase \(\times\) Block) within-subjects ANOVA with RT only showed a main effect for Block, \(F(2.26,90.36)=6.86, p<.001\). Also, the difference between block 4 and block 5 was not significant ( \(p>.05\) ).

In a dense category, there were two relevant dimensions and four irrelevant dimensions. Therefore, the weighted proportion of looking to the relevant dimension was calculated by multiplying two to the numerator instead of five as in Experiment 1. The overall weighted proportion for all learning blocks was \(.65, S D=.23\) (Phase 1: \(M=.63, S D\) \(=.23\), Phase 2: \(M=.65, S D=.23\) ). All blocks showed a significantly higher proportion of looking to the relevant spatial dimension, paired t-test, ps \(<.005\) (see Figure 3c). A \(2 \times 4\) (Phase \(\times\) Block) within-subjects ANOVA did not show any main effects or interactions, \(p s>.05\). Also, a significant drop was not found between block 4 and 5, \(p\) \(>.05\).

The results show no evidence of cost for the looking time data. Also there was no evidence of attention optimization (i.e. increased looking to the relevant dimension). However the accuracy is very high compared to the sparse condition, indicating that learning the dense category was easier than learning sparse category. Therefore it is possible that attention optimization occurred quickly, and the cost of attention was weak early in the block.

Figure 3. Results from Experiment 2. (a) accuracy at Test, (b) reaction time at Test, and (c) looking time during Learning. The proportion of looking to the relevant dimension are weighted values in that the dotted line at .5 indicate chance level of equally looking to the relevant and irrelevant dimensions. Note that all error bars represent +/one standard error.

To capture the early attention optimization in block 1 a moving window of 3 trials were used to calculate the proportion of looking to the relevant dimension, instead of using the whole block. Then a one-sample t-test was conducted against the chance level of .5. Results show that attention optimization occurred around the window 3, which would be around the \(4^{\text {th }}\) trial and lasted throughout the block (see Figure 4a). The same method could be applied to Block 5 where the second category was introduced. Results show that attention optimization occurred around the window 3, which would be around the \(4^{\text {th }}\) trial (see Figure 4b).

On the other hand, the cost of attention could be captured by comparing the last trial of block 4 and the first trial of block 5 instead of comparing the whole block. Results showed marginally significant drop from the last trial of block 4 ( \(M=.59, S D=.44\) ) to the first trial of block 5 ( \(M\) \(=.43, S D=.36), p=.068\), indicating a cost of attention.

In sum, dense categories were learned quicker than the sparse categories (faster attention optimization), and the cost of selective attention was weaker.

Figure 4. Attention optimization of block 1, block 5 in Experiment 2. Note that the asterisks represent \(p<.05\), and all error bars represent \(+/\) one standard error.

Then what would have made dense categories have lesser cost and stronger attention optimization? One possibility is that since dense categories have multiple category-relevant dimensions, attention allocation is much more distributed than sparse categories. Therefore, with limited amount of attention there will be smaller attention allocated to a dimension in the dense categories than in the sparse categories (Sutherland \& Mackintosh, 1971), which would lead to an easier/faster attention shift to a newly relevant dimension. On the other hand, it could also be possible because dense categories have more category-relevant dimensions, and thus there is a higher probability of spotting a relevant dimension. In this case, one could perfectly learn the dense categories with attending only one dimension instead of both.

Figure 5. The distribution of looking time between the two category-relevant dimensions in Experiment 2. Values closer to 0 indicate looking equally to the two relevant dimensions, whereas values closer to 1 indicate looking to only one dimension in a trial.
To investigate the latter possibility, the distribution of looking time between the two relevant dimensions was calculated. For each trial, the proportion of looking to one of the dimensions was calculated, where .5 represents equal looking to both dimensions. Then the absolute difference from . 5 was taken. Therefore, the value close to . 5
represents looking to only one dimension, and 0 represents looking to both dimension. Figure 5 shows the calculated values across subjects by block. Results indicate that subjects relied on a single dimension in most of the trials when learning the dense categories.

\section*{General Discussion}

The current study manipulated category density in the course of supervised category learning. Results show that even though supervision was weaker than in previous studies using sparse categories, attention optimization and cost of attention were observed during category learning (Experiment 1). Moreover, the dense categories were learned faster than sparse categories, and even with a stronger attention optimization, dense categories (Experiment 2) had a weaker cost of attention.

In Experiment 1, sparse categories were learned with weaker supervision than in previous studies using similar sparse categories. Note that when the sparse categories used in the current experiment were presented without supervision, participants failed to learn them (Yim, Best, \& Sloutsky, 2011). Supervision in the current experiment consisted of a hint that there is one dimension that is consistently relevant. However, the majority of participants learned the category. Also compared to previous studies where feedback was given on every trial (Hoffman \& Rehder, 2010; Rehder \& Hoffman, 2005), supervision here was only given at the start of each block. However, attention optimization and cost of attention were observed.

First, attention optimization should be closely related to the specific supervision signal. Category learning has mainly assumed that error signals from feedback mediates selective attention (Blair, Watson, \& Meier, 2009; Kruschke, 2001). However, the current task does not provide any feedback. A possible explanation would be that the supervision helps reduce the hypothesis space for the participants. Although knowing that there will be only one relevant dimension does not provide direct error signal, it drastically reduces the hypothesis space of possible category-relevant information. Although the effects of supervised and unsupervised learning on category formation has been discussed (Gureckis \& Love, 2003; Love, 2002), the effects of various kinds of supervision has not been investigated systematically, which should be examined in future research.

Second, although it is known that attention optimization is a precursor of cost of attention, it is possible that the greater cost in the current study originates from the difference of density between the current and previous research. The stimuli in Hoffman \& Rehder (2010) had 2 out of 3 irrelevant dimensions whereas the current study has 5 out of 6 irrelevant dimensions. The sparser the category is the harder it would be to learn the relevant dimension. However, once selective attention is engaged, the cost would be greater for sparser categories. This is because there are more irrelevant dimensions in a sparser category, which means that there will be more unattended dimensions
during learning (i.e. learned inattention). Therefore, when an extra-dimensional shift occurs, the probability of figuring out a newly relevant dimension among the previously irrelevant dimensions will be lower than in a less sparse category. Although it is not possible to directly examine this hypothesis from the current study, the relationship between category density and cost of attention could be examined with controlling the amount of attention optimization through manipulating the number of irrelevant dimensions.

In Experiment 2, most of the participants optimized to one dimension instead of distributing their attention to all relevant dimensions (see Figure 5). Although the categories used in the current study are deterministic and do not require an information integration process (Ashby, AlfonsoReese, Turken, \& Waldron, 1998), there is evidence that adults distribute their attention to all relevant dimensions when learning dense categories that had a similar category structure as the current one (Kloos \& Sloutsky, 2008). One main difference between the previous study and the current study is the presentation time during learning. In Kloos \& Sloutsky (2008), participants observed the category exemplars in a self-paced maner, whereas the current study presented the exemplars for 1.5 sec . Since the category could be learned by using both distributed and non-distrubuted attention, it is highly possible that the fast presentation time leaded the participants to attend to only one dimesion.

Finally, the results may have implications for understanding the development of category learning. Since it is known that children gradually gain the ability to selectively attend (Hanania \& Smith, 2010), it would be hard for them to learn sparse categories, which requires the ability to selectively attend to a small number of categoryrelevant dimensions. Therefore, the role of supervision would be crucial for learning spare categories early in development. If the interaction among the category structure, learning regime, and category learning is well established, it would help to understand the developmental trajectory of category learning.

\title{
Do walking pedestrians stabily interact inside a large group? Analysis of group and sub-group spatial structure
}

\begin{abstract}
We combine video recording and laser range tracking to analyse the geometrical structure of groups of walking pedestrians socially interacting. By recording their relative position and observing their social interaction for a large enough time span we can analyse the stability and universality of their spatial structure. We find that while 2-pedestrian and 3-pedestrian groups have a relatively "time stable" and "universal" geometrical structure (an abreast formation for pairs, and a "V" formation for triads, with the central pedestrian walking slightly behind), no such structure emerges for larger groups. Nevertheless, these larger groups result to be composed of time stable two or three people sub-groups with the same "universal" geometrical structure of isolated pairs and triads.
\end{abstract}

Keywords: Group dynamics; proxemics.

\section*{Introduction}

The spatial relationship of socially interacting people, i.e proxemics, has been largely studied, starting from the seminal works of (Hall, 1969) and (Kendon, 1990) in which the distances between and spatial distribution of people participating in social activities have been investigated. At the same time other researchers have investigated the size of social groups (by size of a group we mean the number of its components) and the probability distribution of these sizes (James, 1953; Coleman \& James, 1961). Many of the aforementioned studies are based on "ecological" observations, i.e. studies in which people are observed in their natural environment while reducing as much as possible the effect of observations on their behaviour. While these studies are obviously based on observations of people behaviour in public spaces, until recently they did not focus on one of the main components of public spaces population (at least in modern urban areas), i.e. walking pedestrians. Here by pedestrian we mean a person in a public space moving between two locations for practical or recreational purposes, or even "wandering around" an environment without any particular goal. Pedestrians are often part of social groups with a specific proxemics determined by their dynamical constraints (the fact that they are walking), but the study of these groups has been traditionally made difficult by the fact that they are moving and located inside a crowd, which makes the observation of their behaviour more troublesome. Nevertheless, lately a few works have focused on the behaviour of these groups (Moussaïd, Perozo, Garnier, Helbing, \& Theraulaz, 2010; Costa, 2010), due also to the growing interest in crowd behaviour of which groups are a non negligible component (Aveni, 1977). This interest is due
to the necessity of simulating crowd behaviour to design better pedestrian facilities (Helbing, Farkas, Molnar, \& Vicsek, 2002), but also to reproduce faithfully the behaviour of virtual crowds for the entertainment industry (Karamouzas \& Overmars, 2012).
While (Moussaïd et al., 2010) report that the spatial structure of a freely walking (i.e. not environmentally constrained) \(n\) pedestrian group is a line of abreast walking pedestrians, that tends to be bent into "V" or "U" formations (i.e., the pedestrians on the sides walk ahead) when the crowd density grows, (Costa, 2010) reports different spatial structures, suggesting for example that the " V " structure is the most occurring one for three people groups (regardless of crowding), and that larger groups tend to split into smaller sub-groups. Nevertheless (Costa, 2010) does not analyse the possible effects of environmental constraints on observed behaviours (the width of the sidewalks pedestrians were observed in was comparable to the group spatial sizes), and does not provide a quantitative study of 2D space structures, nor follows groups for a time interval long enough to analyse their change in time.
The difference between these observations leads us to two related problems in walking group proxemics, to which we try to bring insight in this work:
- Do n-pedestrian groups (i.e. groups composed of \(n\) members) have a prevalent geometrical structure? Here by prevalent we mean universal (common to almost all groups, or at least present in a large majority of them) and time stable (i.e. the positions of pedestrians in an unconstrained group will be given by small oscillations around those of the prevalent structure).
- If such an overall structure does not exist for a \(n\)-pedestrian group, is it possible to find it at the sub-group level?

In order to analyse these issues, we have to observe pedestrians in a situation in which collision avoiding and environmental constraints are not very strong (otherwise it would be impossible to identify the "universal" structure). Furthermore, we have to combine the need to measure with good detail (and for long enough time) the position of pedestrians, with that of observing their social interactions, in order to analyse the group structure. If a large pedestrian group is divided into smaller sub-groups we may expect social interaction inside sub-groups to be more frequent than between different sub-groups, and for this reason in many cases the
belonging of sub-groups to a larger group structure may be determined only if the observation is long enough. To attain this goal we combine a laser range finder tracking technology, that allows us to determine with good precision the position and velocity of each pedestrian in a large public environment, with frontal view (face level) video recordings, that allow us to analyse their social interactions (Fig. 1). As a result, we can follow pedestrian groups for a relatively long time while examining both their social and spatial interactions from a (respectively) qualitative and quantitative point of view. We performed these observations in a large area completely dedicated to pedestrian motion, and in a location and time in which the pedestrian density was relatively low, in order to be able to observe the behaviour of "unconstrained" groups.

Figure 1: Video camera frame of the experimental area. A sensor pole is visible in the bottom-right corner.

\section*{Methodology and definitions}

\section*{Data collection}

We tracked pedestrian motion in two areas of a pedestrian underground facility in Umeda, Osaka (Japan), for a total time of 6 hours in each area. The pedestrian areas consist of a few corridors connecting a railway station to a shopping mall, each area being around \(500 \mathrm{~m}^{2}\). The environments are described in detail in (Zanlungo, Chigodo, Ikeda, \& Kanda, 2012; Zanlungo, Ikeda, \& Kanda, 2012), and the pedestrian tracking data are available at (Zanlungo, 2012). The average pedestrian density in the environment resulted to be \(\approx 0.03\) pedestrians per square meters while the width of the corridors varied between 4 and 7 meters, meaning that the average distance from a pedestrian to another pedestrian outside their group, or to a wall, is expected to be larger than the spatial size of the group (for example a group of 4 people walking in an abreast formation, assuming an interacting distance of 1 meter between first neighbours, should be 3 meters wide, compared to an expected distance between pedestrians \(>5\) meters at such a density). We can thus assume pedestrians to be fairly "unconstrained" by the environment and freely walk in their preferred spatial formation for most of the time.
We used 16 Hokuyo UTM sensors (situated on poles close to the environment walls not to hinder pedestrian motion, Fig. 1) and the tracking algorithm (Glas, Miyashita, Ishiguro, \& Hagita, 2009) to determine pedestrian positions at times intervals \(\delta t \approx 50 \mathrm{~ms}\) with precision \(\approx 50 \mathrm{~mm}\). We smoothed the tracked positions on time windows \(\Delta t=500 \mathrm{~ms}\), to fur-
ther improve the tracking precision. Pedestrian velocity is computed as the ratio of the displacement vector between two (smoothed) consecutive tracking positions (eq. 2), and has an expected precision \(\approx 50-100 \mathrm{~mm} / \mathrm{s}\). As we will see (see also the discussion in (Zanlungo, Chigodo, et al., 2012)) this tracking precision is negligible with respect to the typical interaction distances and velocities of pedestrians.
We also video recorded each experimental area with two different "frontal view" cameras (Fig. 1), located in such a way to allow observing the social interaction between the pedestrians for a sufficient long time (pedestrians are usually tracked and observed for a time of the order of tens of seconds). This camera based observation of social interaction was possible because the cameras are not needed for tracking and the density was relatively low. A "coder" (a non-technical staff member of our laboratory), was asked to identify all the pedestrian social groups in the environment and their members. In order to do that, she was asked to use all the information available from the videos, such as relative position, coherent motion, and social clues including conversation, gaze exchange and even age, sex and clothing (for example she identified a relatively large flock of coherent moving people as a single group because they were all dressed for and carrying similar hiking equipment). She was asked to identify only groups of which she could establish the nature without any reasonable doubt (i.e. she was asked to strongly avoid false positives, while false negatives were allowed). Furthermore, the coder was asked to annotate the groups, and the individuals in each group, for which she could without any doubt identify explicit social interaction clues (namely conversation, or explicit gaze exchange). Table 1 shows the number and size of labelled groups, distinguishing between "fully connected" groups (FCG) for which she could observe explicit social interaction between all the members, and "disconnected" groups (DG) that seemed to be related on the basis of other visual clues but for which explicit interaction could not be observed (or was observed only in smaller subgroups). To avoid false positives, only FCG are analysed in this paper. (The coder identified also six 5-pedestrian groups, six 6-pedestrian groups, one 7-pedestrian group and one 18pedestrian group, not analysed in this work due to the small size of the samples).
\begin{tabular}{|c|c|c|c|}
\hline Size & \(n=2\) & \(n=3\) & \(n=4\) \\
\hline FCG & 1126 & 114 & 17 \\
\hline DG & 91 & 34 & 14 \\
\hline
\end{tabular}

Table 1: Observed fully connected (FDG) and disconnected groups (DG) for each group size \(n\).

\section*{Definitions}

In order to identify the existence of an "universal" structure in a pedestrian group, it is necessary to study it in the correct reference frame. The most natural candidate is the group's
"centre of mass frame" (see Fig. 2). Let us call
\[
\begin{equation*}
\mathbf{x}^{e}\left(t_{k}\right)=\left(x^{e}\left(t_{k}\right), y^{e}\left(t_{k}\right)\right) \quad t_{k}=k \Delta t \tag{1}
\end{equation*}
\]
the position of a pedestrian in the "environment" reference frame, smoothed on regular \(\Delta t=500 \mathrm{~ms}\) time windows, and
\[
\begin{equation*}
\mathbf{v}^{e}\left(t_{k}\right) \equiv \frac{\mathbf{x}^{e}\left(t_{k+1}\right)-\mathbf{x}^{e}\left(t_{k}\right)}{\Delta t} \tag{2}
\end{equation*}
\]
the corresponding pedestrian velocity. Let us consider a \(n\) pedestrian (from now on \(n\)-p) (sub-)group with position and velocities
\[
\left\{\mathbf{x}_{i}^{e}\left(t_{k}\right), \mathbf{v}_{i}^{e}\left(t_{k}\right)\right\} \quad i=1, \ldots, n,
\]
and define the group "centre of mass" position and velocity
\[
\begin{equation*}
\mathbf{X}\left(t_{k}\right)=\frac{\sum_{i} \mathbf{x}_{i}^{e}\left(t_{k}\right)}{n} \quad \mathbf{V}\left(t_{k}\right)=\frac{\sum_{i} \mathbf{v}_{i}^{e}\left(t_{k}\right)}{n} \tag{3}
\end{equation*}
\]

Let us name GCMF the group centre of mass frame (at time \(\left.t_{k}\right)\) with origin in \(\mathbf{X}\left(t_{k}\right)\) and the \(y\) axis aligned to \(\mathbf{V}\left(t_{k}\right)\), i.e. with axis versors
\[
\begin{equation*}
\hat{\mathbf{e}}_{x}\left(t_{k}\right)=\left(\frac{V_{y}\left(t_{k}\right)}{V\left(t_{k}\right)},-\frac{V_{x}\left(t_{k}\right)}{V\left(t_{k}\right)}\right) \quad \hat{\mathbf{e}}_{y}\left(t_{k}\right)=\frac{\mathbf{V}\left(t_{k}\right)}{V\left(t_{k}\right)} \tag{4}
\end{equation*}
\]
(from now on we remove \(t\) from notation for simplicity's sake). The position of pedestrian \(i\) in the GCMF is then \(\mathbf{x}_{i}=\left(x_{i}, y_{i}\right)\) with
\[
\begin{equation*}
x_{i}=\left(\mathbf{x}_{i}^{e}-\mathbf{X}\right) \cdot \hat{\mathbf{e}}_{x} \quad y_{i}=\left(\mathbf{x}_{i}^{e}-\mathbf{X}\right) \cdot \hat{\mathbf{e}}_{y} \tag{5}
\end{equation*}
\]

We also define the polar coordinates \(\left(r_{i}, \theta_{i}\right)\) through
\[
\begin{equation*}
x_{i}=r_{i} \sin \theta_{i} \quad y_{i}=r_{i} \cos \theta_{i} \tag{6}
\end{equation*}
\]
where \(r=\sqrt{x^{2}+y^{2}}\) represents the distance of the pedestrian from the centre of mass (for 2-p groups \(2 r\) is the distance between pedestrians). Fig. 2 illustrates the previously defined quantities in the 2-p case, for which the following holds
\[
\begin{equation*}
r_{2}=r_{1}, \quad x_{2}=-x_{1}, \quad y_{2}=-y_{1}, \quad \theta_{2}=\pi+\theta_{1} \tag{7}
\end{equation*}
\]

It is important to quantitatively study the structure of the

Figure 2: GCMF variables definition.
group in the GCMF, because the distinctive feature of walking groups is the presence of a centre of attention, namely the
direction towards their current sub-goal, which is identified by the velocity of the group. The geometrical structure of the pedestrian groups is determined by the necessity to maintain the focus on the walking direction, and for this reason we will not consider non-moving pedestrian groups (i.e., data points in which at least a group member has \(v_{i}\left(t_{k}\right)<500 \mathrm{~ms}\), a threshold that corresponds to a velocity 3 standard deviations smaller than the typical pedestrian velocity (Daamen \& Hoogendoorn, 2006); see also (Zanlungo, Chigodo, et al., 2012) for a discussion of this threshold). Since we collected data in a passing point between a station and a shopping centre without attraction points (Zanlungo, Chigodo, et al., 2012), only \(\approx 5 \%\) of data are not considered.

It is clear that if a universal and time stable n-p formation exists, then at (almost) all times and for (almost) all groups, the GCMF pedestrian positions should be close to those determined by such a structure. We will compute the empirical 2D probability distribution function (pdf) \(\rho(x, y)\) for each \(n\) averaging on all groups, pedestrians \(i\) and and times \(t_{k}\), and state that such a universal and stable formation exists only if \(\rho(x, y)\) has \(n\) well defined maxima. The formation will be then empirically determined by the position of these maxima.

\section*{Results}

\section*{Whole group GCMF structure for n-p groups}

Fig. 3 shows the pedestrian pdf \(\rho(x, y)\) for \(2-\mathrm{p}, 3-\mathrm{p}\) and \(4-\mathrm{p}\) groups. The 2-p and 3-p groups have a well defined geometrical structure in the GCMF, i.e. their \(\rho\) has, respectively, 2 and 3 well defined maxima, one for each pedestrian. Such a structure is not present for 4-p groups, whose pdf has many local maxima. As we will see, a well defined structure emerges for 4-p only after the whole group is properly divided in two 2-p sub-groups.

\section*{2-p groups}

Let us identify the leftmost \((x<0)\) pedestrian as \(P_{1}\) and the rightmost one as \(P_{2}\). Figs. \(4 \mathbf{a}\) ) and \(4 \mathbf{b}\) ) respectively show the \(\rho\left(r_{1}\right)\) and \(\rho\left(\theta_{1}\right)\) pdfs, while Table 2 shows the average values and standard deviations of all variables. While \(\rho\left(y_{1}\right)\) and \(\rho\left(\theta_{1}\right)\) are well described by a Normal distribution (i.e. a von Mises (Mardia \& Jupp, 2009) one for the circular variable \(\theta\) ), \(\rho\left(x_{1}\right)\) and \(\rho\left(r_{1}\right)\) are not, and for this reason we report also the (approximate) value of their maxima. Our data
\begin{tabular}{|c|c|c|c|c|}
\hline & \(\rho\left(x_{1}\right)\) & \(\rho\left(y_{1}\right)\) & \(\rho\left(r_{1}\right)\) & \(\rho\left(\theta_{1}\right)\) \\
\hline\(<>\) & -387 & -2 & 417 & -89 \\
\hline\(\sigma\) & 87 & 166 & 105 & 17 \\
\hline \(\max\) & -360 & 0 & 365 & -90 \\
\hline
\end{tabular}

Table 2: Average values \((<>)\), standard deviations ( \(\sigma\) ) and maxima for the \(\rho\left(x_{1}\right), \rho\left(y_{1}\right), \rho\left(r_{1}\right)\) and \(\rho\left(\theta_{1}\right)\) pdfs (linear variables in mm , circular in degrees).
show that 2-p groups walk abreast at a distance smaller than twice the average shoulder width (Pheasant, 1986). Such a

Figure 3: \(\rho(x, y)\) for 2-p, 3-p and 4-p groups (respectively, from the left). Blue corresponds to maximum density, red to minimum density (colour bar on the right). Each figure covers a \(2 \times 2\) meters area.
configuration is determined by the need of maintaining both partners in each other's field of view (or better at the border of it) while keeping the main attention focus on the walking direction. By walking abreast the partner is reachable for gaze exchange and conversation through a torsion of the neck (pedestrians can go on walking towards their goal with no gait modification) while the distance allows for conversation without collision or excessive proximity. This configuration is the most comfortable one for walking and interacting socially, but it cannot be extended to larger groups, because in a \(n>2\) abreast configuration the position of first neighbours would hinder gaze contact and conversation with second or larger neighbours. As clear from Fig. 3 and discussed below, this affects larger group configurations.

\section*{3-p groups}

Let us name the pedestrians \(P_{1}, P_{2}\) and \(P_{3}\) starting from the leftmost to the rightmost ( \(x_{1}<x_{2}<x_{3}\) ). It is easier to understand the relation between 2-p and 3-p group structures if we analyse the 3-p variables in all possible 2-p sub-group GCMFs. A variable with subscript \(i j\) will denote the position of \(P_{i}\) in the \(\left(P_{i}, P_{j}\right)\) GCMF. In this way, for example, \(2 r_{12}\) is the relative distance between the leftmost pedestrian and the central one (first neighbours), and so on for each variable and pedestrian pair \(i, j\) with \(i<j\) (the \(i>j\) case can be obtained through eq. 7). Tables 3 and 4 report the values of all such variables, while Fig. 5 a) compares the \(\rho\left(r_{12}\right)\) and \(\rho\left(r_{13}\right)\) pdfs to the \(\rho\left(r_{1}\right)\) distribution of the 2-p case. The same comparison is performed for \(\theta\) in Fig. 5 b ).
The first neighbour distance distributions \(\rho\left(r_{12}\right), \rho\left(r_{23}\right)\) are
\begin{tabular}{|c|c|c|c|c|c|c|}
\hline & \(\rho\left(r_{12}\right)\) & \(\rho\left(r_{13}\right)\) & \(\rho\left(r_{23}\right)\) & \(\rho\left(\theta_{12}\right)\) & \(\rho\left(\theta_{13}\right)\) & \(\rho\left(\theta_{23}\right)\) \\
\hline\(<>\) & 437 & 738 & 441 & -74 & -89 & -105 \\
\hline\(\sigma\) & 125 & 132 & 169 & 23 & 15 & 25 \\
\hline \(\max\) & 365 & 700 & 365 & -80 & -90 & -110 \\
\hline
\end{tabular}

Figure 4: a): 2-p pdf for \(r_{1}\). b): 2-p pdf for \(\theta_{1}\), compared to a best fit von Mises distribution.

Figure 5: a): \(\rho\left(r_{12}\right)\) distribution (blue) compared to the \(\rho\left(r_{13}\right)\) distribution in green and to the 2-p \(\rho\left(r_{1}\right)\) distribution in orange. b): \(\rho\left(\theta_{12}\right)\) distribution (blue) compared to the \(\rho\left(\theta_{13}\right)\) distribution in green and to the 2-p \(\rho\left(\theta_{1}\right)\) distribution in orange.
resented by a Normal one. Defining \(\bar{r}\) as the value \(r\) for which \(\rho(r)\) is maximum, we see that \(\bar{r}_{13} \approx 2 \bar{r}_{12} \approx 2 \bar{r}_{23} \approx 2 \bar{r}_{1}\), i.e. 3-p groups members try to maintain between them the same distances that occur between 2-p groups members, which we interpret as a strong sign of social interaction involving all
three members. The similarity between the \(\rho\left(\theta_{13}\right)\) and the (2-p) \(\rho\left(\theta_{1}\right)\) distributions is particularly striking, suggesting direct social interaction between \(P_{1}\) and \(P_{3}\). This interaction would hardly be possible if we had the same angle distribution for \(\theta_{12}\) and \(\theta_{23}\), because the central pedestrian would hinder the communication. As a result, the central pedestrian steps slightly back (so that their partners remain in the vision field), and the angle between the three of them is, in average, \(\approx 150\) degrees. This "V" configuration had already been reported as the most often occurring one for walking triads (Costa, 2010). (Moussaïd et al., 2010) explain this configuration as the effect of a trade-off between easiness of communication and collision avoiding efficiency, assuming that the free-walking triads walk abreast. On the basis of our data, that as we already stated should not be strongly influenced by environmental constraints, we suggest that the "V" configuration is attained for maximum easiness of communication between the three partners, and occurs even for freely walking pedestrians.

\section*{4-p groups}
(Moussaïd et al., 2010) report that freely walking 4-p groups assume an abreast configuration, that tends to bend in a "U" one with growing pedestrian density, in order to avoid collisions. According to this abreast hypothesis, we should see four clear maxima in a row in Fig. 3 on the right. Furthermore, if we name the pedestrians \(P_{1}, \ldots, P_{4}\) with \(x_{1}<x_{2}<\) \(x_{3}<x_{4}\) in the GCMF, the first neighbour variable distributions, such as
\[
\begin{equation*}
\rho_{f n}(\theta)=\left(\rho\left(\theta_{12}\right)+\rho\left(\theta_{23}\right)+\rho\left(\theta_{34}\right)\right) / 3 \tag{8}
\end{equation*}
\]
and the analogously defined \(\rho_{f n}(r), \rho_{f n}(x)\) and \(\rho_{f n}(y)\), should resemble the 2-p group distributions. This hypothesis is clearly not supported by our data (Figs. 6, \(7 \mathbf{b}\) )). On the opposite, (Costa, 2010) reports different geometrical structures for 4-p groups, but none of these seems prevalent in our data (no clear maxima in Fig. 3 right).
We may then use a different sub-group hypothesis, assuming that the 4-p group may be divided in two sub-groups of 2 pedestrians, with "strong interaction" inside the sub-group and weaker interaction outside it. According to this hypothesis, we may find a universal and time stable structure only at the sub-group level. Let us rename the pedestrians in the following way. We name \(P_{1}\) the pedestrian with the minimum \(x\) value in the 4-p GCMF, and compute the point
\[
\begin{equation*}
\mathbf{p}_{2}=\mathbf{x}_{1}+r_{\text {int }} \hat{\mathbf{e}}_{x} \tag{9}
\end{equation*}
\]
where \(r_{\text {int }}=730 \mathrm{~mm}\) is the maximum for the pdf of distances for 2-p groups (i.e. twice the GCMF \(r\) value reported in Table 2). We then name \(P_{2}\) the pedestrian whose euclidean distance to \(\mathbf{p}_{2}\) is minimum, and \(P_{3}\) and \(P_{4}\) the remaining two. Let us finally name \(\rho_{s g}(r), \rho_{s g}(x), \rho_{s g}(y)\) and \(\rho_{s g}(\theta)\) the pdfs for the corresponding variables when averaged over all subgroups, as in
\[
\begin{equation*}
\rho_{s g}(r)=\left(\rho\left(r_{12}\right)+\rho\left(r_{34}\right)\right) / 2 \tag{10}
\end{equation*}
\]

The average values and standard deviations for these distributions are shown in Table 5, while Fig. 6 shows the \(\rho_{s g}(x, y)\) 2D pdf, presenting two clear maxima. Fig. 7 a) shows the comparison between the pdf \(\rho_{s g}(r)\) with the (2-p) \(r_{1}\) distribution. Fig. 7 b) performs the same comparison for \(\theta\) variables, including also the \(\rho_{f n}(\theta)\) (abreast hypothesis) distribution. The presence of two clear maxima in \(\rho_{s g}(x, y)\) suggests
\begin{tabular}{|c|c|c|c|c|}
\hline & \(\rho_{s g}(x)\) & \(\rho_{s g}(y)\) & \(\rho_{s g}(r)\) & \(\rho_{s g}(\theta)\) \\
\hline\(<>\) & -403 & -54 & 530 & -97 \\
\hline\(\sigma\) & 180 & 347 & 195 & 33 \\
\hline \(\max\) & -360 & 0 & 370 & -90 \\
\hline
\end{tabular}

Table 5: Average values \((<>)\), standard deviations \((\sigma)\) and maxima of the pdfs \(\rho_{s g}(x), \rho_{s g}(y), \rho_{s g}(r)\) and \(\rho_{s g}(\theta)\) (linear variables in mm , circular in degrees).

Figure 6: \(\rho_{s g}(x, y)\) under the sub-groups hypothesis. The figure covers a \(2 \times 2\) meters area.

Figure 7: a): Comparison between the 2-p pdf for \(\rho\left(r_{1}\right)\) in orange and \(\rho_{s g}\left(r_{1}\right)\) (sub-group hypothesis) in blue. b): Comparison between the 2-p pdf for \(\rho\left(\theta_{1}\right)\) in orange; \(\rho_{f n}(\theta)\) (abreast hypothesis) in red; and \(\rho_{s g}\left(\theta_{1}\right)\) (sub-group hypothe\(s i s)\) in blue.
that a universal and stable structure is indeed present at the sub-group level. The \(\rho_{s g}(r), \rho_{s g}(x), \rho_{s g}(y)\) and \(\rho_{s g}(\theta)\) distributions in a 4-p group result to be a "perturbed version" of the "proper" 2-p variable distributions, the perturbation being determined by the interaction with the members of the other sub-group. We can give different interpretations for the absence of a universal 4-p spatial configuration, that probably act as con-causes. Since the completely abreast configuration results to be uncomfortable even in the 3-p configuration, it
results to be even more problematic for 4 pedestrians. A solution is to, in a way similar to the "V" 3-p configuration, walk in a "U" or in a "staggered" configuration. Another solution would be to walk on two different abreast rows, for example roughly on the corners of a square. While this configuration has the shortcoming that the members on the back are not in the field of view of, nor can be comfortably watched by, the pedestrians on the front, it has the strong point that reduces the maximum distance between members of more than a factor 2 , and it is more efficient in case of collision avoiding or other environmental influences. If we observe particular groups for a short time, as done by (Costa, 2010), we may observe all these occurrences, but, as shown by Fig. 3 (right) none of them is universal and time stable. What is stable (Fig. 6) is the association of pedestrians in pairs. This does not mean that this pairwise association is invariant (i.e. that the pair composition does not change in time) but the data suggest that this association is far more stable than the wholegroup structures. Even though we do not report a quantitative analysis, we qualitatively observed a few 5-p and 6-p groups, and noticed also for these groups the tendency to part in stable 2-p or 3-p sub-groups.

\section*{Conclusions and future work}

Our observations lead us to the conclusion that the dynamical constraints make social interaction between members of walking groups difficult to attain for subgroups larger than two units. For this reason, larger groups have a tendency to form relatively stable 2-p subgroups. Obviously, since odd-p groups cannot be divided in pairs without excluding a pedestrian, for 3-p (sub-)groups we find a configuration almost as stable as the 2-p one.
Regarding the difference between our observations and those of (Moussaïd et al., 2010), we could speculate on cultural and environmental features. Nevertheless we believe that the main difference may be operational, i.e. that our experimental setting using cameras and laser sensors allowed us to identify sub-groups of pedestrians as part of larger groups, even if their interaction was limited in time. On the contrary, observation methods based on shorter time windows may be biased towards large spatial configurations, because they would tend to consider sub-groups as separate entities. For this reason, despite these differences with previous works, and the limited amount of data for large groups, we may speculate that our work is universal in showing that 2-p and 3-p sub-groups are far more stable than larger configurations, with possible effects on the behaviour of crowds.
In our future work we plan to analyse the dynamical features that have been ignored in this work. In detail we want to study: 1) how pedestrians in (sub-)groups behave away from the equilibrium configuration, and 2) the time stability of, and interaction between, sub-groups inside a larger group. Such an analysis should bring further insight on the social dynamics of walking pedestrians and allow us to extend pedestrian group models in such a way to describe the findings of this
work.

\section*{Acknowledgements}

We thank Tetsushi Ikeda for the organisation of the data collection experiments and Kanako Tomita for labelling the social interactions of pedestrians from video recordings. We also thank the anonymous reviewers whose comments helped in improving the quality of our paper.

\begin{abstract}
Employing the dynamical systems framework, we study the effects of intrinsic motivation on the dynamics of the learning processes. The intrinsic motivation here is the one's desire to learn not because it may cause some benefits in future, but due to the inherent joy obtained by the very process of learning. We study a simple example of a single agent adapting to unknown environment; the agent is biased by the desire to select the actions she has little information about. We show that intrinsic motivation may cause the instability of the learning process that is stable in the case of rational agent. Therefore, we suggest that the effects of human intrinsic motivation in particular and the irrationality in general may be of exceptional importance in complex sociopsychological systems and deserve much attention in the formal models of such systems.
\end{abstract}

Keywords: Mathematical modeling; decision making; learning; dynamical systems.

\section*{Introduction}

Mathematical models of learning play great role in a diverse range of fields, with eminent applications found in cognitive science (Daw, O'Doherty, Dayan, Seymour, \& Dolan, 2006; Burke, Tobler, Baddeley, \& Schultz, 2010; Ahn et al., 2012), artificial intelligence (Sutton \& Barto, 1998) and game theory (Fudenberg \& Levine, 1998). The latter traditionally concentrates on the analysis of the Nash equilibria in games played by perfectly rational agents, thereby imposing "heroic assumptions about the knowledge and calculating abilities of the players"(Macy \& Flache, 2002). It is the learning approach to game theory that addresses this issue by focusing on the adaptive behavior of the players. First, it assumes that the agents initially know little about the game context and should gradually explore the game while it is repeated indefinitely many times. Second, players base their actions solely on the previous observations; they learn by trial and error while their ultimate goal is to maximize the cumulative payoff throughout the game.

In the game learning setting it turns out that the players often fail to eventually come up with a certain efficient strategy (either pure or mixed), so their behavior can not be characterized in terms of Nash equilibria. Therefore, the inherent dynamics of learning becomes vital. A growing number of studies develop the theory behind the applications of dynamical systems to learning. Coupled replicator equations were proposed as a framework for describing the adaptive behavior of multiple learning agents interacting via a simple game (Sato, Akiyama, \& Farmer, 2002; Sato \& Crutchfield, 2003; Sato, Akiyama, \& Crutchfield, 2005). Based on this formalism a whole range of agent behavior properties have been modelled, including noisy perception of op-
ponent's strategies (Galla, 2009, 2011) and scale-free memory (Lubashevsky \& Kanemoto, 2010). Virtually all mentioned studies emphasize that the learning process dynamics in game theoretic setting is naturally rich and non-trivial. Even the simplest systems of two agents learning to play rock-paper-scissors game may produce quasiperiodic tori, limit cycles and deterministic chaos (Sato et al., 2002; Sato \& Crutchfield, 2003); the latter is often reported to be a common behavior of dynamical systems describing learning processes (Sato et al., 2005; Lubashevsky \& Kanemoto, 2010; Galla \& Farmer, 2013).

Indeed, the perfect rationality axiom appears unsuitable in a whole class of problems. As one may see, this fact motivated much current research on the development of the learning approach to game theory and corresponding mathematical models of learning. The canonical game theory implies that a player has full information about both the game played and the opponents faced. In contrast, the learning paradigm hypothesizes that most of this information is concealed from the players, who only possess the complete knowledge about the set of available actions and gradually learn the consequences of these actions. Even so, in the vast majority of situations studied within the learning framework so far the agents are practically assumed to be strictly rational. In other words, even learning agents still act selfishly and optimally; their rationality is bounded only in the sense of having less a priori information. Put within the constraints imposed by the learning paradigm, agents now have to learn the appropriate behavior strategy, but their final goal remains ultimately rational to maximize the total payoff throughout the whole process. It means that in the course of learning the agent behavior is driven only by external factors - the actions of other players and the corresponding payoffs observed previously. In the modern dynamical models of learning the agents basically lack any kind of personality, they posess no emotions, desires or personal preferences. Up to now it is completely unknown how the dynamics of the learning would change if the agents are endowed with any kind of individuality. In the present study we face this problem.

One of the most important aspects of learning processes is the intrinsic motivation, which is commonly defined as an inspiration to do something "because it is inherently interesting or enjoyable" (Ryan \& Deci, 2000). In contrast, extrinsic motivation refers to doing something "because it leads to a separable outcome" (Ryan \& Deci, 2000). In relation to learning, an intrinsically motivated person learns something not (or not only) because it will lead her to a tangible reward
or payoff, but for the sake of joy obtained by the learning itself. Such person innately likes the very process of gaining new knowledge. The concept of intrinsic motivation is widely studied in psychology (Deci \& Ryan, 1985; Ryan \& Deci, 2000) and has vital applications in education, as well as in organizational psychology and psychotherapy. Besides, intrinsically motivated reinforcement learning (Oudeyer, Kaplan, \& Hafner, 2007; Oudeyer et al., 2007; Singh, Lewis, Barto, \& Sorg, 2010) is a hot topic in computer science: machine learning algorithms inspired by human cognitive processes demonstrate improved performance in a wide class of tasks. Still, despite the solid theoretical basis of intrinsically motivated learning, the dynamics of such learning processes remains a murky subject. What is the impact of the intrinsic motivation on the outcome of a learning process? Can we expect that intrinsic (and in a certain sense irrational) desire to learn will change the agent behavior substantially? Do the intrinsic motives deserve as close attention as the extrinsic ones?

Employing the dynamical systems framework, we propose a toy model capturing the effects of intrinsic motivation to learn. We study the example of a single agent facing an unknown environment, who is forced to make a repeated choice between two rewarded alternatives. The purpose of the agent is to maximize the total sum of the rewards gained throughout the process; the agent therefore should learn which of the alternatives is better rewarded. The key point of the present study is that the agent is biased: along with collecting the rewards, she also satisfies the internal need to acquire new knowledge. Therefore, the agent behavior is governed by two factors: objective (to gain as much reward as possible) and subjective (to satisfy the internal desire to learn). Our global aim in the present paper is to demonstrate on this simple example how such subjective factors may greatly impact on the dynamics of systems describing human behavior.

\section*{Model}

We construct the continuous-time reinforcement learning model of a single agent adaptation, or learning, under the effect of intrinsic motivation. The discrete-time learning models is the more conventional way to describing the learning processes. However, for purposes of analysis of system dynamics the continuous models are more appropriate. We refrain from discussing the connection between the discretetime and continuous-time reinforcement learning formulation, which is covered in detail in the literature (Sato et al., 2005; Lubashevsky \& Kanemoto, 2010). We only note that the continuous-time process is actually the limit case of the discrete-time learning, when the learning agent repeatedly makes a choice infinitely many times.

In our model the agent interacts with the unknown environment by repeatedly choosing one of the two available actions \(x_{i}, i \in 1,2\) and receiving corresponding reward \(r_{i}\). After each decision, only the action that was actually chosen is being reinforced. In game theory it corresponds to the situ-
ation where the agent is not provided with any information about the foregone payoffs (also known as choice reinforcement (Ho, Camerer, \& Chong, 2007)), in contrast to the conventional weighted fictitious play scheme. The agent accumulates the memories of the obtained rewards, and in such manner builds up an inner myopic model of the outer world. Each time the agent makes a choice she relies on the currently collected information about the quality of both actions, and, at the same time, is affected by her intrinsic motivation to learn, or to obtain new information. We interpret the latter in a sense that the agent inherently likes to select the options that add much new information to her inner model of the world. Therefore, at each instant \(t\) there are three values associated with each option \(x_{i}\) :
1. \(p_{i}\) - the probability of choosing \(x_{i}\) at time \(t\)
2. \(q_{i}\) - the agent memories about the rewards obtained in the past for selecting \(x_{i}\) (objective quality of \(x_{i}\) )
3. \(n_{i}\) - the novelty of the option \(x_{i}\) (subjective quality of \(x_{i}\) )

In order to complete the model, we, first, define how the choice probability \(p_{i}\) depends on \(q_{i}\) and \(n_{i}\). Second, we write the equations describing time evolution of the agent memories about \(x_{i}\) and corresponding values of novelty.

The Boltzmann distribution (sometimes referred to as "softmax" model) fits much experimental data and is commonly used as a model for randomized human choice. We adopt it as a probability of choosing action \(x_{i}\) at time \(t\)
\[
\begin{equation*}
p_{i}(t)=\frac{e^{\beta\left[q_{i}+n_{i}\right]}}{\sum_{j}^{\beta\left[q_{j}+n_{j}\right]}}, \tag{1}
\end{equation*}
\]
where \(q_{i}+n_{i}\) represents the total quality of option \(x_{i}\). Here without loss of generality we assume that objective and subjective factors are equally important for the agent. The constant parameter \(\beta\) defines to what extent the agent choice is randomized ( \(\beta=0\) corresponds to the completely random choice, while \(\beta=\infty\) makes the agent always select the option with the highest total quality).

We describe the evolution of the objective values \(q_{i}, \quad i=\) 1,2 over time by the following differential equations:
\[
\begin{equation*}
\dot{q}_{i}=W\left(q_{i}, q\right) r_{i} p_{i}-\frac{q_{i}}{T_{q}}, \tag{2}
\end{equation*}
\]
where \(p_{i}\) is defined by expression (1), \(r_{i}\) is the reward associated with action \(x_{i}\). Term \(r_{i} p_{i}\) can be regarded as a basic reinforcement, which is subjected to saturation effect. The term \(\frac{q_{i}}{T_{q}}\) stands for the effect of the bounded capacity of the agent's memory. The events in the past separated from the present by the time considerably exceeding \(T_{q}\) practically do not affect the agent's behavior.

The saturation factor \(W\left(q_{i}, q\right)\) is a weighting function depending on \(q=\left(q_{1}, q_{2}\right)\). We chose \(W\left(q_{i}, q\right)\) in such way that it bounds the infinite growth of the objective value function.

In other words, it implements the saturation effect: we tend to underestimate frequent events and overestimate rare ones. We define \(W\left(q_{i}, q\right)\) as logistic function
\[
\begin{equation*}
W\left(q_{i}, q\right)=\frac{1}{1+e^{\frac{q_{i}-\bar{q}}{\gamma}}}, \tag{3}
\end{equation*}
\]
where \(\gamma\) is the saturation coefficient and \(\bar{q}=\frac{q_{1}+q_{2}}{2}\). If the current objective value of \(x_{i}\) is relatively large \(\left(\frac{q_{i}-\bar{q}}{\gamma} \gg 1\right)\), the probability \(p_{i}\) is very high and \(x_{i}\) is selected frequently, so the agent underestimates the reward gained: \(W\left(q_{i}, q\right) \approx 0\). On the opposite, for the rarely selected actions \(p_{i}\) is low (so \(\frac{q_{i}-\bar{q}}{\gamma} \ll 1\) ), and when such actions are chosen the agent pays full attention to their reward: \(W\left(q_{i}, q\right) \approx 1\).

In order to take into account the effect of intrinsic motivation to select the options that brings much information to the agent environment model, we augment system (1-3) with the equations describing time evolution of the novelty values for each option
\[
\begin{equation*}
\dot{n}_{i}=\phi\left(1-p_{i}\right)-\frac{n_{i}}{T_{n}} \tag{4}
\end{equation*}
\]

Here \(\phi\) is the parameter indicating agent's novelty rate that is the same for all of the alternative choices. In analogy to the equation (2) we define the memory capacity coefficient \(T_{n}\) accounting for the characteristic duration of the novelty effect.

Equations (1-4) form the basic model of the agent adaptation under the assumptions stated above. In the rest of the paper we present the preliminary analysis of the results of the numerical experiments aimed at elucidation of the basic properties of the developed model.

\section*{Numerical simulation}

Prior to discussion of the numerical results, we have to underline that the similar system describing the behavior of rational agent have been analyzed previously (Sato et al., 2005). It has been elucidated that the system dynamics in case of rational agent is very simple. Namely, the agent tends to one of the equilibria depending on the system parameters, and the selected equilibria is stable with respect to the perturbations of intial conditions. Therefore, there are very few studies investigating the single agent adaptation problems, due to the absence of any complications of system behavior. We show that introducing intrinsic motivation makes the situation completely different.

Under the assumption of equal rewards \(\left(r_{1}=r_{2}=1\right)\) we numerically simulated the dynamics of system (1-4). We discovered that depending on the values of the system parameters the structure of the system phase space trajectory may take one of two general forms: either the stable equilibrium exists or the system is unstable and has the limit cycle. We have not aimed at analyctically deriving the explicit conditions of the system instability, but the empirical observations indicate that the stable behavior is rather common, while un-

Figure 1: Stable dynamics of the analyzed system. Top frame illustrates the time evolution of the objective quality \(q_{1}\) and novelty value \(n_{1}\); the bottom frame represents the choice probability \(p_{1}\) evolution. The time series were obtained for the time span of 500 units and following values of system parameters: \(r_{1}=r_{2}=1, \beta=5, \phi=1, \gamma=1, T_{q}=70, T_{n}=50\); the initial conditions were chosen randomly.
stable dynamics was found only for relatively narrow sets of parameters.

The typical example of the stable dynamics is illustrated in Fig. 1. The agent eventually learns the mixed strategy \(p_{1}=p_{2}=0.5\), which is the stable equilibrium of the system. However, it is instability that often characterizes the human behavior, so we focus our attention on the second case. Fig. 2 represents the periodic motion of the system at hand. As can be seen from the top two frames, the system trajectory forms a limit cycle. Starting from the randomly selected intial values, system variables undergo periodic oscillations after a short transition process. The observed dynamical patterns correspond to the case when the decision maker changes her preferences from time to time, or, in other words, periodically "switches" from one alternative to another. The implicit dependence between the objective quality and the novelty of the option can bee seen in the bottom left frame of Fig. 2. When the quality of the alternative (as represented in the agent memories) attains local maximum, the corresponding choice probability also peaks. So this alternative is chosen frequently during some period of time and, thus, its novelty takes the lowest possible value. On the other hand, when the probability of \(x_{i}\) being chosen is low, the agent has relatively little information about the consequences of this action (because the memories about it eventually vanish if not reinforced regularly). Therefore, the agent intrinsic desire to learn motivates her to choose this option due to the relatively

Figure 2: Unstable dynamics of the analyzed system. Top left frame illustrates the system trajectory on the plane \(\left(q_{1}-q_{2}, n_{1}-\right.\) \(n_{2}\) ), while top right depicts the projection of the system phase space trajectory onto the ( \(q_{1}, n_{1}\) ) plane. Two bottom frames demonstrate the time evolution of the objective quality \(q_{1}\), novelty value \(n_{1}\) (both on the bottom left frame) and the choice probability \(p_{1}\) (bottom right) for option \(x_{1}\). Represented results were obtained for the time span of 500 units and following values of system parameters: \(r_{1}=r_{2}=1, \beta=2, \phi=0.4, \gamma=4, T_{q}=70, T_{n}=50\); the initial conditions were chosen randomly.
large amount of information that the agent might acquire.
Finally, the evolution of the choice probability \(p_{1}(t)\) (see bottom right frame in Fig. 2) demonstrates that during considerable periods of time the probability of choosing \(x_{1}\) remains close to zero; these intervals slightly precede the periods when \(q_{1}\) is low and \(n_{1}\) is high. Then, after staying within the vicinity of zero, the probability rapidly reaches the maximum value around unity and in turn remains near this value for the next half-cycle.

The conducted numerical analysis confirms that the the system (1-4) actually exhibits the properties one may intuitively anticipate from the intrinsically motivated agent. The agent learns one of the optimal options, but being biased she eventually tends to discard the established strategy that proved its efficiency in favor of the novel one. Moreover, the preliminary analysis of the non-symmetric case revealed that the similar behavior can be observed even when the rewards are not equal. This fact requires a thorough investigation and will be reported elsewhere.

The results presented in the present work already enable us to conclude that even the simplest systems with boundedly rational agents may exhibit non-trivial dynamics. However, more detailed analysis of the proposed model is required. Particularly, the system stability conditions are still to be determined. Also under the scope of future work is the question of how the system dynamics patterns depend on the sysem parameters, namely, the novelty rate, perception thresholds
and the parameters characterizing the capacity of the agent memory.

\section*{Conclusion}

We have proposed a dynamical model of intrinsically motivated learning. In the various learning models developed previously in game theory and cognitive science the learning subject is assumed to act rationally in achieving the ultimate goal - to maximize the cumulative reward gained during the learning. We challenge this approach by assigning a piece of non-rationality to the learning agent. The curiosity is what biases the selfish agent in our model.

We confine our scope to the case of single agent adaptation and follow the reinforcement learning setting. The agent behavior in our model is governed by two stimuli. The objective stimulus is traditional - to maximize the total payoff collected throughout the process. The subjective one is irrational - to engage in active learning as much as possible, because the very learning process is enjoyable. We show that the agent biased in such way at least under some conditions does not stick to the optimal strategy of behavior, in contrast to the rational learning agent. Rather, in such cases the agent preference continuously varies in an oscillatory way. Performing the simple numerical analysis of the model, we demonstrate that the intrinsic motivation leads to the instability of the learning dynamics.

Our results give evidence to the fact that the intrinsic mo-
tivation in particular and the bounded rationality in general may cause the significant changes in the behavior of singleand multi-agent systems. We argue that the intrinsic motives should be paid no less attention than the extrinsic ones, if one considers the systems where human decisions are of the primary importance.

\begin{abstract}
Studies of statistical learning have documented a remarkable sensitivity to structural regularities in both infants and adults. However, most studies of statistical learning have assumed a single underlying causal structure with uniform variance. In previous work in which two structures are presented successively, a primacy effect has been reported in which only the first structure is acquired. The present study explores the conditions under which such primacy effects are observed and learners are capable of acquiring both structures. We argue that learners can detect multiple structures by monitoring the consistency of the input.
\end{abstract}

Keywords: speech segmentation, statistical learning

\section*{Introduction}

Over the past twenty years, research on language acquisition has been transformed by the finding that infant and adult learners can use rudimentary statistics to parse artificial speech streams (Saffran, Aslin, \& Newport, 1996; Saffran, Newport, \& Aslin, 1996). A large number of follow-up studies have replicated and extended the initial findings, determining that statistical learning is neither domain specific (e.g., Fiser \& Aslin, 2002a; Kirkham et al. 2002), nor even restricted to humans (Hauser et al., 2001; Toro \& Trobalón, 2005). The term statistical learning has consequently come to be associated with a wide range of phenomena that rely on implicit calculations based on distributional regularities in the environmental input.

The utility of these statistical learning experiments for simulating the early stages of language acquisition has been widely acknowledged. However, with few exceptions, the input to learners in statistical learning experiments has been characterized by a single, highly invariant statistical structure. This uniform-variance property of the input does not reflect the substantial variability inherent in natural language corpora due to shifts in topic, speaker, accent, and even language (in the case of bilingual acquisition). In some instances, variance in the input may signal to the learner that they are in a new context for which a different statistical structure must be learned (e.g., a language change), but in other cases this variation represents noise and should not trigger a new structural representation (e.g., hearing foreign-
accented speech). Thus, the critical challenge confronting language learners is much like Piaget's description of the processes of assimilation and accommodation (Piaget, 1985). The learner must ultimately determine the number of causal models that best characterizes the input, resolving when a new causal model is required and when the existing model can account for the observed data.

There are at least two potential sources of information that may facilitate learners to detect that there has been a change in structure over time, which in turn may facilitate the formation of multiple representations (Gebhart, Aslin, \& Newport, 2009). The first source of information is the availability of a contextual cue that is correlated with a particular statistical structure (e.g., Weiss, Gerfen, \& Mitchel, 2009; Gebhart, Aslin, \& Newport, 2009). The existence of such a cue could result in computations that are performed over a subset of the input and then compared across contexts. If the computations differ by some criterion, it would trigger the learner to form multiple representations to accommodate the inputs associated with each context. A second potential source of information for learners may be derived from monitoring the consistency of the input (Basseville \& Nikiforov, 1993; see Gebhart, Aslin, \& Newport, 2009). If the surface statistics are entirely consistent, the learner may conclude that the input likely has arisen from a single underlying structure. Conversely, if the variance in the surface statistics exceeds some criterion, then the learner may conclude that the underlying structure has undergone some change (see Gebhart, Aslin, \& Newport 2009; Qian, Jaeger, \& Aslin, 2012).

To date, only a few experiments have tested whether contextual cues facilitate the formation of multiple representations when multiple inputs are presented. In a study by Weiss, Gerfen, \& Mitchel (2009), learners were presented with two artificial languages comprised of four words each, in which the words were defined solely by transitional probabilities. The languages were interleaved in two-minute intervals twelve times total. When the languages were presented in a single voice, only congruent language pairs were learned (ones whose statistics, when combined, yielded similar transitional probabilities to the languages
presented in isolation). Incongruent languages (ones whose statistics were incompatible and yielded a higher noise level when combined) were only learned when a contextual cue was added such that one language was presented in one voice and the other in a second voice. Gebhart, Aslin, and Newport (2009) used a similar methodology, presenting learners with two five-and-a-half minute segments of incompatible languages presented consecutively (in the same voice). They reported a primacy effect in which the first language was learned at above chance levels, while the second language was not. However, learners succeeded in acquiring both languages if there was an explicit cue (informing the learners they would acquire two languages) in conjunction with a brief pause between streams. Also, tripling exposure time to the second language allowed learners to perform above chance in both languages, indicating that both languages could be acquired given sufficient exposure to the new language. Together, these results support the notion that the presence of a contextual cue differentiating the inputs can facilitate the formation of multiple representations, perhaps providing the learner with a more efficient route to successful acquisition.

To the best of our knowledge, no study to date has systematically investigated whether and how learners can form multiple representations by monitoring the consistency of the input alone. Arguably, some of the results from the aforementioned studies begin to address this issue, though the findings have not been easy to interpret (e.g., Weiss, Gerfen \& Mitchel reported that repeated presentations of incongruent languages in the same voice resulted in no learning whereas the single presentations in Gebhart, Aslin, and Newport resulted in a primacy effect). In Experiment 1a, we set out to initially replicate the primacy effect of Gebhart and colleagues using their own languages. Subsequently, we manipulate both duration and languageswitching parameters to determine the conditions under which learners can acquire both languages by monitoring the consistency of the input in the absence of contextual cues such as speaker voice or explicit instructions.

\section*{Experiment 1}

In Experiment 1a, our goal was to replicate the primacy effect reported by Gebhart, Aslin, and Newport (2009) by presenting learners with two consecutive artificial languages with no explicit cue to the transition. We subsequently extend the study by manipulating the number of transitions between the two languages during the familiarization phase. Thus, in Experiment 1b, we control for the amount of exposure to each language while adding additional transition points (i.e., presenting four 2-minute 45 -second blocks of each language versus two 5:30 blocks in Experiment 1a).

\section*{Methods}

Participants Thirty-four undergraduate students were recruited from a Psychology 100 subject pool. Participants
were divided into two conditions: 17 (11 female, 6 male) participants in Experiment 1a with a mean age of 19.6 years, and 17 (12 female, 5 male) participants in Experiment 1b with a mean age of 19.6 years. All participants were English monolinguals by self-report.

Languages The speech stream was composed of two languages, each consisting of sixteen trisyllabic words based on 12 unique CV syllables. These artificial languages were previously used in Gebhart, et al.'s (2009) segmentation experiment. Individually, the languages could be segmented by tracking the transitional probabilities (TPs) between syllables, with high TPs between syllables within a trigram (representing a word) and low TPs between syllables across different trigrams (representing word boundaries). See Figure 1 for an illustration of TP-defined words boundaries.

In both languages, two vowel frames and six consonants were used to define the trisyllabic words. The withintrigram transitional probability for syllables was 0.50 . Words within the stream were randomly sequenced yielding a transitional probability of 0.25 between word-final and word-initial syllables. The second language rearranged the vowel frames and consonants of the first language, resulting in a syllable inventory that overlapped by \(50 \%\). The combined transitional probabilities (including all syllables across both languages) varied from 0.33 to 0.67 both within and between words. Consequently, they did not provide consistent cues for segmentation (see Figure 1).

Procedure Participants were instructed to listen to a brief recording of foreign speech and informed that they would later be quizzed on what they had heard. In Experiment 1a, participants listened to 5 minutes and 30 seconds of each language (produced in the same voice) consecutively without any cues to transition. Order of language

Figure 1 - Transitional probabilities defining the structure of each language. When combined, the TPs of each language result in a flat (uninformative) structure.

Figure 2 - Durations of each experiment depicted together. Dark bars represent Language A, and light bars represent Language \(B\).
presentation was counter-balanced between participants, but for simplicity we will always refer to the Language A as the first language presented and Language \(B\) as the second. In Experiment 1b, participants listened to 4 consecutive blocks each consisting of 2 minutes and 45 seconds of one language (2:45 A + 2:45 B + 2:45 A + 2:45 B, order of actual languages was counter-balanced between participants). In both conditions, total exposure to each language was constant (5:30) as well as the total duration of the familiarization phase (11:00).

After familiarization, participants completed a test phase with thirty-two two-alternative forced choice trials in which participants selected between statistically-defined words and partwords. The partwords consisted of either the last syllable of a word followed by the first two syllables of another word or the last two syllables of a word followed by a single syllable of another word. These items occurred during the familiarization but were characterized as partwords since the within-trigram transitional probabilities were low. Participants were asked to judge which of the trigrams sounded more familiar, with statistically-defined words being counted as correct responses.

\section*{Results \& Discussion}

Mean correct responses on the test trials were computed for each language. In Experiment1a, participants scored a mean accuracy of 0.746 ( \(S D=0.152\) ) on Language A and 0.581 ( \(S D=0.192\) ) on Language B . These scores indicated a primacy effect in which accuracy on Language \(A\) significantly exceeded Language \(B\) (paired \(t(16)=2.82\), \(p=0.012\) ). Accuracy on Language A was significantly above chance ( \(t(16)=6.67, p<0.001\) ) while accuracy in Language B was not \((t(16)=1.73, p=0.102)\). By contrast, in Experiment 1b, Language A and Language B did not significantly differ (paired \(t(16)=1.00, p=0.331\) ). Also in contrast to Experiment 1a, Language A significantly exceeded chance (A: \(M=0.673\), \(S D=0.151, t(16)=4.73, p<0.001)\), while Language B was also marginally significant ( \(M=0.603, S D=0.207, t(16)=2.05\), \(p=0.057\) ). Results are illustrated in Figure 3.

In Experiment 1, we successfully replicated the primacy effect of Gebhart, et al. (2009) and discovered that increasing the number of switches between the languages could eliminate the primacy effect. Experiments 1a and 1b differed only in the duration of the individual exposure segments (5:30 vs. 2:45) and the number of switches
between languages in the familiarization phase (1 vs. 3). Two causal hypotheses may be proposed for these results: First, the greater number of switches in the 1b stream may cue the listeners to the existence of two structures, allowing them to begin acquiring Language B . Alternately, in Experiment 1a (and the previous experiment by Gebhart and colleagues), learners may become entrenched in the statistical structure of Language A due to the lengthy duration of initial exposure. This entrenchment may inhibit detection or acquisition of the new structure. Experiment 2 was designed to disentangle these hypotheses.

\section*{Experiment 2}

In Experiment 2, we contrasted the entrenchment and switching hypotheses proposed to explain the results of Experiment 1. We accomplished this by presenting participants with the following sequence of languages without any breaks in between: 5:30 of Language A followed by 2:45 of Language B, 2:45 of Language A again, and finally \(2: 45\) of Language \(B\). The entrenchment hypothesis predicts that the primacy effect found in Experiment 1a should also be present for Experiment 2 since the duration of the initial block of Language A is identical. The switching hypothesis predicts that both languages will be learned at significantly greater than chance levels since there are three transitions. This prediction of learning is somewhat counter-intuitive given that Language B was not learned in Experiment 1a and here we are increasing exposure to Language A.

\section*{Methods}

Participants Twenty Psychology 100 students participated (12 female, 8 male; mean age 19.9 years).

Procedure As noted above, in this experiment the languages were configured as follows: 5:30 A \(+2: 45 \mathrm{~B}+\) 2:45 A + 2:45 B (see Figure 2). All other procedures were identical to Experiment 1.

\section*{Results \& Discussion}

No primacy effect was observed in Experiment 2, where Language A accuracy ( \(M=0.697, S D=0.161\) ) did not significantly differ from Language B accuracy ( \(M=0.694\), \(S D=0.137\); paired \(t(19)=0.07, p=0.943\) ). Moreover, both languages significantly exceeded chance performance
(A: \(t(19)=5.46, p<0.001 ;\) B: \(t(19)=6.31, p<0.001\) ). Our results clearly reject the entrenchment hypothesis, lending support to the switching hypothesis as both languages were learned at above chance levels and performance did not significantly differ between languages.

\section*{Experiment 3}

In Experiment 2, we eliminated the primacy effect found in Experiment 1a by increasing the number of switches between languages, even though Language A possessed a relative advantage in initial presentation duration and overall exposure time. In Experiment 3, we eliminate the last Language B exposure to test whether Language B may have been learned early in the sequence of exposures or whether the learning of B occurred only after the third transition (i.e., the last presentation). Notably, the only occurrence of Language B coincides with the first transition point in the sequence (and there are fewer transitions overall). Understanding when learning occurs may shed light on the type of processing that may be occurring for the unlearned language in conditions eliciting a primacy effect.

\section*{Methods}

Participants Fifteen Psychology 100 students participated (13 female, 2 male; mean age 19.3 years).

Procedure In this experiment, languages were configured as follows: 5:30 A \(+2: 45 \mathrm{~B}+2: 45 \mathrm{~A}\) (see Figure 2 for illustration). All other procedures were identical to those described for Experiment 1.

\section*{Results \& Discussion}

The primacy effect emerged again in this experiment (paired \(t(14)=2.73, p=0.016\) ), as Language A accuracy ( \(M=0.729\), \(S D=0.179\), compared to chance: \(t(14)=4.95, p<0.001)\) significantly exceeded Language B ( \(M=0.546, S D=0.139\), compared to chance: \(t(14)=1.28, p=0.221)\). The contrast between these results and Experiment 2 highlights the
importance of the second presentation of Language B for learning. In the absence of the third switch and additional exposure, performance was at chance levels for Language B. These results raise the question of whether the deficit in Language \(B\) learning was a function of the removal of the third language switch or the decrease in overall Language B exposure (from 5:30 to 2:45).

\section*{Experiment 4}

The primacy effect observed in Experiment 3 emerged in the context of fewer switches and very short overall exposure. Therefore, in Experiment 4, we matched the overall exposure durations of Experiment 2 by providing learners with 5:30 of Language A followed by 5:30 of Language B and then an additional 2:45 of Language A again. This is essentially the sequence presented in Experiment 1a followed by an additional short block of Language A familiarization. Accordingly, the overall duration of each language presentation resembles Experiment 2 (in which both languages were learned), but here only two language switches are provided. Also like Experiments 2 and 3, Language \(A\) is advantaged in total exposure duration relative to Language \(B\).

\section*{Methods}

Participants Seventeen Psychology 100 students participated ( 13 female, 4 male; mean age 19.3 years).

Procedure In this experiment, languages were configured as follows: 5:30 A \(+5: 30 \mathrm{~B}+2: 45 \mathrm{~A}\) (see Figure 2 for illustration). All other procedures were identical to those described for Experiment 1.

\section*{Results \& Discussion}

Although Language A did not significantly exceed chance ( \(M=0.596, S D=0.210, t(16)=1.88, p=0.079\) ) and Language B significantly exceeded chance \((M=0.632, S D=0.132\), \(t(16)=4.12, p<0.001\) ), accuracy in Languages A and B did

Figure 3 - Accuracy of participant responses in familiarity task. Chance level is 0.50 , and error bars denote \(95 \%\) confidence intervals of the mean.
not significantly differ from each other (paired \(t(16)=-0.67\), \(p=0.514\) ). See Figure 3 for illustration. The findings of Experiment 4 provide further evidence that that transitions between the languages alters learning. As in Experiment 2, we made the surprising observation that the additional exposure to Language A could facilitate learning of Language B. It is unclear at this point why Language A's learning was reduced and future experiments will explore the source of this effect. Irrespective of this pattern, the results from Experiment 4 do imply that some processing of Language B occurs even in conditions resulting in a primacy effect for Language A, such as the results reported by Gebhart, Aslin, \& Newport (2009) and our Experiment 1a.

\section*{General Discussion}

In the foregoing experiments, we have explored a range of conditions in which learners were familiarized with two artificial language streams characterized by incompatible underlying statistical structures. Unlike previous studies investigating statistical learning of multiple streams, no extralinguistic contextual cues were provided to the learners to signal the presence of a second language and facilitate learning. Consequently, successful learning of both languages relied on sensitivity to the structures themselves and the transition points between structures. In previous research, when statistically incompatible artificial languages were presented successively, learners have failed to successfully acquire both structures. In instances in which only a single switch was presented, learners exhibited a primacy effect (Gebhart, Aslin, \& Newport, 2009) whereas when many switches occurred, there was a catastrophic interference effect in which no languages were learned (Weiss, Gerfen, \& Mitchell, 2009; Mitchel \& Weiss, 2010). We presented learners with the same languages used in the Gebhart, Aslin, \& Newport (2009) study, and our results suggest that learners are sensitive to the transitions between the languages which can help them acquire both structures.

As noted above, in previous research, when learners receive input from two structures with only a single transition point, a primacy effect is observed (also replicated in Experiment 1a). In the original study, this effect could only be overcome by significantly extending exposure to Language \(B\). Our findings have demonstrated that the primacy effect can also be overcome without increasing exposure at all. In Experiment 1b, exposure to Languages A and \(B\) were equivalent to the original study, though the languages were presented in smaller blocks and interleaved. This manipulation resulted in successful learning of both streams. Likewise, the results of Experiment 2 demonstrate that Language B can be learned even when our manipulation increases exposure only to Language A. That is, adding Language A training can, by virtue of the switching between languages, support learning in Language \(B\) as measured by our posthoc test.

We also explored whether there was any learning of Language B when it occurred after only a single transition. Gebhart, Aslin, and Newport (2009) as well as our Experiment 1a findings leave open the possibility that Language B was ignored altogether or that structures were unlearnable in light of the prior learning of Language A. The results of Experiment 4 cast doubt on either of these interpretations. In Experiment 4, learners acquired Language B at above chance levels despite the fact that Language \(B\) occurred in the exact same context as in the original condition (i.e., 5:30 of Language A followed by 5:30 of Language B). Like Experiment 2, the only manipulation in this experiment involved additional exposure for Language A.

We observed different learning outcomes between Experiments 3 and 4, suggesting that the amount of exposure to Language \(B\) prior to the second switch modulates the success of learning. It is possible that the 2:45 block of Language \(B\) in Experiment 3 did not provide adequate time for learners to sample the language, or perhaps 2:45 is insufficient to support learning (as we do not yet have baseline data for that duration). Because Experiment 3 is the only condition in the present study that limited Language B exposure to \(2: 45\), further conditions will be necessary to explore this issue.
When three transition points are provided in the input (i.e., Experiment 1b and Experiment 2), the two structures become increasingly discriminable to learners, as evidenced by their above-chance performance in both languages. As noted above, the importance of these switches for detection of the second structure is highlighted in those experiments by the improvement in Language \(B\) performance despite only receiving additional exposure to Language A. We therefore conclude that learners are capable of identifying whether input streams contain one or multiple structures by monitoring the consistency of the input. This finding is in accordance with previous speculation regarding the conditions under which changes to statistical structures may be detected (Gebhart, Aslin, and Newport, 2009). The observed primacy effects in previous research and Experiment 1a cannot be attributed to entrenchment in the first language, as it has now been demonstrated that the primacy effects can be overcome with additional transition points between language streams.

While the present experiment made an extensive demonstration of language learning with only lingustic (syllable inventory) or statistical (TP) cues, a similar attempt has yielded markedly different results: Weiss, Gerfen, and Mitchell (2009) observed catastrophic interference when two incompatible languages were interleaved in 2 minute segments for a 24 minute stream. Under the switching hypothesis, we would have predicted significant learning of both languages. However Weiss and colleagues found that neither language was learned significantly better than chance. These two studies used different statistical
structures, had different amount of overlap between the languages, and a different number of switches. Future experiments will try to systematically manipulate these parameters to better understand how overlap (and statistical compatibility) can influence the learning of multiple streams.

It has been hypothesized that describing how learners detect changes in statistical learning may be best explained by a hierarchical Bayesian model of change detection (Qian, Jaeger, \& Aslin, 2012). How learners interpret non-uniform variance in statistical learning appears to rely on the availability of statistical and linguistic cues, such as changes in transitional probabilities or syllable inventory observed at a transition point between languages. These cues may lead learners to consider a second causal model to describe input (accommodation) over a single causal model under which the variance could occur (assimilation). This process of proposing causal models, weighting them by their likelihood, and comparing them to the input stream follows the procedure of Bayesian model comparison. In the case of extralinguistic cues in speech segmentation (e.g., pitch change or pause), this model comparison may be aided by the expectation of a context change and increase the prior probability of a two-model explanation of variance. Linguistic cues, such as the introduction of new syllables or the change in transitional probabilities between syllables may also effect such a change in the prior probability, though by themselves are insufficient. Our results suggest that change detection can be supported by variance-related events such as language switches, and provides further evidence that the Bayesian framework is a valuable analogy for statistical learning in multiple contexts.

Qian, Jaeger, and Aslin (2012) describe statistical cues to context change in terms of prediction error, i.e., a large deviation of the input stream from the learner's current model. Linguistic cues to speech segmentation may elicit such errors at language switches when the inventory or transitions between syllables change. This error-based cuing appears to be evidenced in the present study based on the importance of language switches to learners' performance. While previous research has demonstrated the utility of prolonged exposure to the second structure to detection of two contexts (Gebhart, Aslin, \& Newport, 2009), we demonstrate that a relatively small set of high variation events can also increase the prior probability for a twomodel hypothesis.

Our future work will attempt to determine the nature of processing that occurs during the unlearned streams. It is possible that learners detect the regularities in the second stream but discard it as noise, or that it is blocked by the learning of the first structure. Clearly, some information is gathered during those periods, as evidenced by the results of Experiments 2 and 4. One set of studies underway introduces a third structure into the sequence (either a new learnable artificial language or an unlearnable non-adjacent transitional probability language). Thus, the sequence is
\(5: 30\) of A followed by \(2: 45\) of Language \(C\) (noise or learnable) followed by \(2: 45\) of \(A\) and \(2: 45\) of \(B\). This condition tests whether switches by themselves are useful (without supporting the statistics of Language B). We are also currently engaged in neuroimaging studies to localize and contrast the learning of Languages A and B in a variety of conditions.

\begin{abstract}
Recent theoretical discussion of dyadic coordination has focused on issues of synchronization, entrainment, alignment, and convergence. All of these terms refer to matching of specific behavioral and linguistic events, such that members of a dyad coordinate by "doing the same thing." Communicative behaviors tend to be highly variable, like most human behaviors. These tendencies suggest the possibility of complexity matching: Statistical measures of behavioral complexity may converge in certain types of dyadic interaction. In the present study, acoustic speech signals of interlocutors were measured in two conversational conditions, one argumentative and the other affiliative. Signal complexity was measured in terms of heavy tails and power laws in the distributional and temporal properties of acoustic event series, respectively. Parameters of statistical functions were found to vary by conversation type, as did their matching between interlocutors. Results demonstrate a new way to quantify the coordination of interlocutors in terms of complexity matching.

\begin{abstract}
Measuring individual differences in susceptibility to decision biases has received increased attention in recent years, yet some methodological questions may hinder us from validly assessing the effects of cognitive heuristics. Surveys consisting of measures of several biases often aim to compare rate of occurrence of these biases and to compile a composite index from these measures. Unfortunately, the probability that the participant chooses the normative answer on the test questions often varies between and within studies, thus confounding the results. Another complication in the surveys used is that some incorrect answers are not necessarily the result of the studied bias. In our work, we tried to overcome these methodological challenges in a new survey of 15 cognitive biases. The results of 1127 participants provided insight into several methodological and theoretical questions about measuring individual differences in heuristic decisions.

The Effect of Test Format on Visual Recognition Memory Performance
}

\author{
Nora Andermane \\ University of Bristol \\ Jeffrey Bowers \\ University of Bristol
}

\begin{abstract}
A recent study (Brady et al., 2008) claims that the capacity and fidelity of long-term visual recognition memory has been underestimated. After viewing a massive number of images for nearly six hours participants were highly accurate at identifying a previously seen image in a two-alternative forced choice task even when the foil was extremely similar to the target. In present study we hypothesised that this impressive memory performance might be specific to the test format. To investigate the effect of test format on recognition accuracy we showed participants 1700 images for 2.5 hours and then tested them in a forced choice task and a yes/no task, where participants judged only one image at a time. We found that accuracy was relatively high in both test conditions; however, the performance was lower in the yes/no task ( \(75 \%\) vs. \(86 \%\) ). A follow-up study exploring delayed testing effects will also be described.

Belief Bias in the Perception of Sample Size Adequacy
}

\author{
Richard Anderson \\ Bowling Green State University
}

\begin{abstract}
In two experiments, participants were instructed to set aside their complete knowledge of a statistical population parameter and to take the perspective of an agent whose knowledge was limited to a random sample. Participants rated the appropriateness of the agent's conclusion about the adequacy of the sample size (which, objectively, was more than adequate), along with the agent's intelligence. Whereas previous work suggests that unbelievable statistical conclusions impact reasoning by provoking critical thought which enhances the detection of research flaws, the present studies presented participants an unflawed scenario designed to assess effects of believability on bias. The results included the finding that participants' complete knowledge indeed biased their perceptions not only of the adequacy of the sample size, but also of the rationality of the agent drawing the conclusion from the sample. The findings were interpreted in the context of research on belief bias, social attribution, and Theory of Mind.

\title{
Semantic interference in language production is due to graded similarity, not response relevance
}

\author{
Sabrina Aristei \\ Humboldt Universität zu Berlin, Berlin, Berlin, Germany \\ Rasha Abdel Rahman \\ Humboldt-University of Berlin
}

\begin{abstract}
There is an ongoing debate on whether semantic interference effects in language production reflect competitive lexical selection or post-lexical response exclusion mechanisms driven by the response-relevant status of distractor words.

To disentangle categorical relatedness and task-defined response relevance effects, we combined the picture-word interference task with the conditional naming paradigm in an orthogonal design. Participants were instructed to name objects typically located in or on the water (e.g. canoe) and refrain from naming objects typically located outside the water (e.g. bike), and vice versa. Semantic relatedness and response relevance of distractors were manipulated independently. Linear mixed model analyses were conducted with semantic similarity ratings of target-distractor as continuous predictor.

The pattern of results revealed that semantic similarity beyond categorical relations is critical for interference effects to be observed, and not response relevance. These findings provide support for the assumption that lexical selection is competitive and that semantic interference effects in the PWI paradigm reflect this competition.

\author{
Akira Ishiguchi \\ Ochanomizu University, Bunkyo, Tokyo, Japan
}

\begin{abstract}
Systems contain normal noises even in a stable state, but larger noises in an uncontrollable state. In this study, we investigated different responses between experts and novices in controllability judgment. A half participant was required to discriminate variance magnitude of two sound tone sequences (standard vs. comparison). The sequence consisted of 16 tones whose pitch contained Gaussian noises. They continued to train the variance discrimination task up to a criterion level, and were regarded as experts. Then, the experts and novices participated in the controllability judgment task (i.e. a kind of the risk judgment task) with use of similar stimuli in the discrimination task. They were allowed to continue to judge for gain whether they were in an uncontrollably higher risk state with larger variances. They could stop the trial to make smaller costs. Our results showed experts in the discrimination task increased avoidance responses more than novices.

\title{
Sleep deprivation accelerates delay-related loss of visual short-term memories without affecting precision
}

\author{
Christopher L. Asplund \\ Duke-NUS Graduate Medical School \\ Natalie Wee \\ Duke-NUS Graduate Medical School \\ Michael W.L. Chee \\ Duke-NUS Graduate Medical School
}

\begin{abstract}
Visual short-term memory (VSTM) is a limited information store that supports many higher-order cognitive processes. Here we examined how two challenges to VSTM, sleep deprivation (SD) and maintenance duration, interact to affect the number and precision of stored items. Participants were studied twice, once after a normal night of sleep and once following a night of total SD. For each trial, participants remembered the location and color of three squares over a variable delay ( 1 or 10 seconds), reporting the color of the cued item using a color wheel. The probability of reporting the target item, the precision of report, and the probability of reporting a distractor item were determined using mixture modeling. SD reduced the number of integrated representations that could be reported, an effect compounded by delay. In contrast, SD had no effect on VSTM precision. These results suggest all-or-none memory failures, not gradual degradation, during SD.

Learning Complex Scientific Concepts through Peer Argumentation: The Effect of Belief in Human Presence and Partner's Discourse Style
}

\author{
Christa Asterhan \\ Hebrew University of Jerusalem \\ Miriam Babichenko \\ Hebrew University of Jerusalem
}

\begin{abstract}
This study aims to further our understanding of the social and cognitive processes underlying conceptual change learning through argumentative discourse. We tested the effect of competitive (vs. collaborative) argumentative discourse style and belief of interaction with a human peer (vs. a computerized peer agent) on learning the concept of diffusion through interaction with a disagreeing peer. Peer confederate's verbal behavior was tightly controlled to evoke argumentative discourse, holding content exposure constant but differing in rhetoric style. Students in the collaborative discourse style condition performed better. Moreover even though previous studies have reported that the belief of interaction with a human peer benefits learning in consensual settings, the opposite was found for a settings in which the partner critiques the learner's own solutions: Students performed better when they believed they interacted with a computer agent (vs. with a human peer). Implications for theory as well as task design are discussed.

Emotions in the space: arrangement and biases in preschool children and adults
}

\author{
Maria Atanassova-Trifonova \\ Institute of population and human studies, BAS \\ Dimitar Atanasov \\ New Bulgarian University \\ Pavleta Ognyanova \\ New Bulgarian University
}

\begin{abstract}
With the first experiment of our study we have empirically tested the hypothesis that in adult and in adolescent subjects there is a consistency of the spatial representation of emotion terms. We explore the stability of the association between valence and verticality through modulation effect of the valence priming on spatial arrangement of emotion terms. In the second part of our study we focused on spatial representation of emotions by preschoolers when tested explicitly and implicitly with a task of spatial recall. It was found that the arrangement of emoticons on vertical and horizontal line by preschool children varied significantly as a function of the valence of emotions. The results from our third experiment suggest that the effect of the valence of nonverbal stimuli on the spatial recall was only evident when they were with a negative value and when placed at more central positions near to the horizontal line.

\title{
A Bayesian Analysis of Bias in Single Item Recognition for Continuous Word frequency
}

\author{
William Aue \\ Syracuse University, Syracuse, NY, United States \\ Pernille Hemmer \\ Rutgers University \\ Amy Criss \\ Syracuse University
}

\begin{abstract}
The relationship between word frequency (WF), measured on a continuous scale, and recognition memory was examined in a single item recognition task. The aim was to more clearly map the relationship between word frequency and memory performance. In marked contrastContrary to standard findings of a linear relationship when between WF and recognition, is treated as discrete, we observed a curvilinear pattern. Specifically, discriminability (d') is higher at both the low and very high ends of the WF continuum. In addition, we observe shifts in bias (C) with a conservative bias for very high frequency (HF) words between WF and memory performance. Variations of a Bayesian signal detection model were then applied to the data in order to better understand the influences WF on measures of d' and C. The models examined contrast the current explanations of the WF effect in recognition where C does not influence performance with a model where C is free vary as a function of WF.of a linear relationship between WF and discriminability ( \(\mathrm{d}^{\prime}\) ) in recognition memory, with the curvilinear pattern for both d' and bias (C) with the curvilinear patterns observed in the current data set. Implications for models of recognition memory are discussed.

Exploring Cross-Situational Learning and Mutual Exclusivity
}

\author{
Suzanne Aussems \\ Tilburg University
}

Paul Vogt
Tilburg University

\begin{abstract}
Cross-situational learning and mutual exclusivity are strategies proposed to explain the learning of word-meaning mappings. In this paper, seven possible strategies are explored and compared to the results of an artificial word learning experiment. The fixed order of trials in the experiment allows for an exposure-by-exposure approach to explore the individual learning process of words. The experiment shows that adult learners do indeed integrate knowledge from previous exposures, however they have difficulty in keeping track of cross-situational information for learning all twelve word-meaning mappings, although some learners can. The performance of 78 participants is compared to simulations in which various combinations of strategies were modeled. The results suggest that a random strategy with mutual exclusivity as its sole learning mechanism could explain the performance in the experiment. In this strategy, the learner selects an object at random from the context, provided that this object has not received a label yet.

University of Zadar

\begin{abstract}
The aim of this study was to explore the effect of semantic congruence and spatial orientation on verification time of modus ponens (MP) and modus tollens (MT) conclusions. Factorial experiment ( \(2 \times 2 \times 2\) ) with repeated measures was carried out. Conditionals expressed the vertical relation of two objects in congruent (If cellar is down, then attic is up) or incongruent manner (If attic is down, then cellar is up). Eight pairs of words with clear vertical relation were used. Order of vertical relations in the conditional was also manipulated. Conditionals were in the form of "If P down, then Q up", or "If P up, then Q down". Participants \((\mathrm{N}=48)\) had to verify the presented conclusions in 64 tasks as quickly as possible. Significant effects for valid MP conclusions were obtained. Conclusions containing "down-up" order of relations in conditional premise were processed faster. Congruent spatial relations also facilitated faster answers.

\title{
Does interaction matter? Testing whether fast and frugal heuristics can replace interaction in collective decision-making
}

\author{
Dan Bang \\ Department of Experimental Psychology, Oxford University \\ Riccardo Fusaroli \\ Center for Semiotics, Aarhus University \\ Kristian Tylén \\ Center for Semiotics, Aarhus University \\ Karsten Olsen \\ Interacting Minds Centre, Aarhus University \\ Peter Latham \\ Gatsby Computational Neuroscience Unit, University College London \\ Jennifer Lau \\ Department of Experimental Psychology, Oxford University \\ Andreas Roepstorff \\ Interacting Minds Centre, Aarhus University \\ Geraint Rees \\ Institute of Cognitive Neuroscience, University College London \\ Chris Frith \\ Wellcome Trust Centre for Neuroimaging, University College London \\ Bahador Bahrami \\ Institute of Cognitive Neuroscience, University College London
}

\begin{abstract}
In a range of contexts, pairs of interacting individuals arrive at collective decisions by comparing their confidence in their judgements. This tendency to evaluate the reliability of information by the confidence with which it is expressed has been termed the 'confidence heuristic'. In this study, we tested two fast and frugal ways of implementing the confidence heuristic in the absence of interaction: either directly, by opting for the judgement made with higher confidence, or indirectly, by opting for the faster judgement, the latter exploiting a widely known inverse correlation between confidence and reaction time. We found that the success of these heuristics depends on how similar individuals are in terms of their abilities and, more importantly, that for dissimilar individuals such heuristics are dramatically inferior to interaction. Interaction allows individuals to alleviate but not fully resolve - their differences in ability.

\title{
An ACT-R model of the P300 event-related potential
}

\author{
Adrian Banks \\ University of Surrey
}

\begin{abstract}
The excellent temporal resolution of event-related potentials (ERPs) makes it an ideal technique to test the timing of events within cognitive models which may not be distinguishable using behavioural data. Here a model of an ERP component is presented which tests features of the ACT-R cognitive architecture. The P300 is an event-related potential that is associated with attending to incoming stimuli and subsequent memory processing. It is commonly elicited using an oddball task in which a series of stimuli are presented comprising infrequent target stimuli against a background of frequent standard stimuli. It is influenced by the probability of a target in a sequence of stimuli. An ACT-R model was developed of the oddball task. P300 amplitude was correlated with the activation of the memory of the target stimuli, providing a good account of the component. The implications of these findings for the ACT-R architecture are discussed.

\title{
Context-dependent memory effects on syntax
}

\author{
Brendan Barnwell \\ UC Santa Barbara, Santa Barbara, California, United States
}

\begin{abstract}
Recently, researchers in usage-based linguistics have argued that language should be thought of as a domain-general processing faculty operating on rich memory representations of particular experiences with language. If true, this would imply that context-dependent memory effects ought to be detectable across the language-nonlanguage boundary. Specifically, it would imply that that by manipulating nonlinguistic environmental context, it should be possible to influence people's linguistic production. This study reports three experiments testing whether environmental background color, music, or sound can influence participants' choice of active or passive voice in a picture-description task. Results suggest that the effect, if present, is not as clear-cut as has been argued by some language theorists, but there are promising signs that language production may indeed be susceptible to associative influence from the nonlinguistic environment.
\end{abstract}

\title{
Linguistic differences in explanation requests and their effects on the evaluation of explanations: the case of English and Turkish
}

\author{
Melih Barsbey \\ Bogazici University, Department of Psychology \\ Tania Lombrozo \\ University of California, Berkeley, Department of Psychology
}

\begin{abstract}
How does language shape thought? In particular, do cross-linguistic differences in how explanations are requested affect how explanations are evaluated by speakers of different languages? To address this question we contrasted English with Turkish, which has three distinct words that correspond to "why?" in English. Through two corpus studies and an experimental study, we established that Turkish "why" questions tend to appear in different contexts and elicit different kinds of explanations: the "why" questions vary in the frequency with which they refer to agents and elicit teleological explanations. In an experimental study investigating whether this cross-linguistic difference affects how explanations are evaluated, we found that while English speakers displayed an overall preference for mechanistic explanations in evaluating the stimuli, Turkish speakers provided similar satisfaction ratings for mechanistic and teleological explanations. Our findings have implications for the cognitive science of explanation and for debates about language and thought.

\title{
Effects of orthography on second language phonology: The production of geminate consonants in speakers of English as a Second Language
}

\author{
Benedetta Bassetti \\ University of York
}

\begin{abstract}
We tested the hypothesis that the orthographic representations ('spellings') of second language (L2) words affect experienced L2 speakers' pronunciation. In Italian, double consonant letters represent geminate (long) consonants. We predicted that Italian speakers of English would pronounce English words with longer consonants if spelled with double letter, e.g. a longer [t] in kitty than city. Three groups of Italian speakers of English performed different word production tasks with different stimuli: acoustic, acoustic and orthographic, or orthographic. The target voiceless stop consonants were presented inside 9 word pairs, spelled with one or two letters. Acoustic and auditory analyses revealed that the target consonants were longer in words spelled with double than with singleton letters, regardless of task. We argue that L2 speakers decode L2 orthographic representations using L1 orthography-phonology correspondences. This affects their pronunciation, even leading to the establishment of a phonological contrast (singleton-geminate) that is unattested in the target language.

Aligning Behaviors in Everyday Environments: An Ecological Perspective
}

\author{
Lucas Bietti \\ Institute for Advanced Study in the Humanities
}

\author{
Kasper Kok \\ VU University Amsterdam
}

\section*{Cienki Alan}

VU University Amsterdam

\begin{abstract}
Collaborative remembering is a joint activity that involves the establishment and reinforcement of a common ground. In this study, we investigate some ways in which collaborative remembering involves interactive coordination of non-verbal behaviors. Our data consist of video recordings of small groups of people that are reconstructing holiday memories together. For each 500 ms , these videos have been annotated in terms of the participants' bodily behavior and posture, including variables such as manual gesture, shoulder shrugs, leaning direction and gaze. We compared instances of 'simultaneous alignment' (two or more people concurrently performing the same behavior) and 'sequential alignment' (two people performing the same behavior in short temporal succession) to chance baselines, and found that the latter is more common that the former. Our analysis furthermore suggests that the degree to which participants coordinate their behaviors is stable across the course of the conversation (i.e., time-independent), but connected with specific activities within the larger discourse of collaborative remembering.
\end{abstract}

\title{
Preschoolers understand the representational and communicative nature of iconic gestures
}

\author{
Simone Bijvoet-van den Berg \\ University of Stirling, Stirling, Scotland, United Kingdom \\ Ulf Liszkowski \\ University of Hamburg \\ Elena Hoicka \\ University of Sheffield
}

\begin{abstract}
Twenty 3.5- to 4-year-olds participated in a study to investigate children's understanding of the representative and communicative nature of iconic gestures. Two toys, one of them with a sticker attached, were presented to the child. It was not possible to request the toy with the sticker by asking (experimenter wore headphones) or pointing (toys were too close together), but they could show the experimenter which toy they wanted by performing the correct gesture. Children had to generate the correct iconic gestures themselves as the gestures were not modeled during test trials. On \(70 \%\) of the trials children performed a correct gesture ( \(\mathrm{p}=.045\) ), instead of only producing other response types ( no response, verbal request, wrong gesture, pointing). This study shows that children understand that iconic gestures can represent objects, and also that they can use iconic gestures to communicate.
\end{abstract}

\title{
Modeling the genesis of a novel communicative system
}

\author{
Mark Blokpoel \\ Radboud University, Donders Institute of Brain, Cognition and Behaviour, Nijmegen, Gelderland, The Netherlands \\ \section*{Todd Wareham} \\ Memorial University of Newfoundland, St. John's, NL, Canada \\ Ivan Toni \\ Radboud University, Donders Institute of Brain, Cognition and Behaviour, Nijmegen, Gelderland, The Netherlands \\ \section*{Iris van Rooij} \\ Radboud University, Donders Institute of Brain, Cognition and Behaviour, Nijmegen, Gelderland, The Netherlands
}

\begin{abstract}
Recent work in experimental semiotics has started to investigate the cognitive processes supporting the emergence of human communicative systems. We present a computational model of the cognitive processes involved in establishing a novel referential communicative system, as operationalized with the Tacit Communication Game (TCG). This experimental paradigm has been used to study the socio-cognitive underpinnings of human communication. We model how players of the TCG can successfully generate and understand communicative behavior in a novel, visuospatial domain using Structure Mapping Theory (SMT).

Many of the processes necessary to communicate in this game are forms of analogical reasoning that are captured by SMT (e.g. abstraction and analogical transfer). Yet, we also identify cognitive processes-not yet formalized under SMT—that are necessary for the genesis of new communicative systems. This is an important first step in formally characterizing this creative socio-cognitive ability.
\end{abstract}

\title{
Metacognition in Decision-making - Influences of Signal Strength and Reliability
}

\author{

}

\begin{abstract}
Empirical evidence has accrued suggesting that we are able to evaluate our own thoughts and actions by means of metacognitive judgements. We are interested in how these are formed and what evidence they are based on. It has often been assumed that decision time is a frugal cue for confidence judgements: the longer it takes us to form a decision, the less certain we are. It could be, however, that this association is just a by-product of the underlying mechanisms, one of which could be variability in the accumulation of evidence. In our experiment, participants had to judge whether the average colour of an array of eight coloured shapes was either red or blue. We critically manipulated the variability of information in this multi-element array. Our results suggest that for conditions with matched difficulty, variability had a significant influence on confidence with more variable arrays leading to less confident judgements.

A. McAndrew \\ University of Exeter
}

\author{
Ian P. L. McLaren \\ University of Exeter
}

\begin{abstract}
This paper explores two current issues in human conditioning: It addresses whether human Pavlovian conditioning is the product of a single propositional system (Mitchell, De Houwer, \& Lovibond, 2009) or dual-systems; one propositional in nature and dependent on logical reasoning, the other functional, link-based, and dependent on statistical contingency (McLaren, Green, \& Mackintosh, 1994). Additionally, the current experiment provides insight into the processes underlying both A-B-A and A-B-C contextual renewal in humans; a process that is often explained using functional (Bouton, 2004; Pearce, 2002) or propositional (Havermans, Keuker, Lataster, \& Jansen, 2005) accounts. Participants were exposed to an electrodermal contextual renewal paradigm in a bi-conditional design, whilst measures of both conscious expectancy and autonomic skin response were collected. Our results demonstrated that, despite successful acquisition and extinction for both measures, contextual renewal was only observed for conscious expectancy in the A-B-A renewal condition.

\title{
Mechanisms of Active Causal Learning
}

\author{
Neil Bramley \\ University College London, London \\ David Lagnado \\ University College London,London
}

\section*{Maarten Speekenbrink}

University College London,London

\begin{abstract}
Existing studies on causal structure learning are largely restricted to single-shot interventions, usually in constrained or deterministic scenarios. However, real world causal learning is generally noisy, incremental and constrained only by prior beliefs. Here we describe experiments where participants were incentivised to infer the causal structure of probabilistic models through the free selection of multiple interventions. Participants' sequences of intervention choices and on-line structure judgements were measured against those of an efficient Bayesian learner, which integrates information perfectly and intervenes to maximise expected utility. Successful participants were systematic and learned effectively, but chose markedly different intervention sequences to those of a Bayesian learner. Overall, we find evidence suggesting that causal structure learning is achieved by iteration of simple action-selection and causal-attribution mechanisms.
\end{abstract}

\title{
Collaborative coactivation in visual search
}

\author{
Allison Brennan \\ University of British Columbia, Vancouver, British Columbia, Canada \\ James Enns \\ University of British Columbia
}

\begin{abstract}
Individuals experience a redundancy gain when they respond faster to two signals than one. This benefit can derive from statistical facilitation of independent decisions (Raab 1962) or from the co-activation of signals before a decision (Miller, 1982). Here we applied these tests to the redundancy gain that occurs when pairs of participants work together to detect targets. We also compared gains when each partner was responsible for one of two targets versus a different spatial region. The results showed pairs were more efficient than individuals, and that this gain was greater when the task was divided by target identity versus by space. We also found that the collaborative redundancy gain could be characterized as co-activation, meaning that the benefit of collaboration exceeded that predicted by statistical facilitation. These results serve as a proof of concept that models developed to understand information processing in individuals can help characterize collaborative performances.
\end{abstract}

\title{
What and When of Removing Virtual Gallbladders: Impact of Spatial and Temporal Aspects for Understanding Complex Diagrams
}

\author{
Angela Brunstein \\ RCSI Bahrain \\ Joerg Brunstein \\ Manama, Bahrain \\ Anam Waheed \\ TAMU-Q \\ Bakr Nour \\ WCMC-Q
}

\begin{abstract}
Reading complex graphs has been shown to be difficult for diverse groups of participants from different backgrounds and different levels of expertise in the task domain. This study investigated the impact of temporal and spatial task aspects for reducing complexity and increasing performance for a surgical task with medical students.

85 premedical and medical students solved an anatomy test on the gallbladder, a test on the steps of the procedure of removing the gallbladder, and a test combining both in a web-based survey. For all 3 tasks, performance increases with years in college. More interestingly, medical students performed best for the combined task and worst for the anatomy task.

This implies students could use temporal and spatial relationships to overcome knowledge gaps to solve the complex task. Having an idea what to do first and where to do it, helped students to reconstruct a complex surgical task.
\end{abstract}

\title{
Normative Dimensions of Generic Knowledge
}

\author{
Dennis Bublitz \\ CUNY, New York, NY, United States \\ Sandeep Prasada \\ CUNY, New York, NY, United States
}

\begin{abstract}
Some of our generic knowledge is based upon what we consider to be normal instances of kinds of things. We expect a normal dog to be four-legged; if it is not four-legged, we assume that something is wrong with this particular dog, or that it is incomplete as a kind of thing dog. Prasada \& Dillingham (2009) showed that one reason we expect certain properties to be present is because we understand them to be aspects of the kinds of things. Our research offered an alternative hypothesis: these normative expectations are due to these distinct properties being beneficial in some way. Four experiments investigated this using statements that prompted responses for normative expectations. We found that while the beneficence of these properties does underwrite normative expectations to an extent, the predominant understanding was that these expectations were grounded in the aspectual quality of these properties.
\end{abstract}

\title{
A hierarchical Bayesian model of conceptual knowledge transfer
}

\author{
Steven Buckingham \\ University of Oxford, Oxford, Oxfordshire, UK
}

\author{
Alice Redfern \\ University of Oxford \\ Christopher Summerfield \\ University of Oxford
}

\begin{abstract}
Agents generalise abstract conceptual knowledge across different contexts. For example, an individual negotiating a new computer program will draw upon experience with similar programs, such as how to use a drop-down menu. What are the rules governing such knowledge transfer? Here we offer a formal Bayesian account of generalisation, in which observers update a hierarchical model that incorporates knowledge about the statistical moments of the distribution from which information is drawn. We use this model to predict performance on a foraging task that involved hunting for hidden rewards in a virtual two-dimensional grid environment. In this task, contextual cues signalled not only the likely reward location (bivariate mean), but also the pattern (bivariate dispersion). Observers optimally integrated noisy cues about the probable reward location with information from these cues. This model and data offer a formal account of how humans learn abstract conceptual information.

\begin{abstract}
Acquiring new skills is not a set-in-stone process and students often take various paths to the goal; the acquisition of the required skill. To assess this learning process, previous studies used hidden Markov models to separate the cognitive stages of a problem solving task similar to solving algebraic equations (e.g. Anderson et al., 2012; Anderson, 2012). Because of the slow nature of fMRI recordings, this method can only discriminate between relatively long states in the process. This study extends the approach by including eye movements as a predictor of state, in an attempt to increase temporal resolution of the method. The results show that eye movements can be used to trace the characteristics of the problem the subject is working on. Because tracking eye movements is a non-invasive measure that can be used outside experimental settings, this can benefit the discovery of problems students encounter while solving algebraic problems.
\end{abstract}

\title{
The representation of polysemous words in semantic and episodic memory
}

\author{
Álvaro Cabana \\ Facultad de Ciencias - Universidad de la República, Uruguay \\ Camila Zugarramurdi \\ Facultad de Psicología - Universidad de la República, Uruguay \\ Juan Valle-Lisboa \\ Facultad de Ciencias - Universidad de la República, Uruguay
}

\begin{abstract}
Many controversies in cognitive science hinge around the divide between the general and the particular. In language research, the Declarative Procedural (DP) model proposes that procedural memory deals with the generalizable aspects of grammar, while exceptions are handled by declarative memories. Extending the DP model, we believe that the existence in memory of a semantic component which stores the prototypic information and an 'episodic' component that stores both the exceptions to the prototypes and the exceptionally common stimuli, could explain results on polysemia research. We studied the representation of polysemous words. We tested whether different senses of a polysemous word prime each other. Although in general there is no priming there are items showing positive priming and others showing inhibition. We then used bimodal priming in order to understand the effect of context in both types of items. Our results support the idea that lexical representation uses different memory systems.
\end{abstract}

Lev Michael
University of California, Berkeley
Terry Regier
University of California, Berkeley

\begin{abstract}
Languages partition the world in different ways-for example, the categories named by spatial terms vary substantially across languages. Yet beneath this linguistic variation there may lie universal cognitive tendencies. Khetarpal et al. (2010) found that speakers of Dutch and English, despite differences in their linguistic spatial systems, sorted spatial scenes similarly-and more like the finer-grained language, Dutch. We asked whether this preference for fine-grained sorting extends to two new languages: Máíhiki, a language of Peruvian Amazonia, with a fine-grained spatial system, and Chichewa, a Bantu language of southeast Africa, with a coarse-grained spatial system. Despite the great range in spatial naming represented across these languages-both in the granularity and the shape of their spatial categories-we found that speakers of all four languages sorted finely, and thus similarly to the finer-grained languages, Máíhiki and Dutch. These results suggest that spatial cognition, unlike spatial language, is universally fine-grained.

\title{
Coordinative Dynamic of Hierarchical Visual Processing
}

\author{
Ramon Castillo \\ Universidad de Talca - Univeristy of Cincinnati \\ Heidi Kloos \\ Univeristy of Cincinnati \\ John Holden \\ Univeristy of Cincinnati \\ Michael Richardson \\ Univeristy of Cincinnati
}

\begin{abstract}
In order to navigate and make sense of one's surroundings, a person must integrate pieces of information into larger wholes. On the flip side, the person also must be able to differentiate among more detailed pieces of information. Adaptive functioning requires the coordination of both processes, where one can flexibly switch from integrated higher-order patterns to differentiated details and vice versa. What is the nature of this coordination? Through fractal and recurrence quantification analyses used in three visual tasks (search, matching and classification), we provide evidence that this coordination has properties of dynamical systems, modulated by task features. Findings are discussed in terms of organism-environment coupling; in which local-global visual processing is conceptualized as a soft-assembled and self-organized system.
\end{abstract}

\title{
Language experience modifies the processing of visual input
}

\author{
Sarah Chabal \\ Northwestern University \\ Viorica Marian \\ Northwestern University
}

\begin{abstract}
The current study examined whether language experience affects the processing of visual information. SpanishEnglish bilinguals and English monolinguals completed a visual search task in which no overt linguistic information was provided. Participants were shown an image of a target (e.g., a chair) and were asked to locate that object from an array of four images while their eye-movements were tracked. English Competitor trials contained an item whose English name overlapped phonologically with the English name of the target (e.g., chair-chain); Spanish Competitor trials contained an item whose Spanish name overlapped phonologically with the Spanish name of the target (e.g., silla-silbato [chair-whistle]). Whereas all participants looked more often at English Competitor items than at items that did not overlap phonologically with the target, only the Spanish-English bilinguals looked more often at Spanish Competitor items. Results suggest that speakers with different language backgrounds vary in how they respond to non-linguistic, visual information.

\title{
Understanding Emergent Phenomena with Functional Schema
}

\author{
Margaret Chan \\ Columbia University
}

\begin{abstract}
Previous research has well-documented that naïve learners struggle when attempting to understand emergent phenomena. Misconceptions often arise as learners tend to apply patterns of cause-and-effect between entities to explain these emergent processes. We posited that comprehending emergence requires learners to construct a different conceptual model, namely a functional schema, emphasizing functional relationships among entities and their interactions that are central to how emergent phenomena arise. A promising strategy to promote generation of such functional schema is contrasting examples. This paper reported an intervention study with 86 middle school students examining the effect of contrasting scenarios in helping learners generate a functional-relationship-centered schema to understand global warming. Students' correct and misconceived explanations in pretest-posttest protocols were analyzed. Results showed contrasting scenarios motivated learners to develop the critical functional schema, which led to their eventual understanding of the mechanism of global warming. Implications on schema construction on understanding emergent systems are discussed.
\end{abstract}

\title{
Pedagogy and Technology: Balancing student-centric learning with teacher-centric teaching
}

\author{
Stephen Wee Hun Lim \\ National University of Singapore
}

\begin{abstract}
Technology can be used to create student-centric learning in diverse ways, including the use of social media platform(s) and interactive simulations to teach inductive thinking, and games to facilitate self-directed learning. But, teachercentric teaching is important as student-centric learning is; both aspects contribute to the student learning process, although the former has hardly been considered explicitly. Specifically, while technology develops apace, that teachers might continue to prefer traditional teaching modes and styles is an issue that should not be taken lightly, because teaching performances can be compromised if these modes and styles were compelled to evolve prematurely. I will particularly discuss the apprehensions that teachers might have as a technology-based teaching culture rapidly emerges, and how the dissonance between (non-)preferred modes of teaching and learning in this context might be resolved, in order to promote a technology-enhanced education system that ultimately benefits both teachers and students in a practical way.
\end{abstract}

\title{
Modelling Word and Object Naming in Pure Alexia
}

\author{
Ya-Ning Chang \\ Neuroscience and Aphasia Research Unit, University of Manchester \\ Matthew Lambon Ralph \\ Neuroscience and Aphasia Research Unit, University of Manchester \\ Steve Furber \\ Advanced Processor Technologies Group, University of Manchester \\ \section*{Stephen Welbourne} \\ Neuroscience and Aphasia Research Unit, University of Manchester
}

\begin{abstract}
Pure alexia (PA) is characterised by abnormally strong length effects in word reading times. It is often thought to result from damage to visual processing. This visual damage was also found to cause impaired object recognition performance (e.g., Roberts et al., 2012), suggesting a general visual deficit. Many computational models of reading have successfully simulated different forms of acquired dyslexia (e.g., Coltheart et al., 2001; Plaut et al., 1996). However, an adequate computational account of pure alexia has yet to be produced. We developed a large-scale and complete connectionist model with asymmetric hemisphere processing to support both word and object recognition. When damage was applied to the left visual processing layer in the model, the model produced abnormal length effects and impaired object recognition similar to those seen in PA patients. The results provide evidence to support the view of a common visual processing in visual word recognition.
\end{abstract}

\title{
Masked Repetition Effects of Chinese Compound Words Interact with Word Frequency because of Properties of Compound
}

\author{
Sau-Chin Chen \\ Department of Human Development, Tzu-Chi University, Taiwan \\ Zi-Han Chen \\ Department of Human Development, Tzu-Chi University, Taiwan
}

\begin{abstract}
Masked repetition has been suggested as the reliable paradigm investigating the pre-lexical processing of English words. This suggestion has the supportive evidence that masked repetition effects do not interact with word frequency. Chinese compound words are the combinations of two constituent characters which have independent lexical properties. The lemma model argues that the lemmas of constituents would increase masked repetition effects of low-frequency compound word when the constituent characters have relative higher frequency. To verify this argument, this study manipulated the frequency and the morphological aspects of constituent characters. The critical results are the increased masked repetition effect of low-frequency coordinative words which have at least one high-frequency characters and the null interaction of masked repetition effect and word frequency for the compound words having meaningless constituents. The approaches to modify the current lemma model are discussed according to these findings.
\end{abstract}

\title{
Writing-related Visual-motor Abilities in Children with Developmental Coordination Disorder
}

\author{
Rong-Ju Cherng \\ National Cheng Kung University \\ Yu-Han Su \\ National Cheng Kung University \\ Ting-Hui Wang \\ National Cheng Kung University \\ Yung-Jung Chen \\ National Cheng Kung University
}

\begin{abstract}
Twenty-five children with developmental coordination disorder (DCD) and 25 age- and gender-matched typically developing (TD) children were tested on writing-related visual motor tasks with a self-developed electronic assessment tools: "Writing Start". Children with DCD were diagnosed according to the DSM-IV diagnostic criteria. TD children were recruited from community. Twenty figures with different complexities and sizes were used in the tasks. Error number, error time, and error pathway, each representing a deficit in action, temporal and spatial motor control of writing movement, were compared between groups. The error number was significantly larger in the DCD group than that in the TD group. The error time and error pathway were also longer in the DCD group than that in the TD group, especially when the figures were smaller and more complicated. Children with DCD indeed have difficulties in mastering visual motor skills for writing.
\end{abstract}

\title{
The construal level theory and the dual process theory in multi-attribute decision making: An empirical examination
}

\author{
Itsuki Chiba \\ Department of Psychology, Rikkyo University, Japan \\ Takashi Tsuzuki \\ Department of Psychology, Rikkyo University, Japan \\ Kikuchi Manabu \\ Department of Psychology, Rikkyo University, Japan
}

\begin{abstract}
The compromise effect and attraction effect are examples of irrational choice in multi-attribute decision making. Their underlying mechanisms are assumed to be differences in the trade-off structure of each choice set. Recent research on the construal level theory showed that a high construal level decreases the compromise effect, but increases the attraction effect. Further, studies on the dual process theory showed that the depletion of participants' cognitive resources increases the attraction effect, but eliminates the compromise effect. It is therefore important to examine compensatory (or uncompensatory) information search based on trade-off structure in these context effects. We examined the influence of the construal level of participants' choices and the depletion of participants' cognitive resources for the above two context effects. Furthermore, we analyzed eye movements as a measure of the information search process, to examine the relationship between the construal level theory and dual process theory.
\end{abstract}

\title{
Beyond Berlyne's Conjecture: The Aesthetic Quality of Visual Patterns
}

\author{
Susan Chipman \\ unaffiliated
}

\begin{abstract}
Berlyne, the Canadian psychologist, famously conjectured that the aesthetic preference for visual patterns is an inverted-U function of their complexity. In my own research (Chipman, 1977), I developed and studied a large set of patterns, exploring what determined their judged complexity. These included patterns with several types of well defined structure, as well as randomly generated patterns. Several experiments explored the judged aesthetic quality of such patterns. Judged aesthetic quality was not any simple function of judged complexity. Not surprisingly, there are significant individual differences in aesthetic preference, including differences in preference for different types of visual structure.
\end{abstract}

\title{
Incremental Information Processing on Visual Search: The Critical Role of Delivery Rate
}

\author{
Eric Chiu \\ University of California, Merced (UCM)
}

Michael Spivey
University of California, Merced

\begin{abstract}
Recent studies show that visual search is often not well characterized as either a purely parallel or serial search strategy. Subsequently, the literature and computational models have evolved from traditional parallel and serial descriptions to a continuum of search efficiency. It has been demonstrated that search efficiency does not improve with simultaneous delivery of target features in a conjunction-search task. Interestingly, search efficiency does improve when non-linguistic visual delivery of target features appears incrementally and concurrently with the display onset, but not prior to display onset. In our current experiment, we explore the temporal constraints of the facilitatory effect found with concurrent incremental information processing. The results explain that linguistic and non-linguistic mediation of visual search, provided sufficient time to process, is chiefly due to the incrementality of target feature delivery when search has begun. This finding supports an interactive account of visual attention.
\end{abstract}

\title{
From Logical Positivism to Philosophical Thinking: Impacts and Implications on the Student-Learning Process
}

\author{
Dian Yi Chow \\ Hwa Chong Institution (College) \\ \section*{Stephen Wee Hun Lim} \\ National University of Singapore
}

\begin{abstract}
In schools today, students pursue individual academic subjects, such as physics, mathematics, and biology. By compartmentalizing these subjects, students may not be able to connect concepts from different disciplines competently to explain universal phenomena that occur in everyday living. Under this view, it is essential to inculcate an overarching philosophy with which one can capably unify all taught subjects. We first consider Logical Positivism as an overarching philosophy, and the benefits and implications of teaching it to students. We then illuminate the importance of inculcating broad-based philosophical thinking in students, and discuss how this pedagogical approach deepens students' understanding in, and increases their interest towards, the subject matter that they learn, as well as trains students' abilities to examine and interpret natural phenomena in logical ways.
\end{abstract}

\title{
FOXP2 as the Genetic Basis for the Capacity to Shift Between Analytic and Associative Modes of Thought
}

\author{
Courtney Chrusch \\ University of British Columbia \\ Liane Gabora \\ University of British Columbia
}

\begin{abstract}
It was previously proposed that the burst of creativity in the Middle/Upper Paleolithic following the appearance of anatomically modern humans was due to the onset of contextual focus, the capacity to shift between an associative mode of thought conducive to forging connections and breaking out of a rut, and an analytic mode conducive to logical problem solving. Hominids could then generate ideas in an associative mode, and refine them in an analytic mode, and process representations at multiple levels of detail, and from different perspectives. This resulted in richer understandings of their world. It is proposed that the FOXP2 gene, which evolved at this time, is responsible for onset of contextual focus. FOXP2 thereby created an unprecedented need for language to (a) keep track of representations for oneself, and (b) capitalize on different perspectives of others. This explains why FOXP2 is implicated in language but not uniquely associated with it.
\end{abstract}

\begin{abstract}
In Chinese, character configuration and orthographic combination are acknowledged to influence character recognition. Also, it was widely accepted that lexical access ability progresses as reading skills improved and vocabulary increased. The present study aims to reveal the effects of configuration type and radical properties by comparing different development stages of Chinese learning. A character decision task was used in which radical position-based frequency and radical position regularities within two different configurations were manipulated. 15 third-grade 27 sixth-grade schoolers, and 41 undergraduate students were asked to identify whether the 120 pseudo-words conform to radical position regularities. Accuracy was recorded as measurement to examine the effects of configuration and orthographic combination. The analysis revealed different patterns of frequency effect and regularity effect between the two configurations. Furthermore, age variation was observed for both types of configurations. In conclusion, orthographic and configuration knowledge are acquired gradually and play distinct roles in Chinese recognition.

\begin{abstract}
Previous research assumed the eye movement patterns change along with the growth of word knowledge while children become skilled readers. In this study, the effects of orthographic and configuration information on Chinese character recognition were investigated by comparing eye movement patterns from a developmental perspective ( 15 third-grade 27 sixth-grade schoolers, and 41 undergraduates). Eye movement patterns were recorded in a character decision task by varying configuration type (left-right, up-down), radical position-based frequencies (HH, HL, LH, LL), and radical position regularities (P, SN, WN). The results showed that the two different configurations lead to different eye movement patterns: (1) radical position regularity effect was only significant at the left-right configuration for all age groups; (2) frequency effect and development variation appeared for both two configuration types. These findings highlight the importance of configuration knowledge and orthographic awareness for learning Chinese characters.
\end{abstract}

\title{
"You talkin' to me"? Understanding communicative intentions recruits the mirror and the mentalizing system
}

\author{
Angela Ciaramidaro \\ University of Frankfurt \\ Cristina Becchio \\ University of Turin \\ Livia Colle \\ University of Turin \\ \section*{Bruno Bara} \\ University of Turin \\ Henrik Walter \\ Charité University of Berlin
}

\begin{abstract}
In our daily social interactions we can infer others people intentions from the observation of their actions. In general, two brain systems, the mentalizing and the mirror neuron system, have been implicated in understanding other's intentions. However, there is little knowledge whether and how these two systems may cooperate in correctly understanding communicative interactions. We used functional MRI to establish how mirror and mentalizing regions contribute to the implicit encoding of communicative intentions, proposing that being directly involved during social interaction would be mediated by both systems. In particular, we investigated the involvement of those systems in distinguishing communicative from private intentions as well as other directed ("third-person perspective") from self-directed ("second-person perspective") intentions. Categorical and functional connectivity analyses showed that the mentalizing and the mirror neurons system were simultaneously involved in processing communicative intentions in general and more strongly coupled in self directed communicative actions.

How does this thing work? Evaluating computational models of intervention-based causal learning
}

\author{
Anna Coenen \\ New York University
}

\author{
Bob Rehder
}

New York University

\section*{Todd Gureckis}

New York University

\begin{abstract}
The present study explores how people learn about a causal system by interacting with it. Participants were given the task to identify the operation of virtual '"computer chips" by setting the value of various components and observing how those interventions influenced the setting of other components. Across conditions we manipulate the complexity of the causal system (i.e., number of nodes and connections), the number of alternative hypotheses (i.e. possible causal graphs) on each trial, and aspects of the "temporal stability" of the learning environment (if repeated interventions were made on a single, stationary system or if the system reset to different starting states following each intervention). Interventions were modeled by comparing them to an optimal Bayesian learner who chooses interventions to quickly reduce uncertainty about the structure. Our results suggest that naive Internet-recruited subjects choose highly informative interventions, but also deviate from the predictions of the optimal model in certain ways.
\end{abstract}

\title{
Individual differences in shape bias are predicted by non-linguistic perceptual ability
}

University of Calgary

\author{
Bernard Grela \\ University of Connecticut
}

Tammie Spaulding
University of Connecticut
Jay Rueckl
University of Connecticut and Haskins Laboratories
James Magnuson
University of Connecticut and Haskins Laboratories

\begin{abstract}
Children with Specific Language Impairment (SLI) lag behind peers with typical language (TL) in vocabulary. We ask what impact this lag has on shape bias (generalization based on shape in Naming contexts ["here's a dax; find another dax"] but not Classification contexts ["look at this; find another like this"). Smith (2000) argues that shape bias depends on and drives vocabulary development; vocabulary is a basis for detecting covariation between objects and names, and name learning accelerates once the bias emerges. 51 three and four year-old children ( 16 SLI, 16 matched TL, 19 additional TL) participated in Naming and Classification tasks, a paired visual association (PVA) task, and an assessment battery. The SLI group was significantly worse at PVA and did not exhibit a shape bias. Individual differences revealed wide variation in both groups, and that shape choices in Naming were better predicted by PVA than standardized assessments.
\end{abstract}

\title{
Temporal motor dynamics in inductive reasoning
}

\author{
Steve Croker \\ Illinois State University, Normal, Illinois, USA
}

\section*{Corinne Zimmerman}

Illinois State University

\begin{abstract}
We investigated the temporal dynamics of response choice in a decision-making task by examining the evolving implicit responses indicated by hand movements made before an explicit response is selected. Participants ( \(\mathrm{N}=31\) ) judged which of two cars would go faster when the underlying rule was plausible or implausible and when two response choices differed with respect to one or two causal variables. Participants completed 300 trials in five blocks. We found an interaction between trial type, block, and plausibility of rule. In earlier trials in the implausible rule condition, there was greater deviation towards the distracter response before selecting the correct response. Participants given implausible rules demonstrated less activation of competing representations over time as they induced the underlying rules, particularly on trials in which response choices differed on both causal variables. Mouse trajectories did not change across blocks for participants given the plausible rule, suggesting they learned the rule early.
\end{abstract}

\title{
Where is the insight in insight problems?
}

\author{
Amory H. Danek \\ Ludwig-Maximilians-Universität München, Munich, Germany \\ \section*{Michael Öllinger} \\ Parmenides Foundation and Ludwig-Maximilians-Universität München, Munich, Germany
}

\begin{abstract}
Insightful problem solving is a vital part of human thinking, yet very difficult to grasp. The "Aha! experience" is often regarded as the defining characteristic of insight. Traditionally, insight has been investigated by using a set of established "insight tasks", assuming that insight has taken place if these problems are solved. However, the debate about which problems actually trigger insight is still not resolved, since there is no clear behavioural marker for the occurrence of insight. In the present work, we therefore aimed at testing the validity of three classical insight problems by directly asking participants about their solution experiences. Our results suggest that participants solve insight problems also without any Aha! experience, casting doubt on the common approach of using a priori defined insight problems. Consequently, we advocate the use of direct insight ratings by participants, determining for each problem individually whether it was solved with insight or not.
\end{abstract}

Graphical Overviews Structure Online Learning: Evidence from Eye-Tracking
}

\author{
Sarah Davies \\ University of Utah \\ Kirsten Butcher \\ University of Utah
}

\author{
Anne Cook \\ University of Utah
}

\begin{abstract}
Previous research has examined the use of graphical overviews as a way to structure students' self-regulated, online learning. Although findings have suggested that graphical overviews can improve learning from online content, there has been little direct evidence as to why this benefit may occur. In this research, eye tracking and verbal protocols were gathered as 26 pre-service teachers used a graphical overview or keyword interface to choose online resources for an educational task. Fixation times and pupil diameter were analyzed as measures of cognitive effort; results demonstrated that pupil diameter was significantly lower when participants used the graphical as compared to the keyword interface. Protocol analysis was used to examine the depth of processing during search and evaluation; results showed that participants using the graphical overview engaged in deeper analysis of domain content. Results provide evidence for the importance of graphically-based cognitive offloading during "searching to learn" tasks.

Cultural Variation in Families' Shared Engagement
}

\author{
Andrew Dayton \\ University of California Santa Cruz \\ Barbara Rogoff \\ University of California, Santa Cruz
}

\begin{abstract}
Cultural Variation in Families' Shared Engagement
This study examines whether Indigenous-heritage Mayan mothers and their young children are more likely than middleclass European American mothers and their children to engage by blending agendas in fluid collaboration while exploring novel objects together. Fluid collaboration appears to be encouraged in many Indigenous communities of the Americas, where children often collaborate in ongoing family and community endeavors (Rogoff, 2003; Mozier \& Rogoff, 1993, 2003). The present research submits audio signals of videotaped observations of mothers and their children in home interactions to microanalysis using spectrographs, to compare the interactions of Mayan and European American families (Gratier, 2003, 2013; Malloch, 1999; Trevarthen, 2008). In the visual representations of their vocalizations, we find evidence that the Mayan families more frequently use smooth collaboration whereas the middle-class European American families appear to struggle more to establish a shared rhythm in their interactions.

\title{
High level influences on visual action recognition
}

\author{
Stephan de la Rosa \\ Max Planck Institute for Biological Cybernetics, Tübingen, Germany \\ Stephan Streuber \\ Max Planck Institute for Biological Cybernetics \\ Martin Giese \\ Centre for Integrated Neuroscience at the University of Tübingen \\ Heinrich Bülthoff \\ Max Planck Institute for Biological Cybernetics, Tübingen, Germany \\ \section*{Cristobal Curio} \\ Max Planck Institute for Biological Cybernetics, Tübingen, Germany
}

\begin{abstract}
Action recognition is important for social interactions. Because little is known about the visual tuning properties of processes involved in action recognition, we examined the visual tuning properties of action recognition by means of a behavioral adaptation paradigm. Participants were adapted to images showing a person hitting or waving and subsequently categorized test images showing an ambiguous action as either hitting or waving. We found the perception of the test images to be significantly biased away from the adapted action (action adaptation aftereffect (AAA)). Subsequent experiments ruled out that the AAA was not merely driven by the adaptation of local visual contrast or the emotional content of the action. However adaptation to action words (e.g. "hitting" or "waving") did not induce an AAA. Finally we found evidence for the AAA being modulated by the social context in which an action is embedded, suggesting high level influences on action recognition.

\title{
Variables Influencing the Nature of Learned Categorical Perception Effects
}

\author{
Josh de Leeuw \\ Indiana University \\ Jan Andrews \\ Vassar College
}

\section*{Ken Livingston}

Vassar College

\begin{abstract}
Considerable research has demonstrated so-called learned categorical perception (CP) effects, where learning to classify a set of stimuli leads to either compression (within-category stimuli judged to be more similar and/or confusable than before learning) or expansion (between-category stimuli judged to be less similar and/or confusable than before learning) or both. The issue of why category learning causes one type of effect or the other has not been systematically investigated, but previous research suggests that highly discriminable stimuli may tend to produce compression while stimuli that are difficult to discriminate may tend to produce expansion. We report a series of studies testing the effect of stimulus discriminability on the type of learned CP effect produced using both similarity and XAB measures of the effects. Preliminary results suggest that different measures of categorical perception reveal different effects, and that category structure may also be relevant.

Limits in Reasoning about False Beliefs in Adults: the Effect of Priming or the Curse of Knowledge?
}

\author{
Agnieszka Debska
}

University of Warsaw
Krystyna Komorowska
University of Warsaw

\begin{abstract}
Birch \& Bloom (2007, Psych. Sc. 18, 382-386) suggest that adults' reasoning about others' mental states is influenced by their privileged knowledge about reality. When asked where a person described in the story would search for a missing object, subjects tend to judge with higher probability that the person would search in a particular box, when they know that the object is indeed in that box. However, the results of their experiment could be an effect of unintended priming in the materials, i.e., the increased attention towards the box might be also caused by reading about it in the task instructions. In a new version of the experiment, we controlled for this factor by priming different locations in the instructions. The results show that it is unlikely that priming is the source of the Birch and Bloom's observations: only knowledge about reality changes the strategies in reasoning about others' actions.

\title{
Agency and attention influence the perceived speed of a moving stimulus
}

\author{
John Dewey \\ Central European University
}

\author{
Thomas Carr \\ Michigan State University
}

\begin{abstract}
The sensory consequences of intentional actions are perceived to be attenuated compared to equivalent but externally generated stimuli. It is thought that forward models in the sensorimotor system partially cancel predictable reafferent sensory feedback in order to bias attention towards more novel or unexpected stimuli. But does merely observing familiar actions also trigger forward models with attendant sensory attenuation? Previous studies investigated this question in the auditory modality with conflicting results. We conducted two attenuation experiments in a visual modality to conceptually replicate and generalize previous findings (Exp 1), and to control for differences in temporal predictability and attention which may have confounded previous studies (Exp 2).

We found that movements initiated by humans (self or other) were attenuated compared to computer movements, and selfinitiated movements were the most attenuated. Adding Go signals prior to movements counteracted attenuation. Perceived speed is thus influenced by agency as well as attention.
\end{abstract}

\title{
When does the causal information externally given affect causal inferences?
}

\author{
Kyung Soo Do \\ Sungkyunkwan University, KOREA \\ Rae-yeop Park \\ Sungkyunkwan University, KOREA
}

\begin{abstract}
Many previous studies showed that the causal information externally given (hereafter external information) did not succeed in changing the causal structure driven from the covariation data when the external information and the covariation data were in conflict. We speculated that the salience of the external information is crucial in causal inference. The external information did not affect the causal inference when the external information and the covariation data were simultaneously presented in Experiment 1. However, when the external information and the covariation data were sequentially presented and participants were asked to report the causal structure and the strength each time in Experiments 2 and 3, participants were more likely to report the causal structure of the external information when the covariation data were drawn from a different causal structure. Results of the three experiments showed that the external information can override the covariation data under certain conditions.
\end{abstract}

\title{
Do voices survive lexical consolidation?
}

\author{
Nicolas Dumay \\ Basque Center on Cognition, Brain and Language \\ Jeffrey Bowers \\ University of Bristol, UK
}

\begin{abstract}
Learning new words involves consolidation. After one night's sleep, not only is explicit knowledge about the novel words enhanced, but the new words also now compete with similar-sounding existing words (Dumay \& Gaskell, 2007) during word recognition. The present study assessed whether lexical consolidation strips off surface details of newly learned words, producing more abstract representations. We manipulated the speaker's voice between exposure and test. Participants learnt one set of novel competitors (such as 'shadowks' for 'shadow') seven days before the test, and another set immediately before the test. Each word was learnt in a male or a female voice, and was tested in either the same or the other voice. Cued recall and phoneme monitoring showed stronger memory for the seven-day old items and, if anything, an enhanced voice effect (i.e., better performance in the same voice condition) after seven days. Crucially, our most indirect measure of lexical competition showed that only the seven-day old items (as expected) engaged in lexical competition, but only when the input preserved the voice in which they had been encoded. These findings indicate that consolidation does not make word representations more abstract: voice specific details do not just survive lexical consolidation; they are enhanced by it.
\end{abstract}

\title{
External Normalization: Testing a Cognitive Offloading Account
}

\author{
Timothy Dunn \\ University of Memphis, Memphis, TN, United States \\ Srdan Medimorec \\ Arizona State University, Tempe, AZ, United States \\ Evan Risko \\ University of Memphis, Memphis, TN, United States
}

\begin{abstract}
When individuals are presented with complex arrays at non-canonical orientations (e.g., rotated text) they frequently physically rotate to approximate the orientation of the stimulus (i.e., external normalization). One view of this natural behavior is that individuals are offloading internal cognitive demands (e.g., internal normalization) by adopting an external solution (i.e., external normalization). We test this account here by combining a stimulus rotation manipulation with a stimulus repetition manipulation. Previous research has demonstrated that stimulus repetition reduces the cost of stimulus rotation on performance. In other words, repetition putatively reduces the "internal" costs of stimulus rotation. Thus, stimulus repetition should reduce the frequency of external normalization. Consistent with the cognitive offloading account, repetition reduced the frequency of spontaneous physical head rotations while individuals read rotated text. Discussion focuses on the implication of these results for understanding cognitive offloading and the embodied and embedded nature of cognition.
\end{abstract}

\title{
Examining the transitions between decision strategies
}

\author{
Gilles Dutilh \\ University of Basel \\ Benjamin Scheibehenne \\ University of Basel \\ Han L. J. van der Maas \\ University of Amsterdam \\ Jörg Rieskamp \\ University of Basel
}

\begin{abstract}
In many domains of cognitive psychology, it is proposed that people are equipped with a repertoire of strategies to solve the problems they face. For instance, it is proposed that when people use multiple cues to make a probabilistic inference about a criterion, they sometimes rely on simple heuristics and sometimes apply more elaborate additive strategies. Indeed, many studies suggest that people's inferences can be described by different strategies in different situations. However, critics of this view suggest that people do not apply different strategies but instead adjust one single strategy to the characteristics of each situation. Here we examine the strategies that individuals use when available resources change. Therefore, we continuously change the cost of deliberation time. The behavior of participants at the transition from fast and simple behavior to slow but optimal information integration offers insight into whether people select different strategies or continuously adjust one single strategy.
\end{abstract}

\title{
The Influence of Direct and Indirect Speech on Mental Representations
}

\author{
Anita Eerland \\ Open University \\ Jan Engelen \\ Erasmus University Rotterdam \\ Rolf Zwaan \\ Erasmus University Rotterdam
}

\begin{abstract}
Language can be viewed as a set of cues that subtly modulate the comprehender's thought processes. For example, the literature suggests that people perceive direct speech as more vivid and perceptually engaging than indirect speech. We sought to address how this alleged vividness is evident in comprehenders' mental representations in a series of experiments. Our results do not support the idea that, compared to indirect speech, direct speech enhances the accessibility of information from the communicative or referential situation during comprehension. Neither do our results support the idea that the hypothesized more vivid experience of direct speech is caused by switching from the visual to the auditory modality. However, our results do show that direct speech leads to a stronger mental representation of the exact wording of a sentence than does indirect speech. These results show that language has a more subtle influence on memory representations than was previously suggested.
\end{abstract}

\title{
Explanation and Fractions: How Preferences for Types of Explanations Affect Learning
}

\author{
Emma H. Geller \\ UCLA \\ James W. Stigler \\ UCLA
}

\begin{abstract}
Explanation is often cited as an effective learning tool, but much work remains to determine the influence of explanations on different types of material to be learned. Evidence from category learning suggests that explanation may drive the learner to identify underlying regularities that fit a general pattern (Williams \& Lombrozo, 2010). In a pilot study, we examined whether explanation could be used to improve understanding of fraction magnitudes and whether explanations of specific inequalities are more or less effective than explanations of sets of inequalities. Results revealed that generating single or set explanations did not affect test or transfer accuracy, but individuals indicated strong and consistent preferences for particular types of explanations (i.e. conceptual, procedural, or rule-based). Further studies are being conducted to identify individual differences that may predict preferences for different kinds of explanations and their effect on subsequent learning and understanding.
\end{abstract}

\title{
Language and Spatial Attention: Words Evoke Independent Codes for Objects and Locations
}

\author{
Zachary Estes
}

Bocconi University

\author{
Michelle Verges \\ Radically Independent
}

James S. Adelman
University of Warwick

\begin{abstract}
Many common words have spatial associations (e.g., "bird," "snake," "jump", "crawl") that influence perception at congruent and incongruent locations. For example, "bird" hinders identification of a square at the top of a display. Many researchers have attributed this spatial interference to location-specific perceptual simulations: The word "bird" shifts attention upward and evokes the perceptual representation of a bird, which impairs identification of an unrelated visual target either by visually masking it or by engaging the neural systems necessary for visual perception. However, we report that a large sample of nouns (Experiment 1) and verbs (Experiment 2) of high and low imageability (and visual strength) elicited equivalent spatial interference. Thus, perceptual simulation failed to explain the spatial interference effect. Experiment 3 instead supported an event coding explanation: Target objects are coded for their congruence with both the cue word and its implied location, and conflicting codes interfere with responding.

\title{
The temporal dynamics of choice blindness: flat detection rates and short-term preference alterations
}

\author{
Ilya Farber \\ Institute of High Performance Computing, A*STAR \\ Fumihiko Taya \\ SINAPSE Institute for Cognitive Science and Neurotechnologies, National University of Singapore \\ Swati Gupta \\ Institute of High Performance Computing, A*STAR \\ O'Dhaniel Mullette-Gillman \\ Department of Psychology and SINAPSE Institute for Cognitive Science and Neurotechnologies, National University of Singapore
}

\begin{abstract}
Since the original experiments on choice blindness for faces (Johansson et al 2005), many studies have extended the phenomenon to other domains but few have focused on attaining a deeper understanding of the phenomenon itself. We here report on an experiment which closely follows the original study (albeit in computerized form and with a Singaporean population), with additional elements aimed at explicating the causal structure and temporal dynamics of the underlying processes.

Contrary to intuition, we find that subjects who notice and immediately report a "manipulation" trial still miss about half of subsequent manipulation trials. Detection is also found to be highly sensitive to the form and timing of the opportunities to report. We also investigate the effects of choice manipulation on attractiveness ratings, finding that manipulations do modulate subsequent attractiveness ratings but that this effect falls below significance after a 2 -week interval.
\end{abstract}

\title{
Perceptual Word-Form Typicality Effects Are Modulated by Strength of Expectation During Reading
}

\author{
Thomas Farmer \\ Department of Psychology, University of Iowa \\ Klinton Bicknell \\ Department of Psychology, University of California-San Diego \\ Michael Tanenhaus \\ Department of Brain and Cognitive Sciences, University of Rochester
}

\begin{abstract}
A growing literature suggests that readers generate predictions about various aspects of incoming linguistic input. Do expectations from context map onto lower-level expectations, and if so, how? We propose that comprehenders use internally generated predictions to explain the source of the input. In two experiments, we tracked eye-movements as subjects read sentences that generated strong (The boy saved the xxx) or weak (Mary had the word "xxx" tattooed ...) expectations for nouns. Across contexts, subjects encountered target words (xxx) that had visual-form features that were either typical or atypical of nouns. In strongly predictive contexts, first-fixation and gaze duration measures were longer when the form of the target word was atypical with respect to the predicted category. In the less-biased contexts, no effect of word-form typicality occurred. These experiments provide eye-movement evidence that linguistic context is used to generate perceptual expectations about form-based properties of upcoming words during reading.
\end{abstract}

Towards identifying principles for clinical intervention in developmental language disorders: Establishing a neurocomputational foundation
}

\author{
Anna Fedor \\ Birkbeck College London \\ Wendy Best \\ University College London \\ Jackie Masterson \\ Institute of Education University of London
}

Michael S. C. Thomas
Birkbeck College London

\begin{abstract}
We used a simple artificial neural network model to begin the work of understanding what principles underlie effective interventions for developmental disorders of language and cognition, from the perspective of neurocomputational mechanisms of development. The work aims to complement a clinical perspective of the principles of effective intervention. Our study explored the effectiveness of different types of intervention modeled as items added to the normal training set. We assessed whether best interventions were specific to problem domains, specific to deficit types, and/or dependent on when in development they take place.
\end{abstract}

Harald Baayen
Tubingen University

\begin{abstract}
Models of word recognition assume that information about the orthographic form of a word (morpheme) must be available before access to that word's (morpheme's) meaning is possible. In prior work we have demonstrated that semantic similarity influences even early morphological priming (Feldman, Kostić, Gvozdenović, O’Connor, \& Martín, 2012; Feldman \& Martín, 2009).

In two experiments conducted in English, we used a forward-masked lexical decision task to assess whether processing differs after exhaustively decomposable (stem+affix; e.g., pastor-PAST) and partially decomposable (stem+nonmorphemic string; e.g., pasta-PAST) primes in semantically dissimilar prime-target pairs.

Results using linear mixed effect models on inverse transformed (-1000/RT) latency data with two separate PCs for the contributions of form (negative) and for frequency (negative) and previous RT as a predictor, failed to show different patterns of facilitation after exhaustively and partially decomposable primes; both of which differed from unrelated controls. Spelling did not interact with prime type but poor spellers varied more across the session.
\end{abstract}

\title{
Supporting Self-Regulated Learning in Conceptual Feedback Environments
}

\author{
Kirsten R. Butcher \\ University of Utah \\ Lisa A. Ferrara \\ University of Utah
}

\begin{abstract}
Prior research in learning with graphic organizers has revealed that learners can make use of graphical overviews to increase their learning in online environments, especially when these visual supports are provided before learning. This research examined the extent to which the format of feedback in an online learning environment impacts students' processes and outcomes during a self-regulated learning task. Students wrote scientific essays that were analyzed by a personalized learning service (the customized learning service for conceptual knowledge: CLICK). Feedback on essay content was presented using either a visual (node-link) representation or a (text-based) list view. Preliminary data reveal that learners presented with the visually-based feedback engaged in more effective self-regulated learning processes (i.e., planning and goal-setting) compared to learners provided with list-based feedback. Results demonstrate that the format of external feedback in self-regulated learning environments play an important role in supporting students' implementation of effective self-regulated learning strategies.
\end{abstract}

\title{
Do Parents Adapt Descriptions of Spatial Relationships to Child Knowledge?
}

\author{
Katrina Ferrara \\ Johns Hopkins University, Baltimore, MD, US \\ Colin Wilson \\ Johns Hopkins University, Baltimore, MD, US \\ Katherine Kelliher \\ Johns Hopkins University, Baltimore, MD, US \\ Malena Silva \\ Johns Hopkins University, Baltimore, MD, US \\ Barbara Landau \\ Johns Hopkins University, Baltimore, MD, US
}

\begin{abstract}
Language is a collaborative act: to successfully communicate, speakers must generate semantically valid utterances that are sensitive to the knowledge state of the listener. We asked whether parents' spatial descriptions are tuned to their children's spatial knowledge. Parent-child pairs ( \(n=16\), m child age \(4 ; 1\) ) viewed identical complex spatial arrays on separate computer screens. Parents were asked to describe target objects so that their child could identify them on their own screen. Children's knowledge of left/right was independently tested using a comprehension task. A hierarchical statistical model of the experimentally elicited spatial language predicted that the probability of parents using left/right was greater for children that achieved higher comprehension scores, indicating successful communicative adaptation. This result did not hold for parents of children with severe spatial impairments (Williams Syndrome), suggesting that there is considerable variation in how well parents tune their language to their children's level of spatial language and knowledge.
\end{abstract}

\title{
Using Graphical Organizers to Improve Self-Regulated Learning: Constructive Activities Enhance Deep Learning with Online Materials
}

\author{
Lisa A. Ferrara \\ University of Utah
}

\author{
Kirsten R. Butcher \\ University of Utah
}

\begin{abstract}
The interactivity framework (Chi, 2009) proposes learners experience greater learning benefits as they become more generative with learning material. This research investigated the active-constructive-interactive framework in the context of graphical organizers before a self-regulated, online learning task. Graphical displays were node-link diagrams, where nodes identified important domain concepts and link labels described the relationship between concepts. Conditions examined: passive (in which nodes and links were provided); active (in which nodes were provided and learners revealed link labels on demand); and constructive (in which nodes were provided and learners generated link labels). Findings were consistent with the interactivity framework for constructive learners, who integrated more concepts into posttest concept maps and included more deep (relational/causal) statements in their posttest essays. However, there were no significant differences for passive and active conditions. Results demonstrate that constructive activities may be necessary to support deeper learning outcomes in activities used before self-directed learning tasks.
\end{abstract}

\title{
Constant entropy rate and related hypotheses versus real language.
}

\author{
Ramon Ferrer-i-Cancho \\ Universitat Politecnica de Catalunya
}

\section*{Lukasz Debowski}

Polish Academy of Sciences

\begin{abstract}
Constant entropy rate (CER) and uniform information density (UID) are two hypotheses that have been put forward to explain a wide rage of linguistic phenomena. However, the concrete definition of these hypotheses is unclear for statistical research and a direct and in-depth evaluation of these hypotheses from their definition is missing to our knowledge. Here we consider four operational definitions of UID: full UID (UID holding for any combination of elements making the utterances), strong UID (UID holding for any utterance that has non-zero probability) and initial UID (strong UID holding for utterances beginning with a particular element). Here we examine the logical dependencies between these hypotheses. The comparison of the assumptions and predictions of these hypothesis with Hilberg's law and other statistical properties of real human language indicates that CER and related hypotheses are qualitative different from actual language and suggests that these hypotheses are incomplete and must be revised.
\end{abstract}

\title{
The origins of analogy
}

\author{
Alissa Ferry \\ Scuola Internazionale Superiore di Studi Avanzati \\ Susan Hespos \\ Northwestern University \\ \section*{Yin-Juei Chang} \\ Northwestern University \\ Emily Hollenbeck \\ Northwestern University \\ Dedre Gentner \\ Northwestern University
}

\begin{abstract}
We investigated the origins of analogical ability in 7-month-old infants, using the simplest and most basic relation - that of sameness and difference between two things. Experiment 1 showed infants were unable to detect and generalize these relations from a single exemplar (as suggested in Tyrrell et al., 1991). Experiment 2 used a habituation-dishabituation paradigm and found that infants could generalize the same-different relation to novel objects with six to nine training trials. Experiment 3 demonstrated that labels influenced performance: labeling the relation enhanced performance, but labeling the individual objects hindered performance. In addition, we varied infants' prior experience with the objects and found signatures of relational learning have continuity across development. In summary, abstraction of relations can be facilitated by comparison across exemplars, disrupted by the saliency of individual objects, and manipulated by labeling. These findings are discussed in light of recent debates about phylogenetic continuity in relational abilities.
\end{abstract}

Using Xbox Kinect to explore spatial-numerical association of arm movements in parity judgments.
}

\author{
Yariv Festman \\ University of Potsdam
}

Oliver Lindemann
University of Potsdam

\author{
Martin Fischer
}

University of Potsdam

\begin{abstract}
Spatial-numerical associations were initially studied using chronometric methods to reveal the orientation of the mental number line (SNARC effect; Dehaene, Bossini, and Giraux, 1993). Recent evidence has shown that unconstrained spatial movements can be valuable in the study of embodied number representations (Fischer and Campens, 2009). We used the Xbox Kinect to record arm movements in a parity judgment task. We replicated SNARC in the horizontal dimension and found a similar trend in the vertical dimension. Movement amplitudes were also affected by number magnitude. Together, these results generalize evidence for the mental number line to everyday behaviors and suggest that natural user interfaces (NUI) can be used to study embodied cognition.
\end{abstract}

\title{
From Complex to Collaborative Problem Solving
}

\author{
Andreas Fischer \\ Heidelberg University, Heidelberg, Germany \\ Daniel Holt \\ Heidelberg University, Heidelberg, Germany \\ Julia Hilse \\ Heidelberg University, Heidelberg, Germany \\ Joachim Funke \\ Heidelberg University, Heidelberg, Germany
}

\begin{abstract}
Research on human problem solving may be about to face a conceptual change from individual to collaborative problem solving. Many challenging problems in the real world are solved by groups or teams. This is increasingly recognized by the problem solving research community, which traditionally has emphasized cognitive processes in individual problem solving. In this paper we argue how approaches for investigating complex problem solving can be conceptually extended towards collaborative problems solving. We will present several current examples of how to measure collaborative processes in a standardized way. One example is the InBox HD, a computer-based in-basket simulation with collaborative elements. The second example is the scenario Product Planning, implemented in the ColPS HD framework, which involves chat-based human-to-agent communication. We will elaborate on how these tools can be used to emulate realistic collaborative processes in the standardized setting of a psychological laboratory and indicate directions for future developments.
\end{abstract}

\author{
Institute of Psychology \& Courant Research Centre Evolution of Social Behaviour", University of Göttingen, Germany \\ Stephen Butterfill \\ Department of Philosophy, University of Warwick, UK \\ Hannes Rakoczy \\ Institute of Psychology \& Courant Research Centre Evolution of Social Behaviour", University of Göttingen, Germany
}

\begin{abstract}
Children solve explicit false belief (FB) tasks around age 4 but implicit tasks (e.g. helping) in infancy (e.g. Buttelmann et al., 2009). Nativist accounts claim early conceptual competence, masked by performance factors (e.g. Leslie, 2005); sceptical accounts deny competence before age 4 (Perner \& Ruffmann, 2005). A recent two-system-theory (Apperly \& Butterfill, 2009) provides an alternative explanation: an early mindreading-system (1) tracks simple forms of mental states and a later flexible capacity (2) allows cognitively demanding inferences based on a fully-developed concept of belief. Because system 1 operates on relational rather than propositional attitudes it has clear flexibility-limits: it can represent FB 's about object location but not FB's about identity.

We contrasted 2.5 -year-olds' helping behavior in a 2 (identity/location) X 2 (false/true belief) design. Results suggest limited performance in the identity compared to the location task. Implications of this finding are discussed and follow-up studies will be presented.
\end{abstract}

\title{
Individual differences in 3D pointing performance between passengers and drivers
}

\author{
Julia Frankenstein \\ Freiburg University, Freiburg, Germany \\ Christoph Hölscher \\ Freiburg University, Freiburg, Germany
}

\begin{abstract}
While most studies in the spatial cognition literature focus on pointing in a two-dimensional context, (i.e., directional estimates in a horizontal plane), the mechanisms of pointing in 3d-space (i.e., direction estimates including up and down) are much less clearly understood. Based on a paradigm of Vidal \& Berthoz, a virtual tube system providing a highly controlled environment, we designed a study comparing 3d pointing performance (i.e., pointing backward to the starting point or pointing forward to the end point of the experienced route) following active (drivers) vs. passive (passengers) exploration. Furthermore, we assessed the individual memory strategies reflected in self-reports and related these to pointing performance and reaction times.
\end{abstract}

\title{
Automatic classification of patients with mental disorders according to voice dynamics
}

\author{
Riccardo Fusaroli \\ Aarhus University, Aarhus, Denmark \\ Kristian Tylén \\ Aarhus University, Aarhus, Denmark \\ Arndis Simonsen \\ Aarhus University, Aarhus, Denmark \\ Ethan Weed \\ Aarhus University, Aarhus, Denmark
}

\begin{abstract}
Anomalous aspects of speech and voice, including pitch, fluency, and voice quality, are reported to characterize many mental disorders. However, it has proven difficult to quantify and explain this oddness of speech by employing traditional statistics methods.

In this study we employ Recurrence Quantification Analysis (RQA) to investigate the temporal dynamics of voice in three mental disorders. We elicited monological descriptions of short videos in patients with schizophrenia, depression and Asperger's, as well as in related matched controls. We applied RQA to fundamental frequency, speech pause sequences and speech rate. The Rqa indexes (trend and entropy in particular) enable us to quantify and automatically discriminate between populations with \(>85 \%\) of accuracy, highlighting distinctive voice dynamics in each diagnoses.
\end{abstract}

\title{
Conversation, Coupling and Complexity: Matching Scaling Laws Predict Performance in a Joint Decision Task
}

\author{
Kristian Tylén \\ Aarhus University, Aarhus, Denmark \\ Drew Abney \\ UC Merced, Merced (CA), USA \\ Bahador Bahrami \\ UCL, London, UK \\ Christopher Kello \\ University of California, Merced (CA), USA \\ Riccardo Fusaroli \\ Aarhus University, Aarhus, Denmark
}

\begin{abstract}
We investigate the linguistic co-construction of interpersonal synergies. By applying a measure of coupling between complex systems to an experimentally elicited corpus of joint decision dialogues, we show that interlocutors' linguistic behavior displays increasing signature of multi-scale coupling, known as complexity matching, over the course of interaction. Furthermore, we show that stronger coupling corresponds with more effective interaction, as measured by collective task performance.
\end{abstract}

\title{
Completing the Puzzle: Online Processing during Novel Noun Generalization
}

\author{
Megan Galligan \\ University of Iowa \\ \section*{Larissa Samuelson} \\ University of Iowa
}

\begin{abstract}
When building a lexicon, young children must first learn individual word-object mappings and subsequently extend these mappings to new category instances. Recent methodological advances demonstrate that processing efficiency during the initial mapping process increases between 15 and 24 months-of-age. The current study investigates real-time processing during the second word learning step, generalization. Using a head-mounted eye-tracker, 18-month old children completed a novel noun generalization task with novel solid objects. Many participants generalized names for solid objects based on similarity in shape rather than similarity in material. The addition of eye-tracking data in the current study reveals children's comparison of test and exemplar objects both before and after novel name presentation. Integrating eye-tracking data with measures of vocabulary knowledge can elucidate how vocabulary organization speeds the generalization decision. Future work will manipulate syntactic context to examine how children's knowledge of count and mass nouns further influences the generalization decision process.
\end{abstract}

Bilingualism change axonal structural network organization
}

\author{
Lorna Garcia Penton \\ Basque Center on Cognition, Brain and Language (BCBL), Donostia, Guipuzcoa, Spain
}

\author{
Alejandro Perez Fernandez \\ Basque Center on Cognition, Brain and Language (BCBL), Donostia, Guipuzcoa, Spain \\ Yasser Iturria-Medina \\ Cuban Neuroscience Center (CNC), La Habana, Cuba. \\ Manuel Carreiras \\ Basque Center on Cognition, Brain and Language (BCBL), Donostia, Guipuzcoa, Spain
}

\begin{abstract}
How the brain deals with more than one language and whether we need different or extra brain language subnetworks to support more than one language is unanswered question. Here, we investigate structural brain network differences between early bilinguals and monolinguals. Using diffusion-weighted MRI (DW-MRI) tractography techniques and a networkbased statistic (NBS) procedure (Zalesky et al., 2010), we found two structural sub-networks more connected by white matter (WM) tracts in bilinguals than in monolingual; confirming WM brain plasticity in bilinguals (Luk et al., 2011; Mohades et al., 2012; Schlegel et al., 2012). One of these sub-networks comprises left frontal and parietal/temporal regions, while the other comprises left occipital and parietal/temporal regions and also the right superior frontal gyrus. Most of these regions have been related to language processing and monitoring (Abutalebi and Green, 2007); suggesting that bilinguals developed specialized language sub-networks to deal with the two languages. Additionally, a complex network analysis showed that these sub-networks are more graph-efficient in bilinguals than monolinguals and these increase seems to be at the expense of a decrease in whole network graph-efficiency.

\title{
Infants' ability to discriminate between statements and questions
}

\author{
Susan Geffen \\ University of Southern California \\ Toben Mintz \\ University of Southern California
}

\begin{abstract}
Children must distinguish between statements and questions in order to accurately acquire language, but it is unclear when or how they do it. Experiment 1 examined whether prosodic characteristics of infant-directed questions and statements could differentiate them. Statements and yes/no questions differed on several dimensions, but statements and wh-questions did not. Experiment 2 tested whether 11-13-month-olds could nevertheless distinguish sentence types using lexical information. Half the infants were familiarized to statements, the remainder to questions. All infants were tested on new sentences of both types. Sentences were resynthesized to have monotone pitch and matched utterance-final vowel length, neutralizing any prosodic differences. Overall, there was a significant novelty preference and no interaction of trial type with familiarization type. Thus, while prosody is insufficient for distinguishing wh-questions from statements, by 11-months infants can use word order to distinguish statements and questions. This ability could provide an important foundation for acquiring syntactic knowledge.
\end{abstract}

\title{
Neural Correlates of Perceiving Dyadic Social Interactions
}

\author{
Alexandra Georgescu \\ University Hospital of Cologne, Cologne, NRW, Germany \\ Bojana Kuzmanovic \\ University Hospital of Cologne, Cologne, NRW, Germany \\ Natacha Santos \\ University Hospital of Cologne, Cologne, NRW, Germany \\ Ralf Tepest \\ University Hospital of Cologne, Cologne, NRW, Germany \\ Gary Bente \\ Department of Psychology, University of Cologne, Cologne, NRW, Germany \\ Marc Tittgemeyer \\ Max-Planck Institute for Neurological Research, Cologne, NRW, Germany \\ Kai Vogeley \\ University Hospital of Cologne, Cologne, NRW, Germany
}

\begin{abstract}
The aim of the present study was to determine the differential contributions of the action observation network (AON) and the social neural network (SNN) to the experience of naturalness in observed dyadic social interactions. To this end, we used short animation sequences displaying social interactions between two virtual characters and systematically manipulated kinematic features of the social dynamics. A group of 21 male participants rated the "naturalness" of the observed scenes on a four-point scale while undergoing fMRI. Using the ratings of each participant as a parametric modulation of their general neural response to the stimuli, we found that an increase in naturalness experience was associated with higher activations in the AON. The SNN was preferentially recruited with a decrease in naturalness experience. This indicates that understanding familiar interactions involves an automatic kinematic processing of intentionality, while interactions perceived as artificial require higher-level inferential processing.
\end{abstract}

\title{
Imagined Effort Affects Object Localization and Sense of Agency
}

\author{
Devin Gill \\ Illinois State University \\ \section*{J. Scott Jordan} \\ Illinois State University
}

\begin{abstract}
Individuals who continually track an object that suddenly vanishes indicate perceived vanishing points displaced beyond the actual vanishing point (i.e., forward displacement: FD) (Hubbard, 1995). Jordan, Coey, and Tsippaaoutis (2009) demonstrated that FD increases with implied friction (i.e., low to high friction) if one controls stimulus movements. Metcalfe and Greene (2007) showed that manipulations of stimulus control affected judgments of agency. The present experiment examined the extent to which implied friction and conceptual factors (Reed \& Vinson, 1996) affect feelings of agency during stimulus control. Participants controlled the movements of a trapezoidal stimulus labeled as either a "bullet train" or a "house" in two levels of implied friction. Results revealed a marginally-significant increase in FD with implied friction. Agency also varied significantly between implied friction conditions, but only when participants conceptualized the stimulus as a bullet train and implied friction decreased across blocks (i.e., implied effort became optimal).

Explorations in Human and Machine Learning of Decision Trees
}

\author{
Kevin Gluck \\ U.S. Air Force Research Laboratory \\ Jack Harris \\ U.S. Air Force Research Laboratory \\ Thomas Mielke \\ U.S. Air Force Research Laboratory \\ \section*{Christopher Myers} \\ U.S. Air Force Research Laboratory \\ Vladislav Veksler \\ U.S. Air Force Research Laboratory
}

\begin{abstract}
We explore the boundaries of learnability, ecological rationality, and decision robustness in uncertain, non-stationary, finite-sample environments. Our approach combines machine-learning-based heuristic search techniques with the Integrated Learning Model (ILM) computational cognitive process theory of human and animal learning. The scientific contributions of this research are in understanding whether and how decision heuristics are acquired in binary classification contexts, with an emphasis on fast and frugal decision trees. The real world relevance of this research is in improved decision training and aiding.
\end{abstract}

\title{
The Role of Conceptual and Perceptual Information on Inductive Reasoning in Early Childhood
}

\author{
Karrie Godwin \\ Carnegie Mellon University
}

\author{
Bryan Matlen \\ Carnegie Mellon University
}

\author{
Anna Fisher \\ Carnegie Mellon University
}

\begin{abstract}
There is an ongoing debate about the relative contribution of conceptual and perceptual information to inductive generalization in early childhood. In the classic study bearing on this debate, pictures representing familiar animals were arranged such that category membership was supposed to be in conflict with perceptual similarity. However, later studies revealed that most of the stimuli in this study failed to impose this conflict. The present study revisited this issue. Extensive calibration was conducted to ensure that the two sources of information were in conflict. Despite near-ceiling accuracy in identifying the category membership of objects used in the study (e.g., bird-bird-bat, dog-dog-cow, cat-cat-raccoon, etc.), 4-year-old children relied on their knowledge of category membership only \(55 \%\) of the time when there was strong conflict between category membership and perceptual similarity. These findings will be discussed in relation to alternative accounts of knowledge acquisition and generalization early in development.
\end{abstract}

\title{
Perception and action effects on causal judgment
}

\author{
Kelly Goedert
}

Seton Hall University

\author{
Mengqi Guo
}

Seton Hall University

\begin{abstract}
Recent research suggests that perception and action affect performance on cognitive tasks (e.g., Beilock \& GoldinMeadow, 2010; Landy \& Goldstone, 2007). Here we investigated perceptual and motor influences on causal judgment from contingency using a causal discounting paradigm (e.g., Goedert \& Spellman, 2005). Participants learned about two potential causes of a common outcome on a trial by trial basis. We varied the left/right location of a target cause and the left/right location of the "yes" response button for predicting the cause would produce the outcome. When there was a mismatch between the target location and the "yes" response, participants discounted. However, they did not discount when the two locations matched. Thus, we observed more accurate causal judgment with spatial overlap in the perception and action information. These results are generally consistent with an embodied cognition framework; however, their exact mechanism remains to be explored.

\title{
Effects of Brief Analogical Training after Two-Week Delay
}

\author{
Micah Goldwater \\ Northwestern University \\ Dedre Gentner \\ Northwestern University
}

\begin{abstract}
There is considerable evidence that analogical comparison can foster STEM learning. For example, Gentner, Levine, Dhillon, \& Poltermann (2009) used comparison to teach 6-8-year-old children an important engineering principle: namely, that a diagonal brace confers stability in construction. Children compared two buildings, one with a diagonal brace, and one with a horizontal (nonbracing) piece instead. After the comparison, children were shown an unstable building, and were given a piece to stabilize it. Children who received the comparison training were more likely to attempt to stabilize the building with a diagonal placement of the piece. We extended this research to (a) test for retention after two weeks and (b) examine effects of relational labeling (which has been theorized to support long-term retention) The results indicate that the training utilizing comparison and relational labeling elicited more diagonal placements both after a brief delay, and after a delay of two weeks.
\end{abstract}

\title{
Interactions between bilingualism and non-linguistic spatial processing
}

\author{
Monica Gonzalez-Marquez \\ Cornell University
}

Raymond Becker
Bielefeld University
\(\underset{\text { Cornell University }}{\text { James Cutting }}\)

\begin{abstract}
The relationship between language and space has been intensely investigated. The underlying question has been whether one affects the other, usually within the scope of spatial language. Largely ignored is the possible role of bilingualism. Given that the average person speaks more than one language, and the mounting evidence showing that bilingualism interacts with non-linguistic processes (e.g., Bialystok \& Senman, 2004), we investigated what effect bilingualism would have on nonlinguistic spatial processing.

We tested 120 participants with a range of linguistic abilities using four classic spatial tasks, e.g. mental rotation. We found patterns of systematic interaction between bilingualism and spatial processing. These findings raise questions beyond the relationship between spatial language and spatial cognition, suggesting that language as a cognitive process may share a common neural substrate with space.

\author{
Yongju Kim
}

Korea Military Academy

\section*{Anne Marie Porter \\ UNC Charlotte}

\section*{Kathryn Weatherford}

UNC Charlotte

\begin{abstract}
A series of experiments were conducted to examine conceptual priming within and across modalities with pictures and environmental sounds. In Experiment 1, we developed a new multimodal stimulus set consisting of two picture and sound exemplars that represented 80 object items. In Experiments 2 and 3, we investigated whether categorization of the stimulus items would be facilitated by picture and environmental sound primes that were derived from different exemplars of the target items. The results demonstrated that the categorization of environmental sounds and pictures were facilitated in a similar way by conceptually related exemplars presented in advance, but only when a long inter-stimulus interval ( 1000 ms ) was used. Additionally, conceptual cross-modal priming effects by picture and sound primes were asymmetric with systematic switch costs across modalities and with differences in the time-course of activation.
\end{abstract}

\title{
Taking Someone Else's Perspective: When Body "Position" is More Important than Body "Presence"
}

\author{
Michelle D. Greenwood
}

University of California, Merced

\author{
Justin L. Matthews \\ University of California, Merced \\ Michael J. Spivey \\ University of California, Merced \\ Teenie Matlock \\ University of California, Merced
}

\begin{abstract}
Taking another person's perspective when describing spatial scenes is more common when a person is present in the scene. (Tversky \& Hard, 2009). What about seeing another person elicits an allocentric perspective?

Participants were shown one of a variety of pictures displaying a book and cup placed, side-by-side, on a table. Some photos also pictured a man sitting behind the table, either facing the camera or facing to the left or right. Viewers were more likely to take the man's perspective while describing object locations when the man was facing the camera than when the man was facing to either side.

Many factors influence which perspective people take. These results suggest that the mere presence of a person in a scene does not guarantee a viewer will take someone else's perspective, but rather the way a person is positioned in a scene might also be of critical importance.
\end{abstract}

\title{
Test Expectancy Effects on Metacomphrenesion, Self-regulation, and Learning
}

\author{
Thomas Griffin \\ University of Illinois at Chicago \\ Jennifer Wiley \\ University of Illinois at Chicago
}

Keith Thiede
Boise State University

\begin{abstract}
Metacomprehension monitoring accuracy is defined as the ability to accurately predict how well one will do on a later test of learned material. Metacomprehension monitoring is presumed to be a critical skill for the effective self-regulation of study behaviors that impact learning. In two experiments, ecologically valid science texts and inference tests were employed to examine whether a test expectancy intervention could improve students' metacognitive judgments, self-regulated study, and learning outcomes. Experiment 1 was a lab experiment in which test expectancies were instilled only after reading was complete, thus preventing any encoding effects. Results suggest that test expectancies impact metacomprehension monitoring accuracy via selection of more valid cues at the time of judgment rather than only via encoding effects that impact cue accessibility. Experiment 2 was a classroom study showing that the effect of test expectancies on monitoring accuracy translates into more effective self-regulated study and improved learning.

\title{
Prisoner's Dilemma Games between Friends and Foes: Looking for Simpson's Paradox Effects in Cooperation
}

\author{
Maurice Grinberg \\ New Bulgarian University \\ Stevan Tomic \\ New Bulgarian University
}

\section*{Evgenia Hristova}

New Bulgarian University

\begin{abstract}
The paper explores the cooperation rate in one-shot Prisoner's Dilemma games in three cases - when the game is played among friends, among foes, and among a mixture of friends and foes. The paper checks empirically the prediction that Simpson's paradox like effects are to be expected in this situation (Chater, Vlaev, \& Grinberg, 2008). The existence of a bias for cooperation when playing with friends and for defection when playing with foes, is expected to lead to a reinforcement of cooperation based on higher average payoffs in the mixed condition, i.e. when playing with friends and foes together. At the same time, the average payoff for cooperation remains lower for games with friends and foes taken separately (Simpson's paradox). There results of the experiment support the existence of such effects and suggest that further exploration is worthwhile.
\end{abstract}

\title{
Big Number Politics: The Effects of Training on Large Number Estimation in Fiscal Deficit-reducing Proposals.
}

\author{
Brian M. Guay \\ University of Richmond \\ David Landy \\ University of Richmond
}

\begin{abstract}
How do we make sense of the 43 million or 1.3 billion dollar budget cuts that are being made in Congress? Large quantities such as these are common in our political discourse, yet recent studies demonstrate substantial and systematic biases in evaluating them (Landy, Silbert \& Goldin 2012). We explore how the integration of numerical and political information affects voters' evaluation of political scenarios, and more specifically the effect of number training on this evaluation. The current study investigates the effects of a number training intervention on the numerical estimation task and evaluation of deficit-reducing proposals using a within-subjects design and a typical voting population. Participants in the training condition completed a number estimation task (Siegler \& Opfer 2003) and were shown the accurate location of 1 million on a number line from 10 thousand to 1 billion. Line estimation and situation evaluation were assessed before and after the intervention.
\end{abstract}

\title{
Consistency in Degrees of Morality
}

\author{
Eoin Gubbins \\ Trinity College Dublin, Dublin, Ireland \\ Ruth Byrne \\ Trinity College Dublin, Dublin, Ireland
}

Phil Johnson-Laird
New York University

\begin{abstract}
We examined people's ability to judge the degree of morality of good and bad actions, and their consistency in doing so. Participants judged the degree of morality of actions on a scale from +100 (moral) through 0 (neither) to -100 (immoral). They judged the degree of morality for individual actions e.g., 'a man intervened to stop a fight', 'a man gave blood', and their conjunction, 'a man intervened to stop a fight and he gave blood'. Most judgments were consistent, i.e. the conjunction was judged to be more moral or immoral than its components. However, a reliable number of judgments were inconsistent, i.e. the conjunction was judged to be less moral or immoral than one or both of its components. Consistency improved when participants read the conjunction after the conjuncts, compared to when they read it before. We discuss implications for understanding the mental representation of degrees of morality.
\end{abstract}

\title{
Creativity: Investigating Construct Validity across Cultures
}

\author{
C. Dominik Güss \\ University of North Florida, United States \\ Ma. Teresa Tuason \\ University of North Florida, United States \\ Yetuli de Baessa \\ Universidad Francisco Marroquín, Guatemala \\ Nila Shah \\ Shri Jasani Arts and Commerce College, Rajkot, India \\ \section*{Angela Thomas} \\ University of Pretoria, Republic of South Africa
}

\begin{abstract}
Creativity is the drive for advancement in many aspects of society such as arts, economy, or science. It is unclear if creativity consists of several different skills and abilities or if it is one core construct. It is also unclear to what extent creativity is influenced by culture and to what extent creativity constructs can be generalized across cultures. To investigate these questions, we administered three different creativity tests assessing fluency, originality, flexibility, and creative achievement to over 900 students in five countries: Germany, Guatemala, India, South Africa, and the United States. Results showed weak correlations between the different aspects of creativity speaking for heterogeneity of different creativity constructs, across all cultures. Whereas participants from the five countries did not differ in their creative achievements, they differed in the cognitive creativity measures. Results are interpreted referring to the eco-cultural context and existing cognitive frameworks of creativity.

\title{
Exploration and Discovery in Children with Autism
}

\section*{Hyowon Gweon \\ MIT}

\author{
Hannah Pelton \\ MIT
}

Rebecca Saxe
MIT

\section*{Laura Schulz}

MIT

\begin{abstract}
ASD is diagnosed by perseverative behaviors and social deficits. While ASD children's selective interest in the physical world may lead to more extensive exploration (and learning) of physical objects, they may learn less due to their perseverative behavior. How is exploration affected in children with ASD? We quantified exploration and discovery as children with ASD ( \(\mathrm{N}=35, \mathrm{M}=8.5 \mathrm{yrs}\) ) and their controls ( \(\mathrm{N}=35\), age, IQ matched) explored a novel toy with hidden functions. ASD children showed more perseveration than controls on every measure, and the diversity of their actions was negatively correlated with severity of autism. Furthermore, ASD children discovered less hidden functions than controls. While the control group showed a marked decrease in perseveration with age, ASD group showed a heightened level of perseveration independent of age. These data suggest that children with ASD show marked difference in their exploration of the physical environment, and this difference has real consequences for learning and discovery.
\end{abstract}

\title{
Inferring mass in complex physical scenes via probabilistic simulation
}

\author{
Jessica Hamrick \\ University of California, Berkeley \\ Peter Battaglia \\ Massachusetts Institute of Technology \\ Thomas Griffiths \\ University of California, Berkeley \\ Joshua Tenenbaum \\ Massachusetts Institute of Technology
}

\begin{abstract}
How do people learn underlying properties, such as mass and friction, from objects' interactions in complex scenes? Such inferences are difficult: the parameters cannot be directly observed and have nonlinear effects on the physical dynamics. Yet, people learn them. Participants predicted the stability of blocks stacked in complex tower configurations. After observing the true outcome, they answered, "which blocks are heavier?". Their responses indicate rapid learning of the blocks' relative masses. We view such learning as probabilistic inference in a generative model of Newtonian rigid-body dynamics, and express this hypothesis in a model observer that infers parameters using a procedure of approximate physical simulation. While participants' judgments qualitatively matched the model's, they also deviated in key ways that may be explained by resource limitations. This work advances our understanding of how people infer unobserved physical properties, and offers a framework for modeling such behavior in complex, real-world scenes.
\end{abstract}

\title{
Predictive processing of musical structure: effects of genre-specific expertise
}

\author{
Niels Chr. Hansen \\ Center of Functionally Integrative Neuroscience, Aarhus University Hospital, Denmark
}

\begin{abstract}
Expectations are generated with different degrees of predictive uncertainty prior to onset of musical events. This study explored influences of genre specific expertise in non-musicians, classical, and jazz musicians listening to unfamiliar Charlie Parker solos.

Two probabilistic computational models of expectation were trained: one on folksongs (General), the other on jazz (Bebop). Twenty-four melodies were selected whose final notes differed in Shannon entropy estimated by the two models. Listeners' uncertainty was assessed explicitly and inferred from expectedness ratings of different continuation tones.

The analysis showed that jazz musicians followed 'Bebop' and non-musicians followed 'General'. Classical musicians showed some decoding of the jazz style, utilising a somewhat underdeveloped version of 'Bebop'. Moreover, experts experienced more salient prediction errors in low-entropy contexts, and musical skills predicted the extent of cognitive model optimisation.

Our results suggest that expertise entails both possessing an accurate predictive model and selecting an optimal model for the given context.
\end{abstract}

\title{
On the relationship between perceived foreigness, accentedness and speech comprehension under clear and adverse listening conditions
}

\author{
Adriana Hanulikova \\ University of Freiburg
}

\author{
Frank Eisner \\ MPI for Psycholinguistics
}

\begin{abstract}
Social interaction involves the simultaneous uptake of a range of linguistic and nonlinguistic information. In a seminal study, Rubin (1992) has shown that a lecture spoken by a native speaker of Standard American English presented along with a photograph of an ethnically Asian instructor affected comprehension score and accentedness ratings more negatively as compared to the same lecture and speaker presented with a Caucasian instructor. Here we asked whether such effects could be observed in a multicultural environment, with a lot of interactions with different ethnicities and non-native speakers. Furthermore, we investigated how the effect could be modulated by the quality of the speech input (clear compared to noisy speech). The results showed that ethnicity affects accentedness ratings only under adverse listening conditions and that comprehension scores do not depend on ethnicity of the speaker. Thus, the effect of nonlinguistic information on linguistic processing is constrained in multicultural settings.
\end{abstract}

\title{
Understanding the Role of Context in Memory for Maximally Counterintuitive Concepts
}

\author{
Mary Harmon-Vukic \\ Providence College \\ M. Afzal Upal \\ Defence Research \& Development Canada \\ Caitlin Trainor \\ Providence College
}

\begin{abstract}
The effect of minimally counterintuitive information on memory is well established. However, less work has addressed the processing of maximally counterintuitive stories (i.e., stories containing at least three domain violations). The current study examined memory for maximally counterintuitive stories. The first two experiments investigated whether explicit instruction to make sense of "strange information" influenced memory for maximally counterintuitive stories. Although no such effect was observed, post hoc analyses indicated that the extent to which concepts in maximally counterintuitive stories contained domain violations from similar or different categories influenced memory performance; stories with similar domain violations enjoyed a memory advantage. The third study addressed the believability of concepts with similar domain violations with a rating task. Participants were more likely to agree with two counterintuitive concepts with similar domain violations compared to a single counterintuitive concept. The results are discussed within Upal's (2005; 2009) context-based view of memory for counterintuitive ideas.
\end{abstract}

The effect of goal reification on error rates while solving geometric problems
}

\author{
Robert Hausmann \\ Carnegie Learning, Inc., Pittsburgh, PA, United States
}

\author{
Annalies Vuong \\ Carnegie Learning, Inc., Pittsburgh, PA, United States
}

\begin{abstract}
An effective learning environment is designed to expose student misconceptions because, once explicit, they are available for remediation. How does one design such an environment, and what are the consequences for learning? In a previous study, we demonstrated that a significant revision to the Cognitive Tutor Geometry intelligent tutor had a generally positive effect on the speed of skill mastery (Hausmann \& Vuong, 2012). However, the revised version demonstrated a higher error rate for easy skills. We hypothesized that the revised interface reified certain mental steps that students were previously allowed to complete implicitly. Specifically, students are now required to write an expression for the length of the side of a special right triangle before calculating the length. While the error rate for the calculation remained low ( \(1.71 \%\) ), writing the expression proved to be particularly difficult (13.93\%). We contrast the evidence supporting this hypothesis with evidence for other potential explanations.
\end{abstract}

\title{
Real-Time Strategy: Multi-Level Dynamics in an Uncertain Environment
}

\author{
Robert Hawkins \\ Indiana University
}

\author{
Robert Goldstone
}

Indiana University

\begin{abstract}
As an agent gathers information about its environment and monitors the decisions of other agents, its behavior may fluctuate adaptively over short time scales while still maintaining a long-term strategy. We designed a real-time virtual environment to experimentally investigate the relationship between the micro-level dynamics of dyadic behavior within single games and the macro-level dynamics of outcomes across iterated games.

In one experiment, participants played a real-time game of "chicken," simultaneously guiding avatars toward high-payoff or low-payoff targets. If both participants reached a demarcated vicinity of a target at the same time, that target was destroyed. We recorded their trajectories, and induced uncertainty by adding noise to their movement speeds. At the macro-level, we found evidence of self-organized turn-taking across repeated games. At the micro-level, we found that even within a turn-taking equilibrium, both players competitively pursued the high payoff for a period of time before one of them diverted.
\end{abstract}

\section*{Children's understanding of lying related to intention.}

\section*{Hajimu Hayashi}

Okayama University

\begin{abstract}
Children's conception of lies has been important issues for children's cognitive development. However, little is known about whether children's understanding of lies is different form adults' one. Four kinds of stories were presented for children aged 6- to 7-year olds and undergraduate students. First, a protagonist had a deceptive intention and produced a false statement. Second, he had a deceptive intention but produced a true statement by a false belief. Third, he had a truthful intention and produced a true statement. Fourth, he had a truthful intention but produced a false statement by a false belief. The results showed that undergraduate students judged that these protagonist's statements were lying or not by considering his intentions. By contrast, children judged regardless of his intentions. These results suggest that children's conception of lying is different from adults' one, and that their conception becomes sophisticated after middle childhood.

\title{
Patient Knowledge and Satisfaction in Decisions About Lung Cancer Surgery
}

\author{
Josh A. Hemmerich \\ The University of Chicago \\ Mark K. Ferguson \\ The University of Chicago \\ Daniel P. Sulmasy \\ The University of Chicago \\ Arthur S. Elstein \\ University of Illinois at Chicago \\ Cindy Warnes \\ The University of Chicago \\ \section*{Masha Kochrginsky} \\ The University of Chicago \\ \section*{Rita Gorawara-Bhat} \\ The University of Chicago \\ Kellie Van Voorhis \\ The University of Chicago \\ William Dale \\ The University of Chicago
}

\begin{abstract}
Medical care is increasingly implementing shared decision making that requires participation of informed patients in an effort to maximize treatment-related decision satisfaction (DS). Patient comprehension of relevant information is important in decisions involving high risk and uncertainty, like surgery for lung cancer.

Lung cancer patients ( \(\mathrm{N}=43\) ) completed pre- and post-consult questionnaires, and their consults with the surgeon were audio recorded.

Post consult knowledge was low ( \(53 \%\) ) while DS was moderately low ( \(\mathrm{M}=44.56\), \(\mathrm{SD}=13.71\) ). Higher complication risk ( \(\mathrm{rs}=\) .34, \(\mathrm{P}<.05\) ), external locus of control ( \(\mathrm{r}=.31, \mathrm{P}<.05\) ), belief in a controlling deity ( \(\mathrm{r}=.37, \mathrm{P}<.05\) ), and desire for control ( r \(=-.38, \mathrm{P}<.016\) ) predicted lower DS. Consult recordings showed that patients possess counterfactual beliefs, such as airborne spread of cancer in surgery, and benefit from removing most of the tumor. Experiments are needed to understand how patient comprehension can be improved.
\end{abstract}

\title{
Baby physics: expectations about liquid and sand in 5-month-old infants
}

\author{
Susan Hespos \\ Northwestern University
}

\author{
Alissa Ferry \\ Scuola Internazionale Superiore di Studi Avanzati \\ Emily Hollenbeck \\ Northwestern University \\ \section*{Lance Rips} \\ Northwestern University
}

\begin{abstract}
Infants have expectations about physical properties of solid objects. However, evidence on infants' understanding of nonsolid substances (e.g., water or sand) is sparse and equivocal. We conducted four habituation/dishabituation experiments demonstrating that 5-month-olds have distinct expectations for how objects and substances behave. Experiment 1 found that infants use motion cues from the surface of a contained liquid or solid to predict whether it would pass through or rest on a grid when the container was upended. Experiment 2 extended these findings to show that motion cues led to different expectations about whether a new object will pass through or remain on the top surface of a liquid or solid. Experiments 3 and 4 replaced the liquid with sand. We found that infants expected sand, like liquid, to go through a grid, but did not expect another object to pass through it. These findings begin to characterize infants' understanding of substances.
\end{abstract}

\title{
The timing of turns in mother-infant interactions: A Longitudinal Study
}

\author{
Elma Hilbrink \\ Max Planck Institute for Psycholinguistics, Nijmegen, Netherlands \\ Merideth Gattis \\ Cardiff University \\ Elena Sakkalou \\ Neurosciences Unit, UCL Institute of Child Health \\ Kate Ellis-Davies \\ Cambridge University \\ Stephen Levinson \\ Max Planck Institute for Psycholinguistics
}

\begin{abstract}
Turn-transition in adult conversation is remarkably precise, with a median close to zero milliseconds. This means one needs to predict the end of their interlocutor's turn to come in on time. The interaction engine hypothesis (Levinson, 2006) suggests the ability to appropriately time turns in social interaction is realized early in development, before and independent of language. Few studies have assessed timing of turn-taking in infant development. We analyzed video-recordings of 12 motherinfant dyads at 12 and 18 months in free-play interactions. Findings indicate that in the first half of the second year of life infants become more skilled in taking turns in vocal exchanges as evidenced by decreasing onset times of their turns (median = 700 ms at 18 months) as well as a decrease in number of onsets produced in overlap with their mothers, which at 18 months is at the maternal level of overlapping onsets produced (20\%).
\end{abstract}

\title{
Working Memory and Abstract Representation in the Context of Culture
}

\author{
Mark Ho \\ Brown University, Providence, Rhode Island, USA \\ Fiery Cushman \\ Brown University, Providence, Rhode Island, USA
}

\begin{abstract}
As a species, humans stand out for superior cognitive capacities, including improved working memory and abstract representation. However, these abilities evolved, develop, and are generally utilized within a context of cultural transmission and ongoing interaction with the environment. This raises two complementary questions: To what extent does culture scaffold effective employment of our cognitive capacities, and to what extent is learning possible in culture's absence? Experiment 1 demonstrates that participants given a verbal "hint" can use working memory to optimize rewards in a simple sequential learning task, whereas even after hundreds of trials of experience, those not given a hint can only learn the task suboptimally. Experiment 2 demonstrates similar results for hierarchical rule abstraction. In these experiments, hints are akin to cultural scaffolding, and their influence on learning helps identify how our ability to spontaneously leverage our unique cognitive capacities is limited in isolation from culture.
\end{abstract}

\title{
The Atoms of Cognition: Action Learning and Problem Solving
}

\author{
Seng-Beng Ho \\ National University of Singapore, Singapore, Singapore, Singapore
}

\begin{abstract}
In a previous paper we showed that a set of representations, which we referred to as "atomic operational representations," which are explicit spatiotemporal representations, can perform the function of grounding concepts of activities and interactions in the physical world. In this paper, to demonstrate how these operational representations can function in cognitive processes, we develop the basic ideas further by showing 1) how actions and their consequences can be observed and captured in operational representations; 2) how causal rules of actions can be learned and encoded in the form of operational representations through an unsupervised causal learning process; and 3) how the learned causal rules can be used in problem solving processes that produce desired action plans. We show that the same representations can be used across the various levels of cognitive processing in a unified manner. Experiments are proposed to test if the brain uses explicit temporal representations.
\end{abstract}

\title{
Measuring the Use of Recognition with the Multinomial r-Model: An Application to Aging and Individual Differences
}

\author{
Sebastian Horn \\ Max Planck Institute for Human Development \\ Thorsten Pachur \\ Max Planck Institute for Human Development \\ Rui Mata \\ Max Planck Institute for Human Development
}

\begin{abstract}
It has been suggested that individuals use simple decision strategies for comparative judgments. According to the recognition heuristic (RH; Goldstein \& Gigerenzer, 1999), people infer that a recognized object scores higher on a criterion, if one of two objects is recognized, but not the other. Hilbig, Erdfelder, and Pohl (2010) have argued that previous research lacked process-pure estimates of RH use and rigorous model testing and proposed the r-model, a multinomial processing tree (MPT) model. Addressing these methodological issues, we present a first MPT analysis of differences in RH use between younger and older adults. Model-based analyses indicated that in both age groups the RH was used adaptively more often in the environment with higher recognition cue validity (cities), as opposed to a domain with lower cue validity (diseases). The validity of further knowledge or recognition as decision cues did not differ between age groups. Moreover, we examined the model estimates on the individual level by applying a Bayesian hierarchical approach and compared these estimates with behavioral indices and measures derived from signal-detection theory. The resulting comparisons with standard RH-adherence rates indicated high correlations. Further implications are discussed.
\end{abstract}

\title{
Belief Updating in Moral Dilemmas
}

\author{
Zach Horne \\ University of Illinois at Urbana Champaign Derek Powell \\ University of California, Los Angeles, California \\ Joseph Spino \\ University of Illinois at Urbana-Champaign, Urbana, Illinois, United States
}

\begin{abstract}
Research on two classic moral dilemmas, Trolley and Footbridge, suggests that one's past moral experiences can affect one's subsequent moral decisions. These dilemmas have interested moral psychologists, in part, because they have found that people's judgments about the dilemmas are affected by the order in which the dilemmas are considered. Furthermore, this effect is asymmetrical: people that consider Trolley after Footbridge have significantly different judgments than people in control conditions, but the converse is not true. We argue that this asymmetry is the result of a difference in how the each dilemma affects pre-existing beliefs regarding the importance of saving lives. In two experiments, we show that Footbridge disconfirms these beliefs, while Trolley does not significantly affect them. Consistent with predictions of a belief adjustment model of ordering effects, these findings offer a clear and parsimonious account of the asymmetry.
\end{abstract}

\title{
The effects of caregivers' instruction on children's learning in easy and difficult tasks
}

\author{
Shumeng Hou \\ The Chinese University of Hong Kong, Hong Kong, Hong Kong, China \\ Zinnia Lam \\ The Chinese University of Hong Kong, Hong Kong, Hong Kong, China \\ Wing Chee So \\ The Chinese University of Hong Kong, Hong Kong, Hong Kong, China
}

\begin{abstract}
Previous research has shown that gestures produced by caregivers and teachers facilitate children's learning in problem-solving tasks. However, little is known about whether such facilitating effect varies with the task difficulty. We here asked twenty-eight three-year-old children to participate in two puzzle games (12-piece and 20-piece), with three episodes in each game. In Episodes 1 and 3, children played alone. In Episode 2, caregivers instructed their children (e.g., "Let's put this piece upside down" while rotating left hand clockwise). For both puzzle games, children assembled more puzzles in Episode 3 than in Episode 1, suggesting that caregivers' instructions were beneficial for children's learning. However, such benefit was significantly greater in 12 -piece than in 20-piece, \(\mathrm{t}(27)=1.71, \mathrm{p}<.05\). This finding lends support to Vygotsky's theory in which children can gain more from caregiver's scaffolding when the task is within their capacity than when the task is beyond their capacity.

Are beliefs biased by logic? The effect of a secondary load and complexity on belief and logic based judgments.
}

\author{
Stephanie Howarth
}

Plymouth University, Plymouth, England
Simon Handley
Plymouth University

\author{
Clare Walsh
}

Plymouth University

\begin{abstract}
Dual-Process accounts claim that responses to reasoning tasks often default to automatically cued belief-based responses. However, recent findings show that when participants are instructed to evaluate the believability of a conclusion, its logical status interferes with their judgment. This finding is inconsistent with the view that belief based judgments are cued automatically. In this paper we present the results of three experiments that examined the impact of a secondary task (random number generation) on belief and validity judgments. Experiment 1 examined simple modus ponens arguments, experiment 2 included disjunctive syllogisms and experiment three employed a blocked presentation design. In line with previous research belief judgments took longer and resulted in more errors than validity judgments. However, in general, RNG impacted more on validity than belief based judgements. These finding suggest that both belief and logic judgements require effortful processing but draw upon different types of executive resource.
\end{abstract}

\title{
SRNEngine: A Windows-based Neural Network Simulation Tool for the Non-programmer
}

\author{
Steven R. Howell \\ Keystone College, La Plume, Pennsylvania, USA \\ \section*{Suzanna Becker} \\ McMaster University, Hamilton, Ontario, Canada
}

\begin{abstract}
SRNEngine is a windows-based application package for training neural networks. The graphical user interface allows the drag-and-drop creation of neural networks with a variety of architectures, without the need for any programming. At present, these architectures/learning algorithms include Simple Recurrent Networks, Jordan networks, and any kind of feedforward backpropagation network, with up to five each of input, hidden, and output layers (pools of units). A version that adds backpropagation-through-time is in development. The interface is designed to conform to the Microsoft Windows GUI environment that most PC users are already familiar with. SRNEngine includes tools for creating, editing, and manipulating various types of training data, and is especially optimized for working with text/language data, including automatic word-to-input-representation translation at runtime for text corpora. The distributed computing feature allows multiple simulations to be run on a network of workstations, co-ordinated via a central ftp server.
\end{abstract}

\title{
Comparison and explanation in learning: Children's understanding of a basic engineering principle
}

\author{
Christian Hoyos \\ Northwestern University, Evanston, Illinois, USA \\ Dedre Gentner \\ Northwestern University
}

\begin{abstract}
We investigated the roles of comparison and explanation in teaching children an important engineering principle that triangular cross-bracing confers stability to structures. We aimed to discover how best to convey this principle to 4 - and 6 -year-olds and to reveal the cognitive mechanisms involved. Children either compared contrastive cases (a braced building vs. a non-braced building), received an explanation of the principle, or both, and were then tested on their ability to apply the principle to various contexts. We found that 4 -year-olds benefited from comparison, but surprisingly did not benefit from a combination of comparison and explanation. 6-year-olds, however, benefited greatly from the combination, suggesting that more developed abilities are required to combine the two inputs. Performance on a mental transformation task was also related to successful brace placement. These findings suggest that comparison and explanation can both contribute to learning, both singly and together, depending on ability and/or age.
\end{abstract}

\title{
The roles of L1 and markedness on Mandarin L2ers' construction of syntactic representation
}

\author{
Dong-Bo Hsu \\ National Taiwan Normal University, Taipei, Taiwan, Taiwan, R.O.C.
}

\begin{abstract}
Second language learners' construction of their syntactic representation is greatly influenced by their L1 characteristics and the input of their L2. Although it is known that the more universal a pattern is, the easier it will transfer to facilitate the formation of the representation, the role of markedness on such representation remains unclear. The current study tested two groups of Mandarin L2 learners, i.e., native speakers of English and Japanese with three levels of proficiency using the four structures in Mandarin: SVO, ba OV, S ba O V, and topicalization with novel verbs and neutral animacy cues in a forced choice paradigm to investigate what role of markedness plays in such representations. The results indicated that in addition to the initial transfer for the syntactic representation that is affected by learners' L1 cue validity, the degree of markedness exerts impact on learners' rate of acquisition of syntax at different levels.
\end{abstract}

\title{
Word Repetition Priming for Chinese Emotional Words
}

\author{
Yu-Shu Chiang \\ National Cheng Kung University \\ Hsin-Hsuan Wu \\ National Cheng Kung University \\ Yi-Ling Chung \\ National Cheng Kung University \\ Hsueh-Chih Chen \\ National Taiwan Normal University \\ \section*{Jon-Fan Hu} \\ National Cheng Kung University
}

\begin{abstract}
The present experiment was to test if high-arousing Chinese words can lead to increase repetition priming for emotional semantics. Participants were randomly assigned into two groups: one group was presented with positive words and another group with negative words. In Phase 1 of the experiment, participants rated high-arousing words and neutral words for concreteness. In Phase 2, they made decision to determine if it was novel word (half high-arousing, half neutral). In Phase 3, they were told to value the features of Chinese words which were not presented previously in a 5 -point Likert scale and finished some parts of the Basic Personality Inventory (BPI) for assessing and controlling possible cognitive processing bias. The results showed a significant priming effect in two groups and the words presented in Phase 1 had shorter reaction times than the novel words. These findings revealed selective enhancement of Chinese word repetition priming by emotional arousal.
\end{abstract}

\title{
Categorization and recognition in a prototype-distortion task: ERP studies
}

\author{
Yanli Huang \\ The Chinese University of Hong Kong, Hong Kong, Hong Kong, China \\ Zhiya Liu \\ South China Normal University,Guangzhou, Guangdong, China \\ Chi Shing Tse \\ The Chinese University of Hong Kong, Hong Kong, Hong Kong, China
}

\begin{abstract}
We used a prototype-distortion task and adopted ERPs to test between prototype and exemplar theories on categorization, which suggest that categories are represented as a prototype via an abstraction process or via storing previously encountered exemplars in memory, respectively. In Experiments 1 and 2, participants were presented low- or high-distortion category-members (i.e., dot-patterns) without anticipating subsequent categorization or recognition test. They were more likely to process low-distortions via prototype abstraction in both tests, and differently process high-distortions via prototype abstraction in categorization test, but via storing exemplars in recognition test. In Experiment 3, participants were explicitly instructed to do categorization or recognition task. We found that participants did categorization test via prototype abstraction (N1) only for studied items, not for unstudied items. And conversely did recognition via familiarity processing (FN400) only for category-members, not for non-members. In conclusion, the nature of category representations depends on the experimental contexts.
\end{abstract}

\title{
Probabilistic negation: fine-grained preservation and distortion of truth in affirmative and negated statements
}

\author{
Stephanie Huette \\ University of California, Merced
}

\author{
Sarah Anderson \\ The Nielsen Company
}

Michael Spivey
University of California, Merced

\begin{abstract}
Previous work has shown that a continuum of truth is reflected in real-time motor movement behavior (McKinstry, Dale \& Spivey, 2008). In a mouse-tracking paradigm, participants responded yes or no to statements of varying truth-values such as "A thousand is more than a million" or "English is a language" as well as more ambiguous statements such as "Murder is sometimes justifiable". In the present study, we replicated these results along an 11-point continuum of truth-values, finding that the end-points of averaged mouse trajectories vary as a function of truth-value. In addition to this, negated versions of each stimulus were tested and revealed that truth-values for negated sentences follow more complex trajectories and do not preserve the original truth-value of the statement. The evidence found presents a problem for theories of negation that require a revision from the affirmative meaning. Alternative mechanisms for how truth is affected by negation are proposed.
\end{abstract}

\title{
Exploring the boundary conditions of intentional forgetting
}

\author{
Almut Hupbach \\ Lehigh University \\ Lili Sahakyan \\ The University of North Carolina at Greensboro
}

\begin{abstract}
The attempt to forget some recently encoded information can indeed cause later retrieval difficulties. However, such attempts are only effective when new information is learned shortly thereafter. In the present study, we asked whether the new information has to match the format of the to-be-forgotten information for forgetting effects to emerge. Participants studied words or line drawings (L1), and were afterwards instructed to remember or forget these items. Then, a second list (L2) was presented that either matched or mismatched the L1 format. Forgetting effects were only observed when the list formats matched. This result establishes an important boundary condition on intentional forgetting, and can be explained by the context change account (Sahakyan \& Kelly, 2002), which assumes that forgetting occurs when retrieval is guided by temporal context only. Salient cues (such as differences in list format) allow for reinstatement of the L1 encoding context, thus eliminating forgetting.
\end{abstract}

\title{
Purity and Disgust: Same Domain, or Separate Mechanisms?
}

\author{
Gordon Ingram \\ Bath Spa University, Bath, Somerset, England \\ \section*{Karolina Prochownik} \\ Jagiellonian University, Kraków, Poland
}

\begin{abstract}
We argue that much recent literature on disgust, dirtiness and purity has been guilty of conflating two evolved mechanisms: an oral disgust mechanism aimed at avoiding the ingestion of dangerous substances, and a self-grooming (cleanliness) mechanism aimed at eliminating ectoparasites from the skin. Though phylogenetically distinct, these two mechanisms become associated in human ontogeny due to their similar targets and overlapping image schemas: one focused on the mouth, the other on the body as a whole. We show that several puzzles in the literature on disgust and moral purity can be resolved using this model. The idea of contamination so central to purity norms may more plausibly be based on grooming responses to ectoparasites than on disgust responses to endoparasites. The disgust image schema may more easily be extended to moral judgements about others, while the cleanliness schema is more easily extended to judgements about the self, with interesting consequences.
\end{abstract}

\title{
How can an art course in photography inspire students' artistic creativity?
}

\author{
Chiaki Ishiguro \\ The university of Tokyo, Tokyo, Tokyo, Japan \\ Takeshi Okada \\ The university of Tokyo, Tokyo, Tokyo, Japan
}

\begin{abstract}
This study examines whether an art course with various kinds of inspiration derived from others and their artworks is useful in improving undergraduates' photographic creativity and their views of photo taking. In collaboration with a professional photographer, we organized an undergraduate course in artistic photography, which included lecture sessions in basic artistic skills and knowledge, imitation sessions of unfamiliar artistic photographs, photo taking sessions, and presentation of the students' own works in the class. 21 students participated in the course for a semester. We collected students' diaries of their photo taking, their photographs, and questionnaire survey data about their photo taking experiences. The results of data analyses show that the creativity of the students' photographs improved after lecture sessions. The students reported that reflecting on their photography contributed to their acquisition of metacognitive knowledge of artistic creation.
\end{abstract}

\title{
Mental Process of Mindreading: Self and Stereotype as Anchors in Mental State Inference
}

\author{
Tatsunori Ishii \\ Tokyo Seitoku University, Tokyo, Japan \\ Masanori Takezawa \\ Hokkaido University, Hokkaido, Japan
}

\begin{abstract}
Capacities of mindreading are essential for human social life. It is hypothesized that people selectively use two types of mindreading strategies; when a target person is perceived to be similar to oneself, people project one's own mental states to the person (projection): when the target is perceived to be dissimilar, category-based stereotype is used (stereotyping). In this study, we tested this hypothesis with the reaction time paradigm (e.g., Tamir \& Mitchell, in press). Given that the both projection and stereotyping are computationally modeled as anchoring-and-adjustment processes, the reaction time paradigm can be used to detect a strategy used in mindreading. We found the stereotyping was unanimously employed independent of the similarity to the target person and projection was employed only when the perceived similarity was high. Our results are congruent with Tamir \& Mitchell (in press) and confirmed the utility of the reaction time paradigm as a tool for investigating mindreading strategies.
\end{abstract}

\title{
Eye-Movement Strategies in Multiple Target Search for Target Location and Uncertainty Reduction
}

\author{
Christian P. Janssen \\ The Smith-Kettlewell Eye Research Institute \\ Preeti Verghese \\ The Smith-Kettlewell Eye Research Institute
}

\begin{abstract}
Where do people look when searching for multiple targets under time pressure: at salient targets, at locations with high uncertainty about target presence, or somewhere else? Preceding research suggests that people tend to look at salient targets. This is suboptimal, because educated guesses can be made about target presence at these locations without looking (Verghese, 2012). We ran an experiment and constructed Bayesian models to test the generality of this finding. Participants saw stimuli at two locations for 400 msec (i.e., allowing only 1 saccade), and then judged target presence at each location. Noise of low or high contrast was superimposed at the two locations. We observed individual differences in saccade strategies. One participant made no saccades, while achieving reasonable performance. Others applied a mixture of strategies, sometimes favoring salient targets, sometimes favoring uncertain locations. This work provides further insight into task and cognitive constraints that influence saccade strategy selection.
\end{abstract}

\title{
'But' how do children reason with it?
}

\author{
Leen Janssens \\ KU Leuven, Leuven, Belgium
}

\section*{Stephanie Drooghmans}

KU Leuven, Leuven, Belgium

\section*{Sara Verbrugge}

Hogeschool Gent, Gent, Belgium

\section*{Walter Schaeken}

KU Leuven, Leuven, Belgium

\begin{abstract}
Our research aimed at investigating whether 8-to-12-year-old children spontaneously make the conventional implicature induced by 'but' -combined with 'so' and 'nevertheless'- in 'p but q' sentences. We presented the children with stories ending with a ' p but q ' sentence. They were instructed to indicate the 'appropriate' conclusion introduced by either 'so' or 'nevertheless'. In addition, we measured children's working memory (WM)-capacity in order to explore the possibility that making these inferences is effortful. Our results show that children do make the inferences to a certain extent but are sensitive to the content of the arguments. Whenever the p - or q -argument is an absurd argument (contrasted with a sensible argument), this argument almost always gets ignored in favor of the sensible argument, irrespective of the 'appropriate' conclusion 'but' directs the reader to. No reliable WM-effect was found. High WM-span children did not make the inference more often than low WM-span children.
\end{abstract}

\title{
Using SpAM to reveal decision processes and complex new context effects in similarity judgment
}

\author{
Gavin Jenkins \\ University of Iowa \\ Larissa Samuelson \\ University of Iowa \\ John Spencer \\ University of Iowa
}

\begin{abstract}
The "Spatial Arrangement Method" (SpAM) has gained popularity for measuring similarity judgments (Perry, Cook, \& Samuelson, 2011; Hout, Goldinger, \& Ferguson, 2012; Kriegeskorte, 2012). In SpAM, multiple stimuli are freely arranged in two dimensions such that more similar stimuli are close together. We performed two SpAM experiments to investigate the process by which participants make multiple simultaneous similarity judgments using novel stimuli. The experiments differed across either two or three feature dimensions. Mouse and Eye-tracking measures, as well as the sequence of stimuli placed, provided a rich picture of participants' decision processes as they made these judgments. Both experiments revealed strong effects of group context. Clustered presentation of stimuli by feature influenced both the order and the timing of placements, and despite equal metric spacing of stimuli along each dimension, participants typically warped placements along dimensions nonlinearly. We discuss implications of these findings for theories and models of similarity.
\end{abstract}

\title{
How Do People Judge Conjunctive Probabilities from Experience? A Hierarchical Bayesian Model Comparison
}

\author{
Mirjam Annina Jenny \\ Max Planck Institute for Human Development, Berlin, Germany \\ Jörg Rieskamp \\ University of Basel, Basel, Switzerland \\ Håkan Nilsson \\ Uppsala University, Sweden
}

\begin{abstract}
Judging whether multiple events will co-occur is an important aspect of everyday decision making; however, the underlying probabilities of occurrence are usually unknown and have to be inferred from experience. Using a rigorous, quantitative model comparison, we investigate how people judge the probabilities of multiple events to co-occur. In a computerized experiment, participants had to repeatedly choose between two pairs of conjunctive events (represented as two gambles). Participants had access to a small sample of information to estimate the probability that both events occur. A hierarchical Bayesian approach used for estimating the models' parameters and for testing the models against each other showed that the plurality of participants were best described by the configural weighted average model. This model assumes that constituent probabilities are ranked by importance, weighted accordingly, and added up. The cognitive modeling approach provides an understanding of the cognitive processes underlying people's conjunctive probability judgments.
\end{abstract}

\title{
Social institutions as tools in normative cognition
}

\author{
Jeppe Sinding Jensen
}

Aarhus University, MINDlab

\begin{abstract}
Humans have the unique ability to have goals, cooperate according to plans and in respect of norms and rules (football is a good modern example). This ability is based on 1) collective intentionality among participants, 2) distributed cognition of the shared plan and 3) normative cognition in the ability to follow rules and 4) evaluate practice in relation to norms.

In cooperative social interaction, social institutions function by uniting these 4 dimensions. Social institutions 'make us smart' collectively when constitutive rules and regulative rules on the socio-cultural level are internalized as constitutive and regulative representations on the cognitive level (knowing 'what counts as what').

Social institutions are cognitive tools with force because they 'store' and 'radiate' normative cognition and often 'crystallize' in rituals, e.g. weddings (fusing 1-4). The functions of normative cognition in social institutions should be an important subject in cognitive anthropology.
\end{abstract}

\title{
Modeling spatial language acquisition as a function of lexical verb development
}

\author{
Kristen Johannes \\ Johns Hopkins University, Baltimore, Maryland, United States \\ Barbara Landau \\ Johns Hopkins University, Baltimore, Maryland, United States \\ Colin Wilson \\ Johns Hopkins University, Baltimore, Maryland, United States
}

\begin{abstract}
Learning to linguistically encode spatial relations is traditionally considered a problem of acquiring the meanings of prepositions (in, on, under). Based on production data from English speaking 4-year-olds, 6-year-olds and adults, we provide evidence for an alternative verb-based hypothesis: children and adults may essentially share spatial concepts and prepositional semantics, differing primarily in their use of lexical verbs (hang, stick, attach) to describe spatial relations. This hypothesis was formalized as a hierarchical generative model in which child and adult spatial descriptions are drawn from a common distribution, modulo a penalty on lexical verbs that is stronger for children. The model accounted for child production data significantly better than a model based on average adult performance, and the strengths of the estimated penalties were overall greater for 4-year-olds than for 6-year-olds, suggesting a developmental process in which lexical verbs gradually become integrated into the linguistic system for describing spatial relations.
\end{abstract}

\title{
Eye movements "steal" response time effect during imagery scanning
}

\author{
Roger Johansson \\ Cognitive Science Department, Lund University \\ Jana Holsanova \\ Cognitive Science Department, Lund University
}

\begin{abstract}
Several behavioral studies have reported functional similarities between visuospatial imagery and visuospatial perception. For instance, in the classic image-scanning paradigm (Finke \& Pinker, 1982) participants first inspect a dot pattern, which later disappears and is replaced by an arrow on a blank screen. The task is to judge whether the arrow points towards one of the previous dots. Results commonly show that the response time (RT) increases linearly with the distance between the arrow and the previous dot and has been taken as evidence for a structural equivalence between perception and imagery. Typically eye movements are prevented in this paradigm. In the present study, eye movements were recorded for 23 participants in a free viewing version of the image-scanning paradigm. Results revealed that saccadic amplitudes increased linearly with the "imagined" scanning distance ( \(\mathrm{p}<.001\) ). But contrary to previous studies there was no significant effect between RT and scanning distance.
\end{abstract}

\title{
Early Event-Related Potentials (ERPs) sensitive to animacy expectations in sentence comprehension are not overridden by context
}

\author{
Alexis R. Johns \\ University of Connecticut and Haskins Laboratories \\ Heather K. J. van der Lely \\ Harvard University \\ James S. Magnuson \\ University of Connecticut and Haskins Laboratories
}

\begin{abstract}
Wh-words in auditory sentences like "Who/What did Barbie push the _-_ into?" generate expectations for animacy at the blank (e.g., a filled potential Wh-gap). Specifically, the animacy is expected to be opposite of the Wh-word ("who" and "what" predict inanimate and animate nouns, respectively). Fontenau and van der Lely (2008) found Early Left Anterior Negativities (ELANs) when animacy matched Wh- animacy in typically developing individuals but not individuals with "Grammatical-Specific Language Impairment". However, to focus attention on the task, they added final noun phrases to violation items ("Who did Barbie push the clown into THE WALL?") but not to expected animacy items ("What did Barney push the clown into?"). We ask whether participants implicitly learn to predict sentence-final anomalies from animacy match. We tested this by presenting one group with the original contingency and another with the contingency reversed. Contra the learning hypothesis, we observed ELANs for both groups.
\end{abstract}

Adult Category Learning Differences Predicted by a Dynamic Neural Field Theory Account of Information Sampled from the Fovea
}

\author{
Jordan Barnes \\ Simon Fraser University
}

\author{
Mark Blair \\ Simon Fraser University \\ Paul Tupper \\ Simon Fraser University \\ R. Calen Walshe \\ University of Edinburgh
}

\begin{abstract}
Here we explore the possibility that the speed of learning is affected by the precision of our sensory estimates for the learned category's diagnostic feature dimensions. Colour information from a foveated stimulus, if represented as a sample on a metric colour dimension, should faithfully represent differences in the shapes and precision of the estimates as a consequence of the sample size. Differences in the sample variability are expected to have affect on exactly what gets associated during learning. We provide evidence that a manipulation in sub-fovea feature size, \(0.18^{\circ} \mathrm{vs} 1.19^{\circ}\) of visual angle, influences learning speed. In both conditions the simple colour features are easy to see and we do not detect any gaze differences as measured by total fixation durations and individual feature fixation durations. Learning methods that metrically represent activity on feature dimensions such as Dynamic Field Theory (DFT) may be able to account for this data.
\end{abstract}

Brooklyn College, CUNY

\author{
Samuel Salamon \\ Brooklyn College, CUNY
}

\begin{abstract}
There is considerable evidence that representations of word meaning are "embodied" and grounded in our perceptual and motor experiences (Barsalou, 2008; Glenberg, 2010). This research has mostly relied on priming and interference procedures, or measuring brain activity. The present study manipulated the perceptual appearance of words, specifically font size, to be congruent or incongruent with an object's actual size (e.g., elephant presented in a large or small font, respectively). Participants were presented with the words prior to a recognition memory test and property judgment task, in the same session and after a 2-week delay, to see if the perceptual font information would be incorporated into the representations of words to potentially alter participants' memory and judgments. Font size generally did not significantly affect how participants represented and processed the words. These results therefore present a challenge for embodied accounts of semantics, but some potential explanations and issues will be discussed.
\end{abstract}

\title{
Navigating the Social Environment: An Ecological Rationality Perspective on Advice Taking Behavior
}

\author{
Juliane Eva Kämmer \\ Max Planck Institute for Human Development, Berlin, Germany \\ Hansjörg Neth \\ Max Planck Institute for Human Development, Berlin, Germany \\ Pantelis Pipergias Analytis \\ Max Planck Institute for Human Development, Berlin, Germany \\ Mehdi Moussaïd \\ Max Planck Institute for Human Development, Berlin, Germany
}

\begin{abstract}
Many decisions are made under the advice of another person. We investigated the environmental circumstances under which two prominent strategies-averaging and choosing-are effective and adaptive and explored how people employ them. We report two experiments, in which participants ( \(\mathrm{N}=111\) and \(\mathrm{N}=90\), respectively) provided initial estimates for general knowledge questions that varied in perceived difficulty. In Experiment 2, they additionally received advice in the form of an estimate and confidence rating of another person before providing a revised estimate. We found that items of different perceived levels of difficulty exhibited distinctive statistical properties, thus constituting different social environments. Environmental structure affected the theoretical performance of strategies (such as averaging and choosing), and the ways, in which people integrate advice. We embed our analyses in the frameworks of ecological rationality and the probability, accuracy, redundancy (PAR) model of advice taking (Soll \& Larrick's, 2009; JEP:LMC, 35).
\end{abstract}

\title{
Be a better multitasker. How a pause in the primary task can turn a rational into an irrational multitasker.
}

\author{
Ioanna Katidioti \\ University of Groningen, Groningen, Netherlands \\ Niels Taatgen \\ University of Groningen
}

\begin{abstract}
Threaded cognition theory predicts that switching is opportunistic and depends on availability of cognitive resources. Laboratory studies of multitasking suggest people are rational in their switch choices regarding multitasking, while observational studies suggest they are not. To establish whether effective multitasking can become ineffective we introduced delays in the primary task.

The participants answered emails by looking up information (similar to customer-service employees) while being interrupted by chat messages. When participants were faced with a delay in the email task, they switched more often to the chat task on high-workload points. Choosing to switch to the secondary task instead of waiting made them slower. It also made them forget the information of the e-mail task half of the time, which slowed them down even more.

We concluded that people's rationality in multitasking behavior is only local, which agrees with the threaded cognition account of switching.
\end{abstract}

\title{
KANSEI Differences between the Child and the Caregiver in Room Arrangement Examined by the Room Arrangement Workshop for Child Room Spaces
}

\author{
Yoko Katsumata \\ Tokyo Denki University \\ Hideaki Kitazume \\ Tokyo Denki University \\ Tetsuya Yasuda \\ Saitama Prefectural University
}

\author{
Harumi Kobayashi
}

Tokyo Denki University

\begin{abstract}
We investigated KANSEI difference between a child and a caregiver in room arrangement workshop. Seven pairs of parents and children volunteered to participate in a workshop held in a university in Japan. In the workshop, each child and caregiver arranged a room layout using a prepared set of furniture. We then interviewed them about the layout of the arranged room and their own room at their home. We categorized their arrangement of the furniture into "center-arrangement" and "corner-arrangement" using video-data. Results show that half of the children arranged a piece of furniture in the center of the room whereas all caregivers arranged a piece of furniture at a corner. Interview data suggested this difference reflected their KANSEI differences such as preferred activities and perspectives toward room arrangement between children and caregivers.
\end{abstract}

\title{
The Influence of Observing Versus Imitating Gestures in L2 Phoneme Instruction
}

\author{
Spencer Kelly \\ Colgate University, Hamilton, NY, USA \\ Yukari Hirata \\ Colgate University, Hamilton, NY, USA \\ Carmen Lin \\ Northwestern University, Evanston, IL, USA \\ Zach Zhao \\ Colgate University, Hamilton, NY, USA
}

\begin{abstract}
Previous research has shown that auditory training helps non-native speakers learn to perceive difficult phonemic contrasts in a second language (L2) (Hirata, 2004), but there is much room for improvement. Given that hand gestures influence many aspects of native language processing (Hostetter, 2011), we examined whether imitating versus observing gestures helps to improve native English speakers' ability to perceive novel phoneme contrasts in Japanese as an L2. Participants were assigned to either a gesture observe or gesture imitate training condition. There was no overall training advantage of imitating gestures over simply observing them. However, in a preliminary analysis of a sub-group of participants with low scores on the auditory pretest, observing gestures was actually more beneficial than imitating them on an ERP post-test of auditory perception. The results suggest that producing gestures does not always help with learning, and for particularly challenging auditory perceptual tasks, may actually interfere with it.

\title{
Tracking Scrambled Word Order While Reasoning with Diagrams
}

\author{
Özkan Kılıç \\ Department of Cognitive Science, Graduate School of Informatics, Middle East Technical University (METU), Ankara, Turkey
}

\begin{abstract}
Word order varies not only across languages but also within a specific language. Turkish, for example, has a nonrigid word order. Therefore, it is a good test-bed to understand the processing complexity driven by the order. One way to observe the complexity is to investigate it via diagrammatic reasoning. In this study, 18 sentences with scrambled word orders and the corresponding diagrammatic representations were analyzed by 20 Turkish native speakers. There were deliberate errors in the representations and the participants were asked to report them. The participants' eye-movement data were also collected. Results indicate that scrambled word ordering also causes latencies in diagrammatic reasoning task. The eye-movement fixation orders showed that the participants favored VSO and VOS eye-fixation orders independent of sentential word orders. It is also concluded that finding the errors in verbal representations were more time consuming than finding the errors in object and subject representations.
\end{abstract}

\title{
The role of Quinian bootstrapping in the acquisition of mental state terms
}

\author{
Szabolcs Kiss \\ Institute of Psychology, University of Pecs
}

\begin{abstract}
The present poster discusses the role of the famous Quinian bootstrapping learning process in the acquisition of mental state terms such as happy, believe, pain, etc. At first, the poster characterises Quinian bootstrapping in which the so-called placeholder structure plays an important role. The placeholder structure consists of symbols whose meanings are initially learned in terms of each other. Later, the placeholder structure is infused with meanings via the so-called modelling processes. A modelling process can be analogical mapping, abduction, induction, etc. Susan Carey (2009) introduced Quinian bootstrapping in her explanation of the acquisition of numeral list representation and rational number as well as certain aspects of intuitive physics. Second, I apply this well-known learning mechanism to the acquisition of the meaning of mental terms. I distinguish between three stages in the learning of the semantics of mental words. The present poster will characterise the three stages in detail.
\end{abstract}

\title{
An Explorative Study of Search of Model Space in Problem Solving
}

\author{
Saskia Kistner \\ Goethe University, Institute of Psychology, Frankfurt, Germany \\ Bruce D. Burns \\ University of Sydney, School of Psychology, Australia \\ Regina Vollmeyer \\ Goethe University, Institute of Psychology, Frankfurt, Germany \\ Ulrich Kortenkamp \\ Martin-Luther-University, Institute of Mathematics, Halle, Germany
}

\begin{abstract}
Building on dual-space theories, the three-space theory of problem solving suggests to add search of a model space in addition to search of experiment and hypothesis space. This study aimed at exploring the three postulated spaces, especially model space, by means of verbal protocols.

Participants ( \(\mathrm{n}=32\) ) were asked to think aloud while working with a computer based learning program. With this program they could learn about torques in physics using interactive graphics in which experiments could be conducted. Their knowledge about torques was tested before and after working with the program. Verbal protocols were analyzed with regard to the amount of search of the three spaces and regarding the quality of the participants' models for torques.

Our results add to the validity of model space, showing that the three postulated spaces could be reliably identified in the protocols and that the model quality score predicted final knowledge beyond prior knowledge.
\end{abstract}

\title{
Distributed Memory System Architecture based on the Analyses of Human Brain Memory
}

\author{
Muneo Kitajima \\ Nagaoka University of Technology \\ Makoto Toyota \\ T-Method
}

\begin{abstract}
A novel human memory system architecture is proposed. The memory system is an integration of three distributed memory systems associated with respective autonomous organic systems, including the perceptual system that takes care of sensory input from the environment, the conscious system that performs deliberate decision making, and the unconscious system that carries out action selections in the environment. This memory system architecture is consistent with the wide range of recent findings in the field of neurosciences. The memory system architecture works as a memory component in the comprehensive real brain model, MHP/RT, published in the Cognitive Science conferences, and the BICA conferences. MHP/RT is capable of simulating human daily behavior considering real time constraints that should define strong mutual dependencies among the three systems. With this memory system architecture, MHP/RT becomes a real brain model to be contrasted with virtual and partial models, such as ACT-R.

\title{
Effects of verbalization on lie detection
}

\author{
Sachiko Kiyokawa \\ Nagoya University \\ Yoshimasa Ohmoto \\ Kyoto University
}

\author{
Kazuhiro Ueda \\ The University of Tokyo / Japan Science and Technology Agency
}

\begin{abstract}
We determined whether verbalization had an effect on lie detection. Participants were randomly assigned to one of the three conditions: the lie condition, the truth condition, or the control condition. They were asked to indicate whether the target man was either lying or telling the truth. Prior to making their judgments, the participants in the lie condition were required to describe some behaviors exhibited by the target individual that indicated that he was lying. Similarly, prior to making their judgments, those in the truth condition were asked to describe some behaviors exhibited by the target individual that indicated that he was telling the truth. The participants in the control condition were asked only to make judgments. The participants in the lie condition detected lies more often than those in the other two conditions. Thus, verbalization influenced lie detection.
\end{abstract}

\title{
Anisotropy of personal space examined in a virtual environment
}

\author{
Takatsugu Kojima \\ Shiga University of Medical Science
}

\section*{Ayae Iwamoto}

Kyoto University

\author{
Masashi Sugimoto \\ Kyoto University
}

\begin{abstract}
How does a person's personal space change when the person approaches or retreats from another person? In this study, we examine the anisotropy of personal space in a virtual room constructed by three-dimensional computer graphics. In two experiments, a participant took the first-person point of view, and an unfamiliar avatar was placed in the virtual room. The stop-distance technique was used to measure the personal space between the participant and avatar. The participant was required to approach the avatar until he or she felt uncomfortable (approaching condition) or to retreat from it until he or she felt comfortable (retreating condition). We also controlled the room size and the unfamiliar avatar's direction. The results clearly showed that the personal space was larger under the approaching condition than under the retreating condition. Moreover, we found that the avatar's direction influenced the effect of the room size on personal space.

\title{
Information flow across individuals in formation of symbol communication systems
}

\author{
Takeshi Konno \\ Japan Advanced Institute of Science and Technology \\ Junya Morita \\ Japan Advanced Institute of Science and Technology \\ Takashi Hashimoto \\ Japan Advanced Institute of Science and Technology
}

\begin{abstract}
In order to study the formation of symbol communication systems, we conducted an experiment based on a game introduced by Galantucci (2005). This involved pairwise communication in which the pairs engaged in a coordination task through an exchange of messages composed of a small set of geometric figures. We analyzed the transfer entropy-which is a measure of the information flow between two information sources or stochastic processes-between the figures used and the actions by individuals. Consequently, we confirmed that the transfer entropy reduced significantly across individuals, but not within each individual. Moreover, it correlated negatively with the performance of the task. From these results, we suggest that the transfer entropy appropriately shows the degree of formation of symbol communication systems. Then, we report the causal relationship between the uncertainty and the performances using a computational model based on reinforcement learning.
\end{abstract}

\title{
Are forgetting processes crucial to category learning?
}

\author{
Lukasz Kopec \\ University College London (UCL), London, London, United Kingdom \\ Brad C. Love \\ University College London
}

\begin{abstract}
In noisy domains where category distributions overlap, people categorise better at test after being trained on idealised category structures. This may happen, because under the assumption that humans selectively sample from memory when performing categorisation, idealised category learning leads to sampling of more appropriate items and better performance. Here we propose that idealisation of category distributions occurs naturally via a process of forgetting and re-estimation of category labels.

We model a process in which items' category membership is forgotten and then re-estimated from the remaining distributions. With time this leads to lowering the variance of category distributions, equivalent to idealising training data. We test this potential idealisation in a paradigm in which we train participants on overlapping category distributions and withdraw feedback for some trials in one group thus enforcing re-estimation of categories. The model predicts that the group with less feedback will perform better at test due to idealisation.
\end{abstract}

\title{
Words activate categorization even before the category forming task has been offered
}

\author{
Alexey Kotov \\ Department of Psychology, The National research university "Higher school of economics" \\ Tatyana Kotova \\ Laboratory of social competencies and social intelligence research, Moscow State University of \\ Psychology and Education \\ Elizaveta Vlasova \\ Department of Psychology, Russian State University for the Humanities
}

\begin{abstract}
The effect of language on category learning is an ongoing debate among researchers. According to previous research words can facilitate category formation even if they aren't used as feedback. However in most research investigating language influence on category learning, the varying of verbal labels often correlates with varying of perceptual features. Such confound doesn't allow to clarify if the language is a means of perception augmentation (language-feedback hypothesis) or a social marker for generalization (word-meaning-as-intention hypothesis). In the present experiment we separated the process of category learning from the label receiving. Two groups of subjects performed visual search task either with or without labels. Right after that task subjects had to form a category on the basis of new perceptual information added to the old one. As a result subjects from label condition form a category but subjects from the no-label condition didn't. The given data agree with word-meaning-as-intention hypothesis.
\end{abstract}

\title{
Influence of Ethnic Group-Membership and Gaze Direction on Emotion perception. An fMRI study.
}

\author{
Katharina Krämer \\ University Hospital Cologne, Germany \\ Gary Bente \\ Department of Psychology, University of Cologne, Cologne, Germany \\ Iva Barisic \\ Department of Psychology, University of Cologne, Cologne, Germany
}

}

Kai Vogeley
University Hospital Cologne, Germany; Institute for Neuroscience and Medicine - Cognitive Neuroscience (INM3), Research Center Juelich, Germany

\begin{abstract}
Emotion perception is not only influenced by the ethnic group-membership of interaction partners but also depends on whether a person is engaged with the encoder of an emotion. To characterize the neural correlates of the influence of ethnicity and engagement on emotion perception, German participants rated the valence of video-sequences while undergoing fMRI. In these video-sequences Asian-looking and European-looking virtual characters expressed a positive (happiness) and a negative (anger) emotion while either gazing directly at the participants or at another agent, thereby varying the perception of engagement. Results show that the ventromedial prefrontal cortex is involved when participants observe ethnic in-group members compared to ethnic out-group members express a positive emotion at them compared to at another person. In contrast, the dorsolateral and dorsomedial prefrontal cortex are involved when participants observe ethnic out-group members compared to ethnic in-group members express a negative emotion at them compared to at another person.
\end{abstract}

\title{
Conceptual Art and Cognitive Science: A Case Study in Space
}

\author{
Alexander Kranjec \\ Duquesne University and the Center for the Neural Basis of Cognition, Pittsburgh, Pennsylvania, United \\ States
}

\begin{abstract}
Conceptual art and cognitive science have more common ground than is acknowledged. For example, both disciplines are principally engaged in describing and visualizing facts about basic categories of mind (space, objects, language, etc.). Along these lines, conceptual art can inform the cognitive science of abstract concepts. Cognitive scientists studying aesthetics can also learn from conceptual artists to push their research forward. While empirical investigations in aesthetics typically focus on perceptual preferences (i.e., "what is beauty?"), conceptual art often goes deeper ontologically (i.e., "what is art?"). This level of analysis can inform questions regarding the evolution of art and object processing. The present study examines the artwork of Mel Bochner who may have staged the first conceptual art exhibition (1966). Bochner's work addresses spatial semantics/representation, and anticipates the neuropsychological distinction between categorical and coordinate spatial relations; all while reconsidering what it means for an object to be thought of as art.
\end{abstract}

\title{
Efficiency of feature detection of visual stimuli influences the proportion judgments
}

\author{
Hyun-Min Ku \\ Ochanomizu University \\ Midori Tokita \\ Ochanomizu University
}

\author{
Masami Ikeda \\ Jumonji University
}

\author{
Akira Ishiguchi \\ Ochanomizu University
}

\begin{abstract}
Some studies on judgment and decision-making have demonstrated that uncertainty in probability influenced curvature of function given by judged probability or proportion (i.e., probability weighting function). In this study, we concentrated on proportion judgment about visual input. We investigated the possibility that the efficiency of feature detection of visual stimuli would be related to uncertainty in their proportion judgment. Concretely, our participants in the experiments performed proportion judgment task using two sets of visual stimuli pairs, "red vs. green dots" and "right vs. left tilted lines". In addition, we adopted different types of responses; in one condition, the participants were asked to response using numerals; in another condition, they were asked to response by adjusting the line bar which indicated the proportion. Our results suggested that the efficiency of feature detection of visual stimuli influenced the curvatures of the probability weighting function.
\end{abstract}

\title{
The Effect of Set in the process of perception of unconscious information
}

\author{
Natalya Kudelkina \\ Samara State University, Samara, Russia
}

\begin{abstract}
Our research aims to study the Effect of Set in the process of perception of unconscious information. In the experiments, we use serial (multiple) unconscious stimulation and the modified masked priming technique to give unconscious stimuli to our participants. In the experiments we demonstrate that, as a result of the specially organized preliminary experimental series, it is possible to receive the steady priming-effect for the unconscious stimulus which initially didn't render any noticeable influence on the effectiveness of the tasks solutions. We can conclude, that at unconscious level cognitive system analyzes series of unconscious influences. So, the nature of influence of each following unconscious stimulus on the current conscious cognitive activity, by the time of its occurrence, is already set on the basis of the analysis of the previous series of influences. It is possible to model these individual settings in the experimental environment.

\title{
Navigator-driven placement of landmarks: effects on wayfinding performance in a virtual Tate Gallery.
}

\author{
Saskia Kuliga \\ Universität Freiburg \\ Rul von Stülpnagel \\ Universität Freiburg \\ Christoph Hölscher \\ Universität Freiburg
}

\begin{abstract}
Wayfinding difficulties in architecturally ambiguous environments can be overcome by orientating with given landmarks. However, it is not clear at which locations landmarks are most suitable to facilitate orientation. Our study addressed two questions: (1) Is subsequent wayfinding performance facilitated if participants freely place a number of landmark objects in a complex building? (2) Where do participants place the landmarks and which strategies guide effective landmark placement? First, participants were instructed to learn a number of goal locations in a virtual model of the Tate Gallery London. Then, participants in the experimental condition were instructed to place five unique landmarks in order to re-find the goals in a third phase; participants in a control condition could not place landmarks. Finally, participants were tested on their ability to find the goals again, with time and distance as main dependent variables. Results are discussed with respect to placement strategies and environmental properties.
\end{abstract}

\title{
Popout Attention with two foils: linear dependence and dimensional interaction
}

\author{
Kiran Kumar \\ Indiana University \\ Suyog Chandramouli \\ Indiana University \\ Richard Shiffrin \\ Indiana University
}

\begin{abstract}
Automatic parallel processing occurs in visual search when a target differs from other display objects on a salient visual dimension and the phenomenon is termed 'popout'. The present two studies answers the question: Do the interference effects cancel or add? Both studies used a ring of twelve fixed-size green circles with embedded Gabors oriented vertically or horizontally. Targets and foils were one of green square, a larger green circle, or a red circle. Each of these served as a target for one of the three sessions, with the others serving as foils. In one task the observer found the target and reported its Gabor orientation. The other task used targets only on one half the trials and the observer reported target presence or absence. In both tasks accuracy was uniformly high. In both tasks RT interference increased from one to two foils, the slowing mainly isolated to the slowest decile of RTs.
\end{abstract}

\title{
Using Relational Encoding to Promote Creative Problem Solving
}

\author{
Kenneth J. Kurtz \\ Binghamton University \\ Nuoya Zhang \\ Binghamton University \\ Tamar Skolnick \\ Binghamton University
}

\begin{abstract}
The nature and basis of creative thought is the subject of wide-ranging inquiry, yet remains elusive. We focus on a core issue: why do people struggle to solve problems that require a creative insight and what type of support can make success into the norm? Drawing on the idea of relational encoding (e.g., Gentner, Loewenstein, \& Thompson, 2003), we sought to improve creative problem solving by activating structured content (relations between objects) in the problem encoding. We developed an alternative to a comparison task: completing a set of sentence frames explaining how pairs of objects in the problem setting relate to one another. In two experiments, we found evidence that participants in the relational encoding group were significantly more likely to solve an insight problem than controls. An important caveat is that the advantage was only found for the easier problems tested - there were no differences for the more difficult problems. We address implications of this work from both theoretical and applied perspectives.
\end{abstract}

\title{
Not Emergence as Emergence: Emergence in Artificial Intelligence and in Philosophy of Mind
}

\author{
Eliska Kvetova \\ University of West Bohemia
}

\begin{abstract}
Hardly any concept is as frequented as emergence in current cognitive science. For many authors it has become solution of eternal psychophysical problem, for many it has been only a mysterious incantation in regard to this. This poster should point out that concept of emergence as well as many other promising concepts has a fundamental problem with determination, definition and usage. The thesis is evident from the title: not emergence as emergence, or better: like emergence, not like emergence. There are many different concepts of emergence. The contribution is based on the belief that the confrontation of artificial intelligence with philosophy of mind, the comparison of these two areas in which emergence occurs very often, could be interesting and could enable to formulate or outline certain tendencies in understanding and using of the concept.
\end{abstract}

\title{
Predictive coding and the Bayesian brain: Intractability hurdles that are yet to be overcome
}

\author{
Johan Kwisthout \\ Donders Institute for Brain, Cognition and Behaviour \\ Iris van Rooij \\ Donders Institute for Brain, Cognition and Behaviour
}

\begin{abstract}
There is a growing body of evidence that the human brain may be organized according to principles of hierarchical predictive coding. A current conjecture in neuroscience is that a brain, organized in this way, can effectively and efficiently perform genuine Bayesian inferences. Given that many forms of cognition seem to be well characterized as Bayesian inferences, this conjecture has great import for cognitive science. It suggests that hierarchical predictive coding may provide a neurally plausible account of how forms of cognition that are modeled as Bayesian inference may be physically implemented in the brain. Yet, the jury is still out on whether or not the conjecture is really true. In this presentation, we demonstrate that each key sub-computation invoked in hierarchical predictive coding potentially hides a computationally intractable problem. We furthermore identify ways in which computational modelers may or may not overcome these 'intractability hurdles.'
\end{abstract}

\title{
What working memory subcomponents are needed in the acquisition of survey knowledge? Evidences from direction estimation and shortcut tasks
}

\author{
Enia Labate \\ University of Padua, Padova, PD, Italy \\ Francesca Pazzaglia \\ University of Padua \\ Mary Hegarty \\ University of California, Santa Barbara
}

\begin{abstract}
Survey spatial representations are map-like mental representations in which directional relationships among landmarks are preserved. Survey representations allow people not only to re-trace routes already experienced, but also to find new routes and shortcuts (Golledge et al., 1999). This study investigated whether and to what extent verbal and spatial working memory (WM) are implicated in the construction of survey representations. We adopted a dual-task paradigm, asking participants to learn a new environment from navigation and, concurrently, to perform either a verbal or a spatial task, assumed to load verbal and spatial WM, respectively. Ninety undergraduates were assigned to one of three groups according to concurrent task condition: articulatory suppression, spatial tapping, or control (no concurrent task). Acquisition of a survey representation was tested by asking participants to perform direction estimations and shortcut tasks. The results supported the involvement of spatial WM in the acquisition of survey knowledge, showing significant differences between the spatial tapping group and control group for the survey measures.
\end{abstract}

\title{
Investigating Elementary and College Students' Development of Numerosity Judgment Using Eye-Tracking Technology
}

\author{
Meng-Lung Lai \\ National Chiayi University, Chiayi, Taiwan, Taiwan \\ Meng-Jung Tsai \\ National Taiwan University of Science and Technology \\ Liang-Chen Chien \\ National Chiayi University \\ Yi-Chen Chen \\ National Chiayi University
}

\begin{abstract}
Numerosity judgment involves determining the number of items, which highly correlates with mathematical achievement. This study investigated age-related differences on numerosity judgment among middle-level elementary students and college students in terms of strategy use and problem-solving efficiency determined by participants' eye movements. Stimuli were grids consisting of \(7 \times 7\) units which were either "on" (yellow block) or "off" (blank). Participants were asked to determine the number of yellow blocks.

Results showed that given energy- and time- consuming, third graders consistently adopted "addition strategy" on larger numerosity trials. For strategy adaptiveness, adults outperformed younger peers, most of whom starting using "subtraction strategy" on critical and larger trials (e.g., 25 and larger numerosities). Regarding efficiency, adults determined numerosities more efficiently than elementary students, because adults' eye fixations were significantly fewer than those of younger groups, while only marginal difference on the number of fixations was observed for the two younger groups.
\end{abstract}

\title{
Motor Resonance Effects Modulated by Perspective: A Role of Linguistic Contrual on Social Action Perception
}

\author{
Donghoon Lee \\ Pusan National University, Busan, South Korea \\ JaRang Kwak \\ Pusan National University, Busan, South Korea \\ YoungIn Lee \\ Pusan National University, Busan, South Korea
}

\begin{abstract}
We investigated motor resonance effect(MRE) during perceiving interactive social action scenes of two people. Perspectives of the social action scenes were manipulated by the voice (active vs. passive) of sentences describing the scenes. In Exp1, subjects' response time for stepping on a pedal was analyzed for investigating MRE during understanding of the scenes where a person is stepping on a foot of the other person. In Exp2, the response time by the lip action on a microphone were analyzed for exploring MRE during perceiving of the scenes where a person is biting an arm of the other person. In results, the MRE in both experiments was significant only when the scenes were described in the active voice. Our results indicate that the motor resonance effect can occur during perception of social events, but it can be modulated by the perspective of the mental construal of the event.
\end{abstract}

\title{
Psych Predicates: Subjectivity and Evidentiality
}

\author{
Chungmin Lee \\ Seoul National University
}

\begin{abstract}
This work investigates why the psych sentence 'She is dizzy' with the third person subject in PRESENT fine, whereas its counterparts in Korean and Japanese are odd unlike the first person subject utterance na-nun ecirew-e (K) 'I am dizzy.' We have no way of knowing if others' internal psych state is such at speech time. We argue that an evidence acquisition event (ee.a) such as I just heard from Mary/I just saw Mary precedes or is accommodated prior to speech time for the third person present psych sentence even in English. The PRESENT realization is a consequence of "double access" sequence of tense interpretation in English, i.e. Mary was dizzy and still is dizzy. A psych predicate requires the 1st person Experiencer's direct perceptual experience of one's own psych state or of individual object as in predicates of personal taste. First-person interoceptive psych judgments of I am dizzy/in pain have "immunity to error through misidentification," unlike de se thoughts.
\end{abstract}

\title{
Neural representations of language switching in early bilinguals: An fMRI study
}

\author{
Miaomei Lei \\ Tokyo Institute of Technology, Tokyo, Japan \\ Hiroyuki Akama \\ Tokyo Institite of Technology,Japan \\ Brian Murphy \\ Carnegie Mellon University
}

\begin{abstract}
To investigate neural activity with respect to language switching, we measured brain activation with functional magnetic resonance imaging (fMRI) while 5 early Korean-Chinese bilinguals performed a covert property generation task with language switching. Forty stimulus photographs of animals and tools were presented as stimuli, accompanied by captions written either in Korean or Chinese. When the stimuli were shown in Korean, participants were asked to do the covert association production task in Chinese ( \(\mathrm{K}>\mathrm{C}\) ), and vice versa ( \(\mathrm{C}>\mathrm{K}\) ). Results from the fixed effect analysis revealed that the \(\mathrm{K}>\mathrm{C}\) condition (Korean as orthographic stimuli and Chinese as semantic execution language) activated primarily left precentral gyrus and left inferior frontal gyrus while the \(\mathrm{C}>\mathrm{K}\) condition activated primarily the region straddling right precuneus and right middle/posterior cingulum. These contrasting activation patterns might support the hypothesis that the neural representations in language switching tasks hinge on the linguistic typology and the cognitive motor control.
\end{abstract}

\title{
Thinking metaphorically in Alzheimer's Disease: priming cognitive domains to understand inferential content of sentences
}

\author{
Jan Leite \\ Universidade Federal da Paraiba \\ Berla Moraes \\ Universidade Federal da Paraiba \\ Mabia Toscano \\ Universidade Federal da Paraiba \\ Danielly Lima \\ Universidade Federal de Campina Grande
}

\begin{abstract}
This paper looks into the effects of visual/linguistic stimuli in the activation of cognitive domains (e.g. image schemas for primary metaphors) which are necessary for the understanding of sentences content by individuals affected by Alzheimer's Disease (AD). AD studies point out to cognitive impairments at early stages of the disease which make comprehension tasks such as abstract inference, and metaphorical reasoning more costly to AD subjects in comparison to other groups of normal aging. We designed a \(3 \times 3\) experiment in which subjects ( AD and control group) were presented with primes of cognitive domains (words, pictures, and ideograms as control) followed by a choice task of metaphorical, literal, and abstract sentences in order to measure time spent to understand sentences in each condition, and frequency of each choice. Our hypothesis is that when the subject is primed with visual rather than linguistic input of a domain, s/he understands more readily and more accurately the metaphorical/inferential content of a linguistic expression, even though literal understanding frequency keeps higher.
\end{abstract}

\title{
Activities of Mirror System Involved In Coordination Game
}

\author{
Guanhong Li \\ Japan Advanced Institute of Science and Technology \\ Takashi Hashimoto \\ Japan Advanced Institute of Science and Technology
}

\section*{Jiro Okuda}

Kyoto Sangyo University

\begin{abstract}
Intention understanding is necessary during the formation of human communication system. Though the linkage between mirror system and intention understanding has been examined by many studies, the evidence of activities of mirror system during the formation of human symbolic communication system, in which no explicit demonstration of actions is involved, are still limited.

We recorded the neural activities with electroencephalography during a coordination game with message passing, which involves formation of symbolic communication system. In this experiment, two subjects were separated into two rooms, thus they could not see any movement of communication partners or hear any sound from the partners' actions. Significant mu rhythm suppression is found over sensorimotor cortex both when the subjects send and receive messages.

This preliminary result indicates that intention understanding involved in message interpretation can also induce the activities of mirror system, even without explicit referring to actions.
\end{abstract}

\title{
A crosslinguistic look at how metaphor, manner, and aspect propel polititians through campaign races
}

\author{
Patricia Lichtenstein \\ University of California, Merced, Merced, CA, US \\ Marcus Perlman \\ University of California, Merced, Merced, CA, United States \\ Teenie Matlock \\ University of California, Merced
}

\begin{abstract}
Before an election, voters are inundated with messages about candidates running for office. Our work examines the influence of metaphor in messages about political races. Of special interest is the role of manner of motion (e.g., slow, fast) and aspect (e.g., perfective, imperfective) in messages that include motion metaphors (e.g., "Candidate A raced/was racing ahead of Candidate B" and "Candidate A inched/was inching ahead of Candidate B"). We discuss results from our experiments with English and Russian speakers. In line with our predictions, manner of motion and aspect were found to interact in interesting ways, and to systematically influence opinions about who is likely to win an election. These novel results have valuable theoretical and practical implications for political communication and how people conceptualize political elections, and expand prior work on framing effects in political talk, especially motion metaphors and grammatical aspect (Fausey \& Matlock, 2010; Matlock, 2012).
\end{abstract}

\title{
What We Move to Moves Us: Biological Rhythmicity Predicts Musical Preferences
}

\author{
Nicholas Jun Hao Tan
}

\author{
National University of Singapore \\ Sarah Shi Hui Wong \\ National University of Singapore \\ \section*{Stephen Wee Hun Lim} \\ National University of Singapore
}

\begin{abstract}
For at least 350 centuries, humans have invented music that offered special aesthetic appeal. Yet, the reasons for these preferences and effects are not understood. Here, we show that listeners prefer music with an underlying rhythmic structure that closely approximates our biological structure. Specifically, listeners preferred music with musical (rhythmic) structures that correspond to biological rhythmicity (motions). This finding, grounded in a straightforward biological framework, provided an intellectual advancement in the long history of thought and experimental work on the basis of musical preferences.
\end{abstract}

\title{
Scepticism: Genuine unbelief or implicit beliefs in the supernatural?
}

\author{
Marjaana Lindeman \\ University of Helsinki, Helsinki, Finland
}

\author{
Annika Svedholm \\ University of Helsinki, Helsinki, Finland
}

\begin{abstract}
We examined whether skeptics hold implicit supernatural beliefs. In study 1, priming by reading a biological or a religious story about death had no effect on skeptics’ afterlife beliefs. In study 2, participants indicated whether they would partake in a (bogus) scientific study that involved visiting a fortune teller and whether they would prefer a fortune teller who predicts positive and negative events or one who predicts only positive events. Believers chose the positive fortune teller more often than skeptics did. Study 3 investigated whether participants' views about the afterlife, other paranormal phenomena, and ontological confusions differ in speeded and non-speeded response conditions. The results were moderated by thinking style: ontological confusions increased in speeded conditions for intuitive skeptics but not for reflective skeptics. The results indicate that skeptics don't hold implicit supernatural beliefs but intuitively thinking skeptics hold ontological confusions predisposing to supernatural beliefs.
\end{abstract}

\title{
Modeling the ecological rationality of decision strategies based on internet statistics
}

\author{
Daniela Link \\ Université de Lausanne \\ \section*{Julian Marewski} \\ Université de Lausanne
}

\begin{abstract}
Memory processes play a major role in many models of decision making. Several fast-and-frugal heuristics assume a sequential search of information in memory (e.g. the take-the-best heuristic). Fast-and-frugal heuristics exploit regularities in the structure of the environment and basic cognitive capacities, such as memory. However, until now only few attempts have been made to relate models of memory and decision making to the structure of information in the environment. The ACT-R architecture provides a quantitative theory about the interplay between the information structure in the environment and the memory system. Based on internet statistics, we use ACT-R to predict people's recognition and knowledge about objects in the world, as well as the associated retrieval time distributions of respective memories. We show how a corresponding model integrating memory and decision processes within ACT-R allows predictions about the ecological rationality of decision strategies that operate on the accessibility of information in memory.
\end{abstract}

\title{
The Roles of the Goal and Internal Models in Motor Representation: A Pragmatic Explanation
}

\begin{abstract}
Motor representation is understood by Grush (2004) and Pezzulo (2008, 2011) in terms of simulation/emulation: internal models simulate motor effectors and environmental conditions. Motor intentionality, thus, is regarded as based on the standing-for relation.

In their thesis of motor representation, knowing in preparation of motor actions is highlighted but the system's doing when manipulating on-going motor activities is overlooked. That 'system's doing', however, retains an essential role in motor intentionality, a role which accounts for complexities of real environment, animate apparatus to be represented, and goal-oriented nature of motor movements.

Contrasted to Grush and Pezzulo's thesis, my research highlights a pragmatic role of motor representation, pragmatic in sense of explaining how a motor agent can successfully achieve a goal by maintaining motor movements. Internal models, in my account, not only supply emulation but serve to assist the motor system in its goal-achieving activities, resulting in efficient control and flexible movements.

The interaction of the wrap-up effect and uncertainty factors in speech processing
}

\author{
David J. Lobina \\ Universitat Rovira i Virgili \\ Josep Demestre \\ Universitat Rovira i Virgili \\ José E. García-Albea \\ Universitat Rovira i Virgili
}

\begin{abstract}
The click-detection paradigm was employed to probe the load exerted by the parser within simple Spanish sentences. In Experiment 1, three positions at the beginning of clauses were established and results suggest that Ss are better prepared the deeper into a sentence the click is. Experiment 2 ran an ERP experiment to determine whether these RTs were the result of the "uncertainty" Ss may have felt regarding the click position, the idea being that the amplitude of the P300 would correlate with the click positions. In Experiment 3, click positions were moved to the end of clauses to establish if the end of a sentence results in a specific strain on working memory. RTs show that Ss are slower in the first position but the measures even out after that, with the possibility that Ss may have attempted to "wrap it up" in both the second and the third positions.
\end{abstract}

\title{
The role of inflectional suffixes in lexical processing of Greek words
}

\author{
Sofia Loui \\ University of Athens, Athens, Athens, Greece
}

\author{
Athanassios Protopapas \\ University of Athens
}

Eleni Orfanidou
University of Crete

\begin{abstract}
We examined differences between the processing of inflectional versus derivational morphology in visual word recognition in Greek using masked and delayed priming. A lexical decision task to target verbs and nouns preceded by morphologically related primes of the same grammatical class was used to examine inflectional morphology, whereas the same target words preceded by primes of the other grammatical class were used to examine derivational morphology. Greek, a highly inflected language, allows use of words consisting of a stable stem and verb or noun inflectional suffixes, keeping the orthographic and phonological overlap constant across conditions. Both noun and verb targets were significantly primed by the same grammatical class, consistent with inflectional processing. When preceded by primes of different grammatical class, verb but not noun targets showed priming, precluding firm conclusions about derivational morphological processing.

\title{
Using LEGO Robotics to Engage Minority Students in Science and Technology
}

\author{
Carol M. Lu \\ Teachers College, Columbia University \\ John B. Black \\ Teachers College, Columbia University \\ Sorachai Kornkasem \\ Teachers College, Columbia University \\ Laura M. Lu \\ Teachers College, Columbia University
}

\begin{abstract}
With the underrepresentation of minority students in science, technology, engineering, and mathematics (STEM) related fields, it is important for us to develop ways to narrow this gap. This study examines the use of LEGO robotics to increase the interest and motivation of children, particularly Hispanic and African-American students. Participants were fifth graders from two low SES schools attending an after-school robotics program. Students were randomly assigned either learning science in the traditional classroom setting or learning science with robotics. The results from this study found that learning with LEGO robotics can increase minority students' interest and motivation in science and technology.
\end{abstract}

\title{
The Affect of Embodied Height in Perceptual Estimations
}

\author{
Jeremy A. Luno
}

University of Memphis

\section*{Rick Tillman}

University of Memphis

\begin{abstract}
Studies have shown that vision perception is pliable and that perceptual estimations can be affected by a variety of factors. It has been shown that perceptions of slope, distances, and heights are subject to the influence of physiological, emotional, and/or social variables. The studies conducted and outlined here investigated the impact of an individual's actual height on estimations of slope and object height in analog settings, as well as pictorial and linguistic stimuli as presented from a nonimmersive desktop computer monitor. Results suggest that without a relative horizon to utilize eye-height scaling an individual will instead estimate the height of objects relative to their own height.

\title{
The Less You Know, You Think You Know More; Dunning and Kruger effect in Collective Decision Making
}

\author{
Ali Mahmoodi \\ University of Tehran, Tehran, Tehran, iran \\ Majid Nili ahmadabadi \\ University of Tehran, Tehran, Tehran, iran \\ \section*{Bahador Bahrami} \\ UCL institute of cognitive neuroscience
}

\begin{abstract}
Resolving disagreements by collective decision making requires knowledge about task and others' opinion quality. We tested dyads in a visual discrimination task to first show confidence of their individual decision and in case of disagreement announce their joint decision. Using a Bayesian approach, for each participant we compared the optimal decision rule (i.e. relative reliability of participant's own opinion to that of his partner) to the empirically obtained (fitted) decision rule. The less sensitive observers (i.e. the ones who made poorer individual decisions) were significantly less successful in group decision making compared to their more sensitive partners. These less sensitive observers insisted on their individual decision as the group decision more often than recommended by the optimal decision rule. Our findings extent the previously found DunningKruger effect to social decision making domain: the more incompetent are often less aware of their greater fallibility
\end{abstract}

\title{
The role of semantic content of verbal categories in categorical perception: An ERP study
}

\author{
Martin Maier \\ Humboldt-Universität zu Berlin \\ Philipp Glage \\ Humboldt-Universität zu Berlin \\ Annette Hohlfeld \\ Universität Potsdam \\ Rasha Abdel Rahman \\ Humboldt-Universität zu Berlin
}

\begin{abstract}
Categorical perception describes the phenomenon that visual stimuli can be discriminated more easily when they belong to distinct rather than common linguistic categories. Here we investigate the role of the meaningfulness of linguistic categories in categorical perception. To disentangle the effects of labels and semantic contents of verbal categories we employed a learning paradigm in which participants acquired information about initially unfamiliar objects. Linguistic knowledge was manipulated by labeling object pairs either with the same or different names. Furthermore, the labels could be associated with in-depth knowledge or learned in isolation. Two days after learning, the EEG was recorded while participants performed a lateralized object discrimination task. Verbal labels affected object processing already at about 120 ms , unaffected by semantics, while separate semantic effects were found at about 200 ms , suggesting that the influence of verbal categories on perception may not be modulated by semantic information associated with the categories.
\end{abstract}

\title{
Can we observe frequency-modulated syllable effects in French dyslexic children?
}

\author{
Norbert Maïonchi-Pino \\ Laboratoire de Psychologie Sociale et Cognitive (LAPSCO), Université Blaise Pascal (Clermont-Ferrand \\ 2), France \\ Jean Écalle \\ Laboratoire d'Étude des Mécanismes Cognitifs (ÉMC), Université Lumière (Lyon 2), France \\ Annie Magnan \\ Laboratoire d'Étude des Mécanismes Cognitifs (ÉMC), Université Lumière (Lyon 2), France
}

\begin{abstract}
We report the results of whether syllables are frequency-modulated prelexical units in dyslexic children. Twentytwo French dyslexic children were compared to 44 chronological age-matched and reading-level-matched controls. A syllable compatibility procedure was combined with a visual syllable detection task (Exp. 1) and a visual masked priming paradigm in a lexical decision task (Exp. 2). Dyslexic children exhibited robust frequency-modulated prelexical syllable effects; highfrequency syllables elicited a syllable compatibility effect in both experiments, while low-frequency syllables favored either a CV target length or a CVC prime length effect. The frequency-modulated syllable effects were constant across both experiments following an expected developmental course, especially in a highly feasible task (Exp. 1). However, performance was drastically low in a highly demanding task (Exp. 2), suggesting impaired phonological procedures. We propose that dyslexic children do not have obvious impaired phonological representations but rather delayed or compensated phonological representations with impaired phonological procedures.
\end{abstract}

\title{
Disentangling the cognitive processes underlying the testing effect
}

\author{
Simone Malejka \\ University of Mannheim \\ Edgar Erdfelder \\ University of Mannheim
}

\begin{abstract}
Tests modify memory and can improve memory performance: Practice tests outperform additional study trials as a learning technique when the final memory test is difficult (e.g., delayed in time). This is referred to as the testing effect. Although existing theories propose single mechanisms to underlie this effect, the contributions of different cognitive processes are yet to be dissociated. Because most testing-effect accounts attribute the testing advantage to either encoding, maintenance, or retrieval processes, we propose a multinomial processing-tree model that disentangles the contributions of all three memory processes. By applying this model to testing-effect data, we show that (a) testing memory primarily creates maintenance benefits (i.e., resistance against forgetting) and that (b) the critical interaction of testing vs. study benefits with final-test delay is not driven by different retrieval strengths. Our results thus support maintenance accounts of the testing effect and are difficult to reconcile with retrieval-based explanations.
\end{abstract}

\title{
Russian Validation Study of the International Affective Picture System
}

\author{
Olga Marchenko \\ Center of Experimental Psychology MCUPE, Moscow State Linguistic University
}

\author{
Alexey Vasanov \\ Center of Experimental Psychology MCUPE, Institute of Psychology RAN
}

\begin{abstract}
The aim of this study was to examine cultural universality of the International Affective Picture System (IAPS) on a Russian sample (Lang et al, 2008). One hundred subjects evaluated 300 IAPS pictures according to their valence, arousal and dominance. Affective space determined by valence and arousal dimensions had a similar distribution to the American sample. There were significantly high correlations between North American and Russian ratings of valence, arousal and dominance. Nevertheless comparison of these ratings showed that there are significant differences between North American and Russian valence, arousal and dominance scores. Such differences suggest cultural specificity f situations which induce emotion and provide evidence of cultural factors effect on the affective experience. Lastly, it shows the importance of using local cultural norms for internationally available stimuli in addition to the original stimuli, even in the study of such universal processes as an emotion. Supported by RFH Grant 12-06-12058.
\end{abstract}

\title{
Changes in information search strategy under "dense" hypothesis spaces
}

Doug Markant
New York University

\section*{Todd Gureckis}

New York University

\begin{abstract}
Research on information search has found widespread evidence of a "positive test strategy" (PTS), where people search for predicted outcomes of a focal hypothesis. A recent analysis by Navarro and Perfors (2011) showed that the PTS is consistent with normative models of search under "sparse" hypothesis spaces, where each possible outcome is predicted by a minority of hypotheses (a property shared by common kinds of categories). Despite this justification, learning often involves a transition to a "dense" hypothesis space as information is accumulated, at which point the PTS becomes markedly worse than a strategy of searching for diagnostic information about multiple hypotheses. Using a perceptual search task, our experiment tested whether people independently switch between these strategies based solely on changes in sparsity. The results show that, in general, people continue to make errors consistent with the PTS even when faced with "dense" hypothesis spaces where that strategy is ineffective.
\end{abstract}

\title{
Analyzing Infant Attention, Interaction and Goals
}

\author{
J. Douglas Mastin \\ Tilburg University, Tilburg, Netherlands \\ Paul Vogt \\ Tilburg University \\ Irene Claessens \\ Tilburg University
}

\begin{abstract}
This study revisits categorization of infant engagement used in infant language acquisition research. We provide a novel, component-based analysis of interaction structures - centered on attention, interaction, and goal-oriented behavior. With this approach, we are able to extend the classification of engagement by differentiating two independent categories of engagement that have been overlooked. To verify this new categorization, an experiment was conducted with 84 participants in regard to the presence/absence of goals in naturally observed infant interactions form a Western and a non-industrial community. Results demonstrate that the extended categorization of engagement levels via interaction components and processes is sound because there are no significant differences between sites, and no significant differences between participants and trained coders. These results further support the use of a more extensive categorization of engagement, as well as the use of natural observation data and cultural immersion in language acquisition studies.
\end{abstract}

\title{
Bridging the Gap Between Friends: How Presence Biases Distance Estimation
}

\author{
Justin L. Matthews \\ University of California, Merced \\ Teenie Matlock \\ University of California, Merced
}

\begin{abstract}
How does social presence influence the perception of a physical environment? People think about social relationships in terms of space. For instance, when drawing routes on maps they draw paths closer to friends than strangers (Matthews \& Matlock, 2011). How does the mere presence of a friend alter spatial reasoning?

Here, participants imagined working for an outdoor magazine. They viewed photos of bridges one might encounter while hiking. Some participants were told they preferred crossing bridges last (in a group), while others were told they preferred crossing them first. All participants estimated bridge length. Those who crossed last, and imagined their friends on the other side of the bridge, provided reliably shorter length estimates than those who crossed first and imagined their friends standing immediately behind them.
\end{abstract}

These results provide new insights into how social presence can influence our perceptions of physical environments.

\title{
Causal Dispositions and Transitivity in Causal Chains
}

\author{
Ralf Mayrhofer \\ University of Göttingen \\ Inesa Hildenbrand \\ University of Göttingen \\ Michael Waldmann \\ University of Göttingen
}

\begin{abstract}
A number of popular philosophical and psychological theories that model causality in terms of causal dependency assume that causal relations in chains are transitive. When A causes B, and B causes C it typically follows that A also causes C. In contrast, dispositional theories focus on intrinsic causal properties (i.e., causal dispositions) of the involved participants of causal relations. According to this account, a causal chain is transitive only when A originally has a disposition towards C. We present an experiment that contrasts scenarios with transitive chains (A disposes towards C) and scenarios with intransitive chains (A does not dispose towards C ), according to the dispositional account. In line with dispositional theories of causation, we found a strong dissociation between cause-effect judgments (A causes C ) and probability judgments, \(\mathrm{P}(\mathrm{C}-\mathrm{A})\), in intransitive scenarios but not in transitive scenarios. Across both types of scenarios judgments for single relations did not differ.
\end{abstract}

\title{
Cross-Linguistic Sound to Meaning Mappings in Spatial Relational Terms
}

\author{
Kelly McCormick \\ Emory University \\ Lynne Nygaard \\ Emory University
}

\begin{abstract}
Previous research has identified systematic sound-to-meaning mappings (sound symbolism) in words for object size, shape, and surface lightness. In the present study we investigate whether sound is used systematically in spatial relational terms in 17 languages, and whether native English-speaking individuals can determine the meanings of these terms. In a forced-choice task, participants were asked to choose the correct English translation for each unfamiliar foreign word. All items were spatial terms with either proximal or distal meanings (translations of English 'here', 'there', 'near', 'far', 'this', 'that'). Participants nominated the correct meanings of the words significantly above chance, suggesting that they used sound structure to infer meaning. Acoustic analyses were conducted to examine the relation of acoustic properties to word meaning, as well as to listeners' judgments. The findings suggest that the sound structure of language can be systematically used to mark relational meanings related to space.

\title{
From symbols to analog magnitudes: A process model of fraction comparison, with fits to experimental data
}

\author{
Cameron Ross Lloyd McKenzie \\ Stanford, Stanford, CA, USA
}

\author{
James McClelland \\ Stanford University
}

\begin{abstract}
Recent evidence suggests that fractions are represented as visuo-spatial analog magnitudes on a "mental number line" (Schneider and Siegler, 2010). In order to test this theory, we evaluated subjects in two tasks: fraction comparison and number-line marking. Both magnitude difference and response time to mark a fraction on the number line predicted response time to compare the fraction's magnitude to a standard held in memory. This supports the notion that even symbolic numerical cognition is grounded in visuo-spatial processing. We also found a symbolic cost to processing: fractions with more digits were processed more slowly. We propose a model of fraction comparison wherein fractions are processed from symbols into analog magnitudes, then compared to a standard by sequential sampling decision-making. This model provides a superior fit when compared to the log distance model, despite having fewer parameters. Furthermore, it has a direct interpretation in terms of psychological processes.
\end{abstract}

\title{
Cue Competition in Human Associative Learning
}

\author{
Rossy McLaren \\ University of Exeter, Exeter, Devon, United Kingdom \\ Fergal Jones \\ University of Canterbury \\ Fayme Yeates \\ University of Exeter, Exeter, Devon, United Kingdom \\ Ian P. L. McLaren \\ University of Exeter, Exeter, Devon, United Kingdom
}

\begin{abstract}
We used a SRT task in which the preceding two trials of a run of three predicted the third \(2 / 3\) of the time, and added another predictive cue, a colored square, which could also predict the next response required. The question was to what extent would these two cues compete for control of behavior? We assessed this by comparing the dual cue group to a color only control and a sequence only control. Our results showed that the dual group learned about both cues to about the same extent as the individual controls, but that when switched to a test phase where each cue could be assessed independently, the dual group showed a marked decline in performance relative to the controls. We interpret this as evidence for overshadowing occurring between the two predictive cues in the dual group.
\end{abstract}

\title{
Children's Production of Referring Expressions: Effects of Age and Visual Complexity on Under- and Over-Descriptions
}

\author{
Mhairi McMullon \\ Northumbria University
}

\author{
Paul Engelhardt \\ University of East Anglia
}

\begin{abstract}
The Maxim of Quantity states that a speaker should provide enough information for an object to be identified but no more (Grice, 1975). However, research has shown that children tend to produce too little information (under-description) and adults tend to provide too much information (over-description). In this study, we examined the production of referring expressions across the course of development (i.e. 7-18 years). Participants were required to generate a referring expression, and we manipulated the presence or absence of a contrasting object and display complexity. Results showed an age effect on the production of under-descriptions: Young children produced significantly more under-descriptions in more complex arrays compared to older children. In addition, an analysis of voice onset times and eye movements investigated whether there are speed-accuracy tradeoffs associated with visual search and the tendency to include extra information. Conclusions focus on the development of reference mechanisms from childhood to adulthood.
\end{abstract}

\title{
The role of action prediction and control in young children's joint action coordination
}

\author{
Marlene Meyer \\ Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen, Nijmegen, Gelderland, Netherlands \\ Harold Bekkering \\ Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen, Nijmegen, Gelderland, Netherlands \\ Rianne Haartsen \\ Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen, Nijmegen, Gelderland, Netherlands \\ Janny C. Stapel \\ Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen, Nijmegen, Gelderland, Netherlands \\ Sabine Hunnius \\ Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen, Nijmegen, Gelderland, Netherlands
}

\begin{abstract}
Coordinating actions with another person can be a challenging endeavor for young children. For smooth coordination of actions with another person two skills are hypothesized to be crucial: action prediction and inhibitory control. In this study, we investigated how developing abilities of action prediction and inhibitory control are related to young children's joint action coordination. Using a simple turn-taking game, \(2 \frac{1}{2}\)-year-olds' joint action coordination performance (timing variability and accuracy) was assessed. Additionally, children's action prediction skills were measured by anticipatory looks using eyetracking. Inhibitory control was tested in an age-appropriate gift delay task. Results show that timing stability during the joint coordination was positively correlated to measures of action prediction. In turn, accuracy in the joint coordination was positively correlated with measures of inhibitory control. These findings indicate a distinctive role of action prediction and inhibitory action control for different coordination qualities (timing variability and accuracy) in young children.
\end{abstract}

\title{
TMS provides evidence of effector-specific premotor contributions to action interpretation
}

\author{
John Michael \\ Copenhagen University, Copenhagen, Denmark
}

\begin{abstract}
Although it is well established that regions of ventral premotor cortex (vPMC) are active during action observation, it remains controversial whether that activation plays a causal role in action interpretation. In the experiment reported here, we used offline continuous theta-burst stimulation (cTBS) to investigate this question. All participants received offline cTBS to the hand area of vPMC in one session and to the lip area in a separate session, and after each session performed an actioninterpretation task in which half of the trials were pantomimed hand actions and half were pantomimed mouth actions. The results show that participants were less accurate in interpreting hand actions after receiving cTBS over the hand area than after receiving stimulation over the lip area, and less accurate at interpreting lip actions after receiving cTBS over the lip area than after receiving stimulation over the hand area. This double dissociation provides evidence in support of the claim that somatotopically organized regions of vPMC contribute causally to action interpretation, and the claim that action production and action interpretation rely on overlapping mechanisms. In more general terms, they reveal an involvement of the motor system in more sophisticated cognitive processes than has hitherto been demonstrated.
\end{abstract}

\title{
Running circles around symbol manipulation in trigonometry
}

\author{
Kevin W. Mickey \\ Stanford University, Stanford, CA, USA \\ James L. McClelland \\ Stanford University, Stanford, CA, USA
}

\begin{abstract}
Recent evidence suggests that we have an intuitive number sense and that visuospatial processes may ground simple mathematical reasoning, but higher level mathematical cognition is often assumed to depend only on the manipulation of symbolic expressions, governed by a set of rules and logical axioms. To assess rule vs. visuospatial thinking in a higher level mathematical domain, we asked undergraduates to solve trigonometry problems and to report their use of rules, mnemonics, and visuospatial representations including the unit circle, right triangle, and sine and cosine waves. Use of the unit circle was reported most commonly, and was associated with better performance, even after controlling for the extent and recency of trigonometry experience. While unit circle users took more time, their performance was robust to problems that rule users tended to fail. Our findings suggest that even higher level mathematical cognition is more than just the manipulation of symbolic expressions.
\end{abstract}

\title{
The Glamorgan Problem Solver (GLAM-PS): A Distributed and Embodied Production System Architecture for Cognition
}

\author{
Gareth Miles \\ University of South Wales
}

\begin{abstract}
The Glamorgan Problem Solver (GLAM-PS), an example of a computationally implemented theory of embodied cognition, is a novel cognitive architecture that has been applied to algebra problem solving, Tower of London problem solving and Stroop Tasks. GLAM-PS is a distributed production system architecture, with all modules playing a role either in perception or action. Each module has its own working memory, production memory and production matching bottleneck. Inter-module communication allows each module to see the working memory of other modules and to coordinate action with activity in other modules. Despite the lack of explicit goal representation the architecture is able to model offline multi-step problem solving in algebra. Action representations are used to hierarchically structure action in Tower of London problem solving, allowing 'subgoaling' of particular disks. Performance on Stroop Tasks highlights the architecture's ability to model controlled behaviour. These domains demonstrate GLAM-PS potential for providing insights into human behaviour.
\end{abstract}

\title{
The Influence of Selective Attention during Memory Retrieval on Subsequent Memory Performance in Young and Older Adults
}

\author{
Jeremy K. Miller \\ Willamette University
}

\author{
Kyle L. Dixon \\ Willamette University
}

Tyler Young
Willamette University

\author{
Marianne Lloyd
}

Seton Hall University

\author{
Ashley Hartman \\ Seton Hall University
}

\begin{abstract}
Much effort has been devoted to exploring the ways in which manipulating attention during encoding influences performance on memory tasks (Craik et al., 1996). However, fewer studies have examined the effects of manipulating attention during memory retrieval. The purpose of this study was to further examine selective attention at retrieval in the young and elderly. Younger and older adult participants were exposed to a study list followed by a recognition test. Participants made memory decisions under selective attention or full attention conditions (Dudukovic et al., 2009). Participants then completed a memory test consisting of items that had been previously tested under full attention, selective attention, and selectively ignored conditions as well as previously untested items. The results suggest that selective attention during retrieval does not result in significant costs for memory decisions regardless of age group. The results are discussed with reference to current theories of aging, attention, and memory.
\end{abstract}

\title{
Nap-related consolidation in learning the grammar and vocabulary of a novel language
}

\author{
Jelena Mirkovic
}

University of York
Gareth Gaskell
University of York

\begin{abstract}
Sleep-associated consolidation plays an important role in language learning (Dumay \& Gaskell, 2007; Gomez et al., 2006). Here we test the hypothesis that greater levels of arbitrariness in the material to be learned are associated with an increased involvement of sleep (Eichenbaum et al., 1999). Two participant groups were trained to equivalent levels on novel words incorporating regularities mirroring a grammatical gender system. After training, participants had a 90-min break filled with either a polysomnographically recorded nap or an awake control task. Subsequently, the nap group outperformed the wake group in recognition and recall of the trained vocabulary items. Both groups showed evidence of generalization of the systematic aspects of the grammar to untrained items, but the nap group outperformed the awake on the grammar test on the trained items. The findings are discussed in the context of the Complementary Learning Systems approach (Kumaran \& McClelland, 2012; McClelland etal. 1995).
\end{abstract}

\title{
How Teacher Support Children's Empathic Understandings toward Characters? -Focusing on the presentations of similar situations-
}

\author{
Satoko Miwa \\ The University of Tokyo, Tokyo, Japan
}

\begin{abstract}
The present study examined how the presentation of similar situation to character's situation would support children's empathic understandings toward character. According to Barnes \& Thagard(1997), people find similar situation of which the target is in, and transfer the emerging emotional state to target to understand his feelings empathically. Therefore, it was expected that teacher's presentation of similar situation to character's situation would scaffold children's understandings toward character's feelings. Sixth graders' 6 moral education lessons were observed and speeches were recorded. The scenes, where similar situations to character's situations were provided by teacher and used by children, were analyzed. As a result of qualitative analysis, the followings were found: 1) Children who had difficulties in understanding characters' feelings were able to imagine it by using presented similar situations. 2) Teacher presented similar situations to emphasize not only "similarity", but "differences" between situations to prompt children's understandings toward characters.
\end{abstract}

\title{
The effects of the harmonization between a word's meaning and its expression style on implicit memory: Differences between typography in vision and prosody in sounds
}

\author{
Kozue Miyashiro \\ University of Tsukuba
}

Etsuko T. Harada
University of Tsukuba

\begin{abstract}
An expression style refers the graphical or phonological style of language. (i.e., letters or phonemes in words). In daily life, typographies or prosodies are often made to harmonize its connotative meanings with words' meanings they convey. To investigate the role of these harmonization, we demonstrated previously that the harmonization between words' meaning and the typography at encoding had effects on implicit memory in the visual word-fragment completion task (WFC), which implied that harmonization facilitated visual processing of presented words. Expecting that harmonization in sound and word's meaning has same effects, we conducted another experiment, which manipulating the harmonization between words' meaning and their prosody in utterance, using an auditory and visual (classical) WFC. The results showed no effects of harmonization. These results suggest that typography in visual processing and prosody in auditory processing had different function in their connotative meanings.
\end{abstract}

\title{
Investigating phonological false memory effects of prior recall and recognition using the Remember-Know paradigm
}

\author{
Mohamed Shan-Rievan Mohamed Salleh \\ National University of Singapore, Singapore, Singapore
}

\author{
Winston Goh
}

National University of Singapore

\begin{abstract}
In this study, the relationship between prior recall and recognition and its effects on false memory was investigated using low and high confusable phonological associates. Participants who had falsely recalled critical words in an earlier phase were less likely to falsely recognize them later. This pattern of results is in contrast with veridical memory, where participants were more likely to recognize a word after correctly recalling it earlier. We further investigated this phenomenon with the remember-know paradigm, and found that recognition of prior recalled words was associated with more remember responses while recognition of falsely recalled critical words was associated with more know responses. These findings suggest that the underlying processes for veridical and false recognition may each involve different aspects of recollection and familiarity for phonological associates.
\end{abstract}

\title{
Learning and task-dependent factors affect production choices
}

\author{
Jessica Montag \\ University of Wisconsin Madison \\ Maryellen MacDonald \\ University of Wisconsin-Madison
}

\begin{abstract}
Production choices are driven by many factors: experience with language statistics, task-or message-specific factors and constraints on human cognition. Understanding how these constraints operate together is crucial for understanding sentence production. Speakers described human and inanimate targets (baby/vase) in scenes showing human agents acting on these targets. The task elicited relative clauses to contrast targets from competitors ("The baby/vase that the woman is carrying/that is being carried by the woman"). Participant utterances were affected by target noun animacy, and this effect persists across languages. This suggests a role for learning; a speaker's lifetime of experience with their language, including structure alternatives afforded by each language, affects production choices. In addition to long-term learning, immediate demands affect production choices. Targets varied in visual salience, which affected structure choices. Effects are consistent with a task-dependent account of visual salience. Immediate and long-term learning motivations for these effects will be discussed.
\end{abstract}

\title{
Worry effects on visuospatial and verbal working memory
}

\author{
Andre Luiz Moreno \\ Federal University of Rio Grande do Sul \\ Juliana Avila deSouza \\ Federal University of Rio Grande do Sul \\ Gustavo Gauer \\ Federal University of Rio Grande do Sul
}

\begin{abstract}
Worry consists of intrusive, repetitive negative thoughts, usually in verbal form, about a future event of uncertain outcome. Excessive occupation of working memory (WM) subsystems by worry-related representations might cause deficits in WM performance and efficiency. Attentional Control Theory (ACT) predicts that worry occupies the central executive, but not the storage components of WM (phonological loop, visuospatial sketchpad). We tested worry effects on visuospatial and verbal WM memory tasks, with and without binding, in 46 Brazilian undergradutes divided into a low-worry (LW, n=21, 11 female) and a high-worry (HW, \(\mathrm{n}=25,23\) female) group. The HW group showed significantly lower accuracy in the verbal tasks and higher reaction times in the visuospatial tasks. Within the HW group, binding caused lower accuracy in the visual task and lower RTs in the verbal task. Results are discussed according to ACT, which predicts differential effects of worry on performance and efficiency accross WM modalities.
\end{abstract}

\begin{abstract}
Altruistic punishment has a central role in cooperation among humans. People punish uncooperative individuals at a cost to themselves, inducing adherence to social norms. Little is known about altruistic punishment comparing ingroup and outgroup context. Using fMRI, we studied the behavior of altruistic punishment during the Third Party Punishment game. This game shows the behavior spending one's own money, without any personal benefit, to punish unfair behavior of Player A who violate cooperation norms to Player B.This behavior may be differently displayed depending on the in-group (Player C and B same nationality) versus out-group (Player C and B different nationality) setting, in favor to one's own group. This attitude is called parochial altruism. Preliminary results showed activation of anterior cingolate cortex involved in conflict between cognitive and emotional motivations in altruistic punishment. Data also show activation of anterior insula that reflects social norm violations during unfair ingroup condition.

\title{
Changes in the Cognitive Control Network Associated with Adapting to Task Environment Modifications
}

\author{
Jarrod Moss \\ Mississippi State University \\ Winston Jones \\ Mississippi State University \\ Hao Bai \\ Mississippi State University \\ Stephanie Doane \\ Mississippi State University
}

\begin{abstract}
Participants were trained to perform a multitasking task involving prioritizing the sorting of a set of objects while frequently being interrupted by new objects to sort. After training, during an fMRI session, participants performed both the original task and a version of the task in which the function of a key part of the interface was modified. Analysis focused on the cognitive control network, a set of regions that decrease in activity with increasing levels of task experience. The functional connectivity of the anterior insula with the other regions of the control net work predicted the degree to which participants successfully adapted to this modified task better than other individual difference variables collected. The anterior insula is thought to be part of a salience network, and this salience network may help to inhibit old rules of the task set that must be replaced by new rules.
\end{abstract}

\title{
Does the anticipation of a partner's reaction affect action planning? Spatial action-effect compatibility in a joint task
}

\author{
Romy Müller \\ Technische Universität Dresden \\ Dietrich Kammer \\ Technische Universität Dresden
}

\begin{abstract}
Actions in joint tasks are affected by the way the partner is acting. As action planning is mediated by an anticipation of their sensory consequences, this influence is likely to encompass the expected reactions of others to one's own actions. If so, it should be easier to perform actions that trigger compatible partner reactions instead of incompatible ones. To test this, we used a spatial action-effect compatibility paradigm in a joint task. Subjects moved virtual objects to different locations on a multi-touch table, followed by either a partner's manual reactions on the same or another object, or by automatic visual effects. There was a tendency for faster performance of actions with compatible effects, and no interaction with effect type. However, for the joint condition alone, no reliable compatibility benefit was found. The results highlight several difficulties in applying the basic research on ideomotor action control to more naturalistic, joint tasks.
\end{abstract}

\title{
Causal Sense-Making as Benefit in Foresight, Rather than Bias in Hindsight?
}

\author{
Edward Munnich \\ University of San Francisco \\ Jennifer Milazzo \\ University of San Francisco \\ Jade Stannard \\ University of San Francisco \\ \section*{Katherine Rainford} \\ University of San Francisco
}

\begin{abstract}
Upon reading headlines like "Traffic Fatalities Fell Last Year," people often overestimate how well they would have anticipated changes. In the present study, participants who estimated fatality statistics and listed possible causes before learning true statistics (Foresight) were more surprised than those who listed possible causes only after learning true statistics (Hindsight). Pezzo (2003) linked hindsight bias to causal explanations that minimize initial surprise after an outcome-but to what extent can people build an expectation for alternative causation before learning the true outcome? Before seeing true statistics, a subset of our Foresight participants listed causes for changes in the opposite of their expected direction. This did not reduce surprise for those who learned that statistics had moved in the opposite of expected direction, but the number of opposite causes they provided reliably predicted their second set of estimates. Moreover, participants frequently explained surprising statistics using their earlier alternative causes.

\title{
Reciprocal Ascription of Intentions Realized in Robot-human Interaction
}

\author{
Shoji Nagataki \\ Chukyo University \\ Masayoshi Shibata \\ Kanazawa University \\ Takeshi Konno \\ Japan Advanced Institute of Science and Technology \\ Takashi Hashimoto \\ Japan Advanced Institute of Science and Technology \\ Hideki Ohira \\ Nagoya University
}

\begin{abstract}
Abstract: One of the promising strains of humanoid robotics is that which focuses on explicating and reproducing "inner" cognitive functions of humans. This approach is motivated by an ambitious aim of realizing a human-like mind in a robot. In this general context, we have been working on the mechanism of joint attention, the ability of which infants acquire during the earlier stage of development. We already succeeded in constructing a robot which can engage in joint attention activity of an elementary level.

In a more matured stage, however, humans ascribe intentions to each other in joint attention. In order to realize this process in a robot, it is not sufficient for them merely to acquire the ability to follow others' eye direction. Our point is that it is necessary to implement in a robot the relevant inferential mechanism which involves an apparatus for emotion-detection and object-categorization. In our presentation, we will show how this mechanism can work well in our infant-robot.
\end{abstract}

\title{
When irrelevance matters! Effects of distractor-response binding in binary choices under uncertainty
}

\author{
Nadine Nett
}

Universität Trier
Christian Frings
Universität Trier

\begin{abstract}
The distractor-response binding effect states (Frings, Rothermund, \& Wentura, 2007) that distractors appearing on a prime display create an association with the response given. This association is retrieved when, in the probe, the distractor is repeated; the retrieved response can be compatible or incompatible to the currently demanded probe response thereby influencing behavior. We tested if the distractor-response binding effect also occurs in decision making processes under uncertainty \((\mathrm{N}=31)\). Participants had to decide whether two consecutive, imagined patients suffered from either of two diseases. Each decision was based on two cues; one did not discriminate between the two diseases and the other was either strongly or mildly associated with one of the two diseases. The repeating of the irrelevant cue influences decision significantly. Furthermore, we replicated these findings when we varied the strength of the discriminating cue as between-subject factor.

Multitasking Performance: Bound By Task Interference?
}

\author{
Menno Nijboer \\ University of Groningen \\ Niels Taatgen \\ University of Groningen
}

\section*{Hedderik Van Rijn}

University of Groningen

\begin{abstract}
When engaging in concurrent multitasking, it quickly becomes clear that some activities combine well, while others do not. But which factors determine the compatibility of different tasks? We propose that the overlap in cognitive resources causes interference between tasks that limit performance, and that this performance can be predicted using a cognitive model. To test this, we built a model of three tasks, each using a well-defined set of cognitive resources. These tasks were executed separately as well as concurrently and the performance of the model was recorded. Afterwards, we ran an experiment where participants had to perform the same paradigm. Our results show that the model prediction has a good qualitative fit to the participant data: task combinations with more resource overlap had lower performance when performed concurrently, compared to combinations with little or no overlap.
\end{abstract}

\title{
Joint Action with Separate Response Sets for Location Relevant and Irrelevant Spatial Compatibility Tasks
}

\author{
Akio Nishimura \\ Sophia University \\ Chikashi Michimata \\ Sophia University
}

\begin{abstract}
When two individuals engage in their tasks with a common stimulus display, the partner's presence, response, task, and/or focus of attention often affects one's own task performance. The present study investigates how the partner's task affects one's own task performance when one of two adjacently sitting participants engages in location-relevant task and the other in location-irrelevant task, with a common stimulus display and separate response sets. The target appeared at left or right. One participant pressed a left or right button according to the color of the target when it was green or red. The other participant pressed a left or right button of another response set according to the location of the target when it was white. Although the spatial compatibility effects were observed within each task, no cross-task (i.e., cross-participant) interference was observed. Results are discussed in terms of what is co-represented in joint task settings.
\end{abstract}

\title{
Temporal coordination patterns of performer and audience in vaudeville settings
}

\author{
Ryota Nomura \\ The University of Tokyo \\ Takeshi Okada \\ The University of Tokyo
}

\begin{abstract}
Story-telling performers often rely on their audience's smiles, sounds of laughter, body movements, and other qualitative observations to gauge whether their performances are appreciated by the audience. The current study aims to capture the temporal patterns between a performer and his or her audience. A professional rakugo story-teller performed live in front of 20 audience members aged 16 to \(67(M=40.6, S D=16.4)\) in a laboratory. Videotaped performances were categorized by a computer-aided coding system, and the audience's reactions were quantified using the face-tracking and background subtraction computer program. Results demonstrated performer-audience correlations only in a particular frequency band. While the audience often smiled in response to incongruent lines and interpreted gestures, the performer sometimes delivered the points only after audience-initiated smiles and movements. This dynamic co-creation may offer suggestions for a variety of orators who speak regularly in front of audiences.
\end{abstract}

\title{
Strategy flexibility in algebraic problem solving: The influence of feedback and learners' characteristics
}

\author{
Daniela Nussbaumer \\ ETH Zurich \\ Michael Schneider \\ University of Trier
}

Elsbeth Stern
ETH Zurich

\begin{abstract}
The ability to choose problem solving strategies flexibly and adaptively is an important part of expertise. However, it is unclear how simple forms of problem solving practice affect flexibility. We investigate to what extent flexibility in strategy use is dependent on learners' characteristics as intelligence, working memory and prior knowledge and to what extent these individual differences influence how a student can exploit a learning situation.

In a microgenetic design with 24 trials of a mathematical problem solving task, we found that ninth-graders adaptivity of strategy choices increased linearly during practice without feedback and that feedback on strategy adaptivity facilitated the process. Adapting strategy choices to problem types led to shorter solution paths, higher solution rates, and higher speed. This is true independently of students' intelligence or working memory capacity. However, prior knowledge was a predictor of adaptivity, thus leading to a faster development of adaptivity.
\end{abstract}

\title{
Extended Methods to Dynamically Estimate Emphasizing Points for Group Decision Making and the Evaluation
}

\author{
Yoshimasa Ohmoto \\ Kyoto University
}

\author{
Misao Kataoka \\ Kyoto University
}

Toyoaki Nishida
Kyoto University

\begin{abstract}
The purpose of this study is to extend a method of dynamic estimation of emphasizing points (DEEP) to estimate the emphasizing points of a group. A preliminary experiment investigated whether the interaction process would differ depending on the interaction style used, avoiding conflict or expressing opinions. The difference is caused by confidence in their opinions and their commitment to the decision making. We also proposed two extended methods corresponding to the different interaction processes. We then conducted an experiment to evaluate the methods using Embodied Conversational Agents. In conclusion, these proposed methods accurately estimate proposals and satisfy participants in the appropriate group. We could also observe that the participants carefully looked to their partner for their reaction in "avoiding conflict" group and that the participants concentrated on execution of the task in "expressing opinions" group.
\end{abstract}

\title{
The effect of spatial layout of objects on special memory through free searching tasks
}

\author{
Kayoko Ohtsu \\ Waseda University
}

\begin{abstract}
The layout of targets is known to affect spatial memory in association with special frames of reference. However, most of the previous studies have been conducted on the learning from specific viewpoints. The present study examines whether the layout, as the structure of special reference points, has any effect on special memory when learning from all sides while walking around targets. In the experiment, participants explored a virtual circular room under the one of two conditions. The objects were arranged like spots on dice. In the Square Array, 4 objects were set in a square shape, while in the Node Array, one more object was added at the center. After the learning phase, they judged the directions of the targets from several imaginary positions of the room. The results suggest that the participants in the Node Array made quicker and more accurate judgments than those in the Square Array.
\end{abstract}

\title{
How expectation of context sharing with audience causes effects on writing arguments.
}

\author{
Ryosuke Onoda \\ The University of Tokyo
}

\begin{abstract}
This study examined how the students' expectation of context sharing with audience causes effects on their writing arguments. Fourth-grade students \((\mathrm{N}=30)\) from elementary school in Japan were assigned to do two writing argument tasks. In each task, students made an argument and persuaded different audiences (transfer student and old friend) at random. The contents of written arguments were categorized into "claims", "evidence", and "reasoning". Moreover, difficulty of each audience's persuasion and its reasons were asked in questionnaire. The analysis suggested followings. (1) Students generated more "reasoning" in transfer student condition than old friend. (2) Students evaluated persuasion of transfer student was more difficult than old friend. Students judged that the transfer students do not share much context with them, so they tried to persuade by giving more information. The students read the degree of context sharing and changed the contents of writing with changing audiences.
\end{abstract}

\title{
Cognitive Residues of Similarity: After-Effects of Similarity Computations in Visual Search
}

\author{
Stephanie O'Toole DCU \\ Mark T Keane \\ UCD
}

\begin{abstract}
What are the "cognitive after-effects" of making a similarity judgement? What, cognitively, is left behind and what effect might these residues have on subsequent processing? In this paper, we probe for such after-effects using a visual search task, performed after a task in which pictures of real-world objects were compared. So, target objects were first presented in a comparison task (e.g., rate the similarity of this object to another) thus, presumably, modifying some of their features before asking people to visually search for the same object in complex scenes (with distractors and camouflaged backgrounds). As visual search is known to be influenced by the features of target objects, then any after-effects of the comparison task should be revealed in subsequent visual searches. Results showed that when people previously rated an object as being high on a scale (e.g., colour similarity or general similarity) then visual search is inhibited (slower RTs and more saccades in eye-tracking) relative to an object being rated as low in the same scale. There was also some evidence that different comparison tasks (e.g., compare on colour or compare on general similarity) have differential effects on visual search.
\end{abstract}

\title{
When is it rational to rely on heuristics?
}

\author{
Paula Parpart \\ University College London \\ Matt Jones \\ University of Colorado Boulder \\ Bradley Love \\ University College London
}

\begin{abstract}
There have been two distinct notions of heuristics, i.e., Kahneman and Tversky's (1974) heuristics as biased approximations to rational inference, and Gigerenzer et al.'s (1999) idea of smart and adaptive heuristics. Despite the conceptual differences, we provide evidence that heuristics can be seen as approximations to a rational account which is at its core adaptive. In a large cross-validation, we demonstrate that a regularized regression model (from machine learning) with a penalty noise parameter could outperform both heuristics and simple linear regression. Importantly, the penalized regression with an L2-norm could be approximated by tallying, whereas the L1-norm was approximated by take-the-best. Results indicate that the penalized regression treats both heuristics and linear regression as extreme cases of the model. The research implies a common rational basis for heuristics and integrative strategies, suggesting that the relation need not be adversarial. Implications for reconciling adaptive and irrational views of heuristics are discussed.
\end{abstract}

\title{
"This could be a new approach against the flu..." - References to tentativeness of scientific knowledge and their impact on decision processes
}

\author{
Elisabeth Paus \\ University of Muenster, Muenster, Germany \\ Regina Jucks \\ University of Muenster, Muenster, Germany
}

\begin{abstract}
People often rely on popular scientific information when seeking advice for health-related issues. In these cases, further usage of such information should be influenced by its presentation. With \(\mathrm{N}=157\) students, we examined how referring to the tentativeness of health information by using hedges and pointing to the origin of scientific knowledge in science-related texts impacts processes of decision-making. We found that decisions were easier to make when there was no indication given. Furthermore, participants' further use of text-related information was more likely when hedges were used. In contrast, individuals rather relied on their own knowledge when there were no linguistic markers of tentativeness. Additionally, participants' decisions were more in favor of the direction implied in the texts when no indication of the sources of the science-related information was given. However, no effect of experimental manipulation on the confidence of the decisions exists. Finally, we discuss how the presentation of information may contribute to engaging in critical and elaborated processing of scientific information.
\end{abstract}

\title{
Beyond the politeness tightrope: Message design for multiple social goals
}

\author{
David Pautler \\ Institute for High Performance Computing, A*STAR
}

\begin{abstract}
In linguistic pragmatics and social anthropology, several influential researchers believe that politeness is essential for maintaining social order by way of disarming potential aggressiveness [Goffman 1967; Brown \& Levinson 1987; Gumpers 1987]. In one of the most detailed of these theories, Brown and Levinson's, speakers pursue a single goal (e.g. getting the hearer to stop doing something) by using a mental model of the hearer to select a position on a one-dimensional spectrum of strategies that identifies the best balance between achieving the speaker's practical goal while avoiding offense to the hearer (as might occur from a purely brusque request). But are speakers actually limited to this one-dimensional spectrum of strategies? And given that people often pursue more than one goal at once, how might they do so in such a simplistic model of polite communication? I describe and evaluate a computational model that generates strategies for multiple simultaneous goals.
\end{abstract}

\title{
Recognition of Common Object-Based Categories Found in Toddler's Everyday Object Naming Contexts
}

\author{
Alredo Pereira \\ University of Minho
}

\author{
Linda Smith \\ Indiana University
}

\begin{abstract}
Previously, we investigated the distribution of instances of early-learned object-based categories in toddler's realistic everyday learning episodes; we found important differences in terms of frequency and variability (3D vs. 2D; real object vs. realistic toy vs. simple shape).

Using a picture book task we tested 24-36 month olds' recognition of these categories in four conditions: Realistic; Features (only parts of the photo visible); Silhouettes; and Geons (a shape caricature version made with only 3-4 parts and no color or texture). Results show similar recognition for all Realistic and Silhouette versions; Geons were lower than the first two; and Features had the lowest recognition rate. Critically, categories with the highest variability in our previous study were readily recognized by Features but difficult to recognize in Geon version. These results suggest that abstracting global shape is influenced by the specific trajectory of experienced exemplars.
\end{abstract}

\title{
Complex functional brain network properties extracted from EEG reveal different processing patterns in late second-language learners as compared to native-speakers when performing a morphosyntactic task
}

\author{
Alejandro Pérez \\ BCBL, Donostia, Gipuzkoa, Spain \\ Margaret Guillon Dowens \\ Division of English, University of Nottingham, Ningbo, China \\ Nicola Molinaro \\ BCBL, Donostia, Gipuzkoa, Spain \\ Yasser Iturria-Medina \\ Neuroimaging Department, Cuban Neuroscience Center, La Habana, Cuba \\ Paulo Barraza \\ Centro de Investigación Avanzada en Educación, CIAE, Universidad de Chile, Santiago 8330014, Chile \\ Manuel Carreiras \\ BCBL, Donostia, Gipuzkoa, Spain
}

\begin{abstract}
Complex network analysis is applied to study late second language (L2) acquisition using highly proficient late L2 learners when compared to monolinguals performing a morphosyntactic task. Specifically, we assess for (dis)similar topological properties of the functional networks associated with a gender mismatch condition between article and noun at the beginning of a sentence in a Spanish monolingual group and a group of late learners of Spanish whose native language is English (which does not encode gender as a grammatical category). Our results suggest that the detection of incorrect grammatical gender agreement in Spanish recruits the neural networks that subserve the cognitive processing differently in each group. This result provides insight into the functional cooperation and interactions of brain areas while processing an L2 trait not present in L1.
\end{abstract}

\title{
Vocal Charades: The Emergence of Conventions in Vocal Communication
}

\author{
Marcus Perlman \\ University of California, Merced, Merced, CA, United States \\ Rick Dale \\ University of California, Merced \\ Gary Lupyan \\ University of Wisconsin Madison
}

\begin{abstract}
Human communication compresses a massive amount of conceptual structure into conventionalized speech patterns. How do these patterns emerge? Experimental semiotics offers new empirical techniques to address such questions (Fay et al., 2008; Galantucci, 2005; Garrod et al., 2007; Kirby et al., 2008). We devised an experiment to observe the emergence of communicative conventions. The study explores the development of vocal communication systems through an iterative Vocal Charades game. The game is played by two players each given a stack of 12 cards. Written on each card is a word from six antonymic pairs (rough/smooth, bad/good, etc.). Over ten rounds, players took turns "vocalizing" the meaning of their words without using language or gestures. Analyses reveal how sounds conventionalize, leading to stereotyped forms and improved guessing. The conventional forms that develop are predicted by iconic correspondences with meaning, but also exhibit more arbitrary features that distinguish semantically similar words.
\end{abstract}

\title{
Perception of collaboration in joint musical performances
}

\author{
Ana Pesquita \\ Department of Psychology, University of British Columbia \\ Timothy Corlis \\ Department of Music, University of British Columbia \\ James T. Enns \\ Department of Psychology, University of British Columbia
}

\begin{abstract}
Humans are exquisitely sensitive to social interactions. This study explored whether this extends to interactions in music performance. Jazz musicians are fluent at working together to produce music that is more than the sum of its parts, and listeners claim anecdotally to hear when musicians are 'in the groove'. We employed jazz-standard duets varying in the opportunity for collaboration (two-way, one-way, none), to test listeners' perception of collaboration. In experiment 1, participants rated random selections from these recordings in the dimensions of synergy, creativity, emotionality, and engagement. Results showed considerable sensitivity to collaboration, with sensitivity varying both with social intelligence and musical training of the participant. In experiment 2, participants made explicit judgments of whether the selections involved collaboration, with the results showing they could not. We conclude that the degree of collaboration in joint musical performances influences the implicit experience of listeners, but is not accessible for explicit judgments.
\end{abstract}

\title{
I did not write you this before, did I? Destination Memory in Computer-Mediated Communication
}

\author{
Stephanie Pieschl \\ Westfälische Wilhelms-Universität Münster \\ Verena Karwinkel \\ Westfälische Wilhelms-Universität Münster
}

\begin{abstract}
In face-to-face communication people have problems recalling which facts they have disclosed to whom. We explore if such destination memory (DM) problems also exist in computer-mediated communication (CMC). Participants ( \(\mathrm{N}=64\) ) disclosed 50 pieces of personal information to 50 fictitious partners in a sham Skype environment in two conditions, one-sided "telling" and communicative "turn-taking". Their recall for facts, faces, and fact-face-pairs was measured as dependent variables. ANOVA results show a significant main effect of type of recall \((\mathrm{F}(2,61)=222.47, \mathrm{p}<.001)\) : recall for facts was better than for faces or fact-face-pairs, indicating that DM problems emerge when faces are previously unknown. Additionally, we found a significant main effect of conditions \((\mathrm{F}(1,62)=6.75, \mathrm{p}=.012)\) : contrary to expectations recall in the "telling" condition was best. These interesting findings and those of a second study will be discussed considering the specific characteristics of CMC.
\end{abstract}

\title{
Structural Alignment in Young Children's Shape Categorization: Different Roles for Learning from Comparisons and Contrasts
}

\author{
Raedy Ping \\ University of Chicago \\ Micah Goldwater \\ Northwestern University \\ Bryan Matlen \\ Carnegie Mellon University
}

\author{
Linsey Smith
}

Northwestern University

\author{
Susan Levine \\ University of Chicago \\ Dedre Gentner \\ Northwestern University
}

\begin{abstract}
Creating correct shape categories requires young children to overcome reliance on perceptual features and surface similarity as cues for membership and to use abstract rules as bases for categorization (e.g., triangles are enclosed shapes with three sides). Relying on surface similarity, children often wrongly include non-triangles that resemble familiar triangles in the triangle category, and exclude unfamiliar actual triangles. This study attempted to improve preschool-age children's triangle categorizations by presenting structurally aligned comparisons that either shared a common structure or that highlighted a contrasting structure. Across both types of comparisons, the exemplars were either highly or lowly superficially similar (both variables manipulated between subjects). We hypothesized that low-similarity common-structure comparisons would support extension of the triangle category beyond prototypical exemplars, while high-similarity contrastive alignments would highlight category boundaries. Preliminary results suggested that improvement in categorization accuracy was primarily driven by a reduction in erroneous identification of a non-triangle as a triangle.
\end{abstract}

\title{
Fixation on Failure: Failing to Solve a Problem Hinders Subsequent Problem-Solving Ability
}

\author{
Vencislav Popov \\ New Bulgarian University
}

\begin{abstract}
This study explores how previous experience affects current performance. Despite the vast amount of research on transfer and learning effect in problem-solving, as far as we know little to no work has been done on how failure to solve a problem affects subsequent problem-solving ability. The current experiment explores this issue and the role of working memory in the process. Two variables were manipulated - the experienced success or failure on a single multiplication problem and the amount of working memory resources required by the following addition problem. Results show negative impact of failure on subsequent process-time: the problem-solving time for the addition problem was higher for participants who failed to solve the multiplication problem. There was no interaction between experienced performance and the WM resources required by the subsequent problem. These results suggest that researchers must probably be careful to avoid fixation on failure as a confounding variable.
\end{abstract}

\title{
Effects of Gestures while Studying Language Animations
}

\author{
Lysanne Post \\ Erasmus University Rotterdam, Rotterdam, The Netherlands \\ Tamara van Gog \\ Erasmus University Rotterdam, Rotterdam, The Netherlands \\ Fred Paas \\ Erasmus University Rotterdam, Rotterdam, The Netherlands \\ Rolf Zwaan \\ Erasmus University Rotterdam, Rotterdam, The Netherlands
}

\begin{abstract}
Two experiments will be presented. Experiment 1 examined whether simultaneously observing and making gestures while studying animations would lighten cognitive load and facilitate the acquisition of grammatical rules, as would be predicted by theories of embodied cognition and cognitive load. However, results showed that children in the gesturing condition performed worse on a subsequent test than children in the control condition. This was particularly true for children with low levels of general language skills, whereas children with high language skills experienced no detrimental effects of gesturing. Because simultaneously observing and making gestures hampered learning, the question is whether only observing gestures would be effective. Moreover, because it is still unclear whether seeing animated sentence transformations has a positive effect on learning, Experiment 2 compares the effects of three instructional conditions for both low and high-ability learners: static pictures, animation without observing gestures, and animation with observing gestures.
\end{abstract}

\title{
How Does Eye Gaze Affect Vocal Imitation in Autism?
}

\author{
Marie Postma-Nilsenová \\ Tilburg University \\ Martijn Balsters \\ Tilburg University \\ Mariska van Kastel \\ Tilburg University
}

\begin{abstract}
Earlier studies showed an important role of vocal imitation in social interactions. At least some kinds of social imitative behavior, including gesture and pitch adaptation, appear to be triggered by direct eye gaze (Wang, Ramsey \& Hamilton, 2011). Past research indicated that autistic individuals may have difficulties with both shared gaze focus and joint attention. Therefore, we might expect that their vocal imitative behavior would differ from the behavior of TD individuals. In our study, we explored vocal imitation by autistic speakers in an experiment with stimuli eliciting eye contact (shared focus), joint attention or a disruption of eye contact.
\end{abstract}

Semantic Intuitions in Statistical Causal Reasoning
}

\author{
Benjamin Quack \\ University of Göttingen
}

\author{
Ralf Mayrhofer
}

University of Göttingen

\author{
Michael Waldmann \\ University of Göttingen
}

\begin{abstract}
In psychology, philosophy, and linguistics there has been a debate about two competing frameworks of causal reasoning. Dependency theories, especially causal Bayes nets, focus on causally motivated statistical or counterfactual dependencies between events (causes and effects). In contrast, force dynamic theories implement causation as arising (deterministically) from force interactions involving agents impinging on the prior tendencies of patients. To date force dynamic theories have primarily focused on the representation of different semantic causal concepts in scene descriptions. Our goal is to bring the two competing frameworks together. We will present a model that implements the interaction between agents and patients in terms of probabilistic forces. We have tested this new model in an experiment in which we tested how contingency information interacts with the assumptions about intrinsic tendencies of patients in people's usage of semantic causal concepts (e.g., CAUSE, PREVENT, HINDER, HELP, ALLOW, and ENABLE).
\end{abstract}

\title{
Simulating the N400 ERP component as semantic network error: Insights from a feature-based connectionist attractor model of word meaning
}

\author{
Milena Rabovsky \\ Humboldt University at Berlin
}

\author{
Ken McRae \\ University of Western Ontario
}

\begin{abstract}
The N400 ERP component is widely used in research on language and semantics, but the specific underlying mechanisms are currently unclear. We explored the mechanisms underlying the N 400 by examining how a connectionist semantic network's performance measures covary with N 400 amplitudes. We simulated six N400 effects obtained in empirical research. Network error was consistently in the same direction as N400 amplitudes, namely smaller for high frequency words, words with few semantic features, semantically related targets and repeated words. Furthermore, the repetition-induced decrease was stronger for low frequency words and words with many features. In contrast, semantic activation corresponded less well with the N400, and instead seemed related to lexical decision performance. Our results suggest an interesting relation between N400 amplitudes and semantic network error. In psychological terms, network error has been conceptualized as implicit prediction error. Thus, N400 amplitudes may reflect implicit prediction error in semantic memory (McClelland, 1994).
\end{abstract}

\title{
Scaling-up Perception-Action Links: Evidence from Synchronization with Individual and Joint Action
}

\author{
Veronica Ramenzoni \\ Donders Institute for Cognition
}

\author{
Natalie Sebanz \\ Central European University
}

\author{
Günther Knoblich
}

Central European University

\begin{abstract}
How do we map joint actions we participate in onto joint actions we observe others performing, such as when a couple dancing tango observes another couple dancing tango? We investigated this question using a task where participants were instructed to perform individual or joint movements in synchrony with individual or joint movements observed on a computer screen. The observed movements started slowly and then continuously increased in tempo (from 1.75 Hz to 3 Hz ). The results showed that, with regard to spatial parameters, joint performance was more accurate when observing joint performance than when observing individual performance. Individual performance was more accurate when observing individual action than when observing joint action. There were no systematic differences with regard to timing parameters. These results suggest that mechanisms of temporal coordination may be less susceptible to differences between individual and joint action than mechanisms of spatial matching.
\end{abstract}

\begin{abstract}
The cognitive mechanisms that underlie beliefs in the supernatural are not well understood. In an attempt to understand this phenomenon, we hypothesized that the cave environment "affords" such usage. In our experiment, 52 participants completed a survey about their metaphysical beliefs inside a room providing a great deal of natural light, while another 52 participants completed the same survey in a dark and windowless room. The survey asked participants to rate their beliefs in a variety of supernatural phenomena and also included multiple-choice questions which described bizarre scenarios that could be explained either scientifically or supernaturally. The supernatural responses to both the rating-scale questions and to the multiple-choice questions were significantly higher in the cave-like condition. These results are consistent with anthropological claims that the dark zones of caves may have played a role in the environment of evolutionary adaptedness that contributed to humans' tendency toward magical thinking.

\title{
Approximating the Value Function in the Actor Critic Architecture using the Temporal Dynamics of Spiking Neural Networks
}

\author{
Jeffrey Rodny \\ University of California, Merced \\ David Noelle \\ University of California, Merced
}

\begin{abstract}
The human ability to learn from sparse rewards has been modeled with the temporal difference learning mechanism, using an actor-critic architecture (Montague, Dayan, \& Sejnowski, 1996). These models incorporate an "adaptive critic" which learns a "value function": a mapping from the learner's current situation to expected future reward. In complex environments, a "value function approximator" (VFA) must be implemented to allow generalization between similar situations. While some implementations of VFAs have been successful (Tesauro, 1992), this approach does not consistently converge to a solution (Boyan and Moore, 1995). With the goal of developing a general and reliable VFA mechanism, capturing human level learning performance, we have explored the use of spiking neural networks, including liquid state machines, as a technique for VFA learning in complex environments. We report on simulations demonstrating the benefits and pitfalls of using the temporal dynamics of neural spikes to encode the learner's state.
\end{abstract}

\title{
Distractor frequency effects in language production: An ERP study
}

\author{
Lana Rohr \\ Humboldt-Universität zu Berlin, Berlin, Germany \\ Rasha Abdel Rahman \\ Humboldt-Universität zu Berlin, Berlin, Germany
}

\begin{abstract}
In the picture-word interference paradigm low-frequency words have been shown to induce longer naming times, and thus more interference, than high-frequency words. In this study we used event-related potentials (ERPs) to explore the time course and locus of frequency effects within the language production system. Furthermore, we tested whether frequency effects are related to non-lexical variables such as valence and arousal. We presented pictures and superimposed high and lowfrequency distractors and additionally varied the emotional valence and arousal of the distractor words. The effects of distractor frequency in naming times and ERPs - starting at about 300 ms - were modulated by arousal, suggesting that non-lexical mechanisms can modulate distractor effects in the picture-word interference paradigm.

\begin{abstract}
Infant language learners are faced with the difficult inductive problem of determining how new words map to novel or known objects in their environment. Bayesian inference models have been successful at using the sparse information available in natural child-directed speech to build candidate lexicons and infer speakers' referential intentions. We begin by showing that when a Bayesian model is optimized for monolingual input (Frank et al., 2009), the model does not sufficiently handle bilingual input, especially as referential ambiguity increases. Here we propose an extended Bayesian model that approximates infants' mutual exclusivity bias to support the differential demands of monolingual and bilingual learning situations. The extended model is assessed using corpora of real child-directed speech, showing that performance can be optimized for both monolingual and bilingual contexts. We show that including both monolingual and bilingual demands in model optimization yields significantly different results than when only one context is considered.

\title{
Producing ambiguous messages
}

\author{
Sebastian Rose \\ Humboldt-Universität zu Berlin, Berlin, Germany \\ Katharina Spalek \\ Humboldt-Universität zu Berlin, Berlin, Germany \\ Rasha Abdel Rahman \\ Humboldt-Universität zu Berlin, Berlin, Germany
}

\begin{abstract}
Recent evidence suggests that lexical-semantic activation spread, including the formation of ad-hoc relations, can be dynamically shaped by contextual factors (Abdel Rahman \& Melinger, 2011). In this study we investigated whether cognitive processing modes can affect lexical-semantic activation during single word production. Specifically, we tested whether prior processing of linguistic ambiguities, presented in the form of puns, has an influence on the co-activation of unrelated meanings of homophones in a subsequent language production task. In a picture-word interference paradigm with word distractors that were semantically related or unrelated to the non-depicted meanings of homophones we found facilitation induced by related words only when participants listened to puns before object naming, but not when they heard jokes with unambiguous linguistic stimuli. This finding suggests that a cognitive mode of ambiguity processing can induce the activation of ambiguous messages during speech planning.

Explanatory Reasoning in Causal-based Categorization
}

\author{
Anselm Rothe \\ University of Göttingen \\ Ralf Mayrhofer \\ University of Göttingen
}

\begin{abstract}
Research on causal-based categorization focuses on how people categorize exemplars that have causally linked features. One prominent account, the generative model (Rehder, 2003) models membership judgments as a function of an exemplar's likelihood being generated by the category's causal model. In contrast, Mayrhofer and Rothe (2012) found that the explanatory role of the causal model strongly influences membership judgments - indicating the importance of explanatory reasoning processes and that in such tasks people might be guided by explanatory goodness (i.e., how well an exemplar's membership can be explained in the light of the category's causal relations). However, the evidence for this claim was quite indirect so far. In the present categorization study, we collected judgments about category membership, frequency, and explanatory goodness. In contrast to the predictions of the generative model, membership ratings are far better resembled by ratings of explanatory goodness than by subjects' estimations of exemplar likelihood.
\end{abstract}

Learning in a different way: Interaction gestures influence category learning on multi-touch-tables
}

\author{
Susana Ruiz Fernández \\ Leibniz Knowledge Media Research Center \\ Birgit Imhof \\ Leibniz Knowledge Media Research Center \\ Julia Kranz \\ Leibniz Knowledge Media Research Center \\ Stephan Schwan \\ Leibniz Knowledge Media Research Center \\ Barbara Kaup \\ Psychological Institut University of Tübingen \\ Peter Gerjets \\ Leibniz Knowledge Media Research Center
}

\begin{abstract}
This study investigated the influence of interaction gestures on learning using multi-touch-tables. During a learning phase, participants learned how to categorize Renaissance and Baroque paintings either by moving them over the display of the multi-touch-table or by tapping a marked field on the display representing an art epoch. In the testing phase, participants had to categorize paintings known from the learning phase and new paintings in a forced-choice task. The Gestural Conceptual Mapping approach argues that congruency between gesture and mental processes enhances learning. Due to the discrete nature of the categorization process, learning should benefit from a discrete tapping gesture. The Reality-based Interaction approach argues that gestures should map with interaction experiences in the real world to promote learning. Moving objects to places that represent categories can be considered similar to the real world experience of sorting objects and should facilitate category learning. The results support the latter approach.
\end{abstract}

\title{
Social interaction and group dynamics of virtual cooperative agents
}

\author{
Alexei V. Samsonovich \\ George Mason University
}

\begin{abstract}
The challenge of integration of virtual agents and co-robots into the human society requires for these future artifacts to become human-compatible, in addition to being generally intelligent and capable of providing specific expertise. Specifically, a human-compatible agent should be able to induce in humans a sense of co-presence of a potentially equal mind capable of mutual understanding and human-like learning, long-term personal relationships and generous initiative. Achieving these qualities requires social emotional intelligence. In order to be able to implement equivalents of social emotions in artifacts, it is vital to better understand social interactions in small groups based on cognitive architectures like eBICA (Samsonovich, 2013). The present work makes one step further in this direction, continuing the development and computational exploration of the new framework for emotional cognitive architectures. In the focus are relationships of trust and mutual respect, leadership and allegiance, and related to them social and complex emotions.

John Spencer
University of Iowa

\begin{abstract}
The dimensional change card sort (DCCS) task is a model paradigm for studying developmental change attention switching during childhood. In the DCCS, children are asked to sort two-dimensional cards (e.g., blue star) by one dimension and then again by the other. Typically, 3-year-olds fail to switch dimensions, continuing to sort the cards by the first dimension. Four-year-olds readily switch dimensions. The source of this sudden developmental change has been widely debated. A recent proposal is that only older children are able to selectively attend to one dimension, enabling them to flexibly switch the dimension along which they sort. We present results showing that experience matching values along one dimension prior to participating in the DCCS task facilitates 3-year-olds' ability to switch dimensions. We implemented this experience in a dynamic neural field model of DCCS performance and found that it mimicked developmental change in dimensional attention in the model.
\end{abstract}

\title{
Autonomy in Learning Sensorimotor Spaces with Dynamic Neural Fields
}

\author{
Yulia Sandamirskaya \\ Ruhr-Universität Bochum, INI, Germany
}

\begin{abstract}
The metaphor of cognition as a dynamical system - which evolves under external forces, is constrained by the internal structure, and is shaped by the agent's behavioral history - is a fruitful source of inspiration guiding experimental and theoretical work. Dynamic Field Theory offers a framework, in which cognitive processes and their development may be modeled quantitatively as dynamics of activation functions defined over behaviorally-relevant parameter spaces. Although learning through memory trace formation is an integral part of the DFT, the behavioral spaces are assumed to be given. However, these spaces may be shaped autonomously while acting in an environment. The autonomy of learning processes is achieved if the behavioral states have intentional structure, which sustains representations to enable learning and ensures their deactivation when appropriate. In this work, I show how intentional structure realized with Dynamic Neural Fields enables autonomous development of a sensorimotor mapping involved in looking behavior.

\section*{Robert L. Goldstone}

Indiana University

\begin{abstract}
Search requires individuals to balance exploration (finding new resources) with exploitation (making use of current resources) over time. How individuals perceive reward in a temporally extended search may significantly influence their explore/exploit decisions. Furthermore, how individuals perceive reward is related to impulsivity. Different aspects of impulsivity can lead to different predictions for people's search patterns. We tested some of these predictions in a search task with a non-depleting condition where resources would maintain value when exploited, and a depleting condition where resources lost value when exploited. Participants with larger temporal discounting rates (greater impulsivity) started exploiting depleting resources later than those with smaller discount rates, surprisingly appearing more patient and performing closer to the optimal level. However, this difference disappeared when resources were non-depleting. Greater impulsivity might make individuals more risk-seeking in the depleting search environment and thus explore depleting resources longer at the beginning phase of the search task.
\end{abstract}

\title{
Reducing Behaviorism and Cognitivism
}

\author{
Ricardo Sanz \\ Universidad Politecnica de Madrid
}

\begin{abstract}
Behaviorism and Cognitivism are two perspectives in cognitive science that have had significant impact in the evolution of mind theory. Behaviorism is centered in the study of mind from the perspective of externalized behavior. Behaviorism is opposed to the approach to mind analysis from an introspective point of view, even rejecting the existence of internal states. The cognitivist reaction explained some aspects of memory and learning that behaviorism failed to account for. Internal mental states -beliefs, values, intentions- are the common trade of cognitivist models. Cognitivism employs computer-based information processing as the paradigmatic principle sustaining cognitive modeling, where data structures implement the required internal mental states. These two approaches to cognitive science are usually considered as antagonistic; but they are not. The only difference is that they approach the problem of the modeling of mind from an input/output perspective or from a statebased perspective. Behaviorism focuses on using a black box model of minds while cognitivism focuses on white box models. Both are right and complementary approaches and are degenerate forms of a more fundamental approach that may be applied to mind modeling: systems identification.

Modeling biconditionals: Equivalence in an uncertain world
}

\author{
Koji Sawa \\ Japan Women's University, Kawasaki, Kanagawa, Japan \\ Junki Yokokawa \\ Tokyo Denki university, hatoyama, saitama, japan \\ Tatsuji Takahashi \\ Tokyo Denki university, hatoyama, saitama, japan
}

\begin{abstract}
For almost a half century, it has been known that participants consider the truth value of "if \(p\) then q," in a "defective" way, as true when \(p\) and \(q\) are both true, false when \(p\) is true but \(q\) is false, but uncertain whenever \(p\) is false. Recently, researchers has given this truth table a new normative status, under the theory of subjective probability by de Finetti, as of conditional event, \(\mathrm{q}-\mathrm{p}\). On the basis of ample evidence that \(\mathrm{P}(\) if p then q\()=\mathrm{P}(\mathrm{q}-\mathrm{p})\), we study biconditionals, "if p then q , and if q then p ." Here we show the psychological priority of biconditional event to material equivalence. Additionally, we discuss the logical background of (bi-)conditional event and three types of uncertainty. Two are ones in the domain and codomain of the truth-function, and the other is connected to the indefiniteness of a world or the frame problem.

\title{
Integrating Top-down and Bottom-up Approaches in Holistic Perceptual Categorization
}

\author{
Samer Schaat \\ Vienna University of Technology
}

\author{
Alexander Wendt \\ Vienna University of Technology \\ Dietmar Bruckner \\ Vienna University of Technology
}

\begin{abstract}
Perceptual categorization is a key problem for an agent to cope with its internal and external world. Following a functional and subjective approach of cognitive modeling, the primary purpose of perceptual categorization is modeled as the valuation of a stimulus regarding its potential to satisfy an agent's current needs. Additionally an integrated and holistic approach is used, where categorization considers the integration of subjective influences. Such an approach complies with the consideration of top-down perception and priming. Using an activation-based exemplar model, the objective criterion of perceptual similarity, which represents bottom-up aspects of perception, and the subjective expectation-based criterion of cathexis, which represents top-down aspects of perception, are integrated in a holistic multi-criteria model of perceptual categorization. An Artificial Life simulation demonstrates the model's ability to relate stimulus objects to an agent's internal needs. Additionally, the usage of multiple criteria provides a more confident valuation of stimulus objects.

Your mind wanders weakly, your mind wanders deeply: Objective measures reveal mindless reading at different levels
}

\author{
Daniel J. Schad \\ Charité, University Medicine Berlin, Germany
}

Antje Nuthmann
University of Edinburgh, UK
Ralf Engbert
University of Potsdam, Germany

\begin{abstract}
During mind wandering, attention is directed away from the external environment and cognitive processing is decoupled. Mind wandering is usually treated as a dichotomy and often measured using self-reports. We here propose the levels-of-inattention hypothesis, postulating graded decoupling at different processing levels. To measure levels of decoupling during reading we introduce the sustained attention to stimulus task (SAST), which relies on psychophysics of error detection. We found that subjects were less likely to notice errors at higher levels of cognitive processing. Eye tracking showed that before errors were overlooked effects of high- and low-level linguistic variables were reduced in a graded fashion, indicating episodes of weak and deep decoupling. Individual gaze durations predicted overlooking of errors five seconds before they occurred. Our findings support the levels-of-inattention hypothesis and suggest levels of mind wandering can be measured in the SAST. Eye tracking provides a promising tool to detect mind wandering online.

\title{
Automatic processing of metaphor in right hemisphere lesion patients
}

\author{
Gwenda L Schmidt-Snoek \\ Hope College
}

Marguerite McQuire
University of Pennsylvania
Anjan Chatterjee
University of Pennsylvania

\begin{abstract}
While metaphor comprehension deficits were initially reported in right hemisphere lesion patients (RHLs), more recent work fails to find such deficits. One possibility is that the metalinguistic tasks typically used only uncover conscious, controlled comprehension processes. We tested the hypothesis that chronic RHLs would show a deficit in a task that taps automatic processes, even if their performance on a metalinguistic task was not abnormal. Nine RHL were tested on a sentence/matchingword lexical decision priming task with literal and metaphorical sentences and a short SOA. Nine left hemisphere lesion patients and thirteen age and education matched healthy adults served as controls. A two-way mixed ANOVA revealed a main effect of sentence type ( \(\mathrm{F}(1,28)=7.0, \mathrm{p}=.01\) ) but no effect of group. All three groups showed larger priming effects for literal sentences ( \(\mathrm{M}=70 \mathrm{~ms}\) SD=70ms) than for metaphorical sentences ( \(\mathrm{M}=34 \mathrm{~ms}, \mathrm{SD}=68 \mathrm{~ms}\) ). These data suggest chronic RHLs do not have metaphor comprehension deficits even with an automatic processing task.
\end{abstract}

\title{
Interacting with digital maps for indoor navigation
}

\author{
Verena Schnitzler \\ Center for Cognitive Science, University of Freiburg, Germany
}

\begin{abstract}
This contribution presents studies currently underway about the impact of interactive, digital maps in architectural settings. Google Indoor Maps allows users of Android smartphones to identify their position and heading in complex public buildings. The study compares participants with and without access to such a device. Participants perform both spatial learning and free navigation tasks in a building. We evaluate how their wayfinding behavior as well as performance on spatial memory measures differs between groups with respect to: efficiency, effectiveness on the task; satisfaction and perceived competence with both the digital device and the building setting. We further compare groups with high vs. low spatial abilities (perspective taking, SBSOD sense of direction) as well as different cognitive styles (route vs. survey preference), as expect an impact on both strategies of interacting with the device and task success.
\end{abstract}

\title{
The conversational style of mothers interacting with their two- and five-year-old children
}

\author{
Tanja Schorch \\ Max-Planck-Institute for Human Cognitive and Brain Sciences, Leipzig, Sachsen, Germany \\ Jens Brauer \\ Max-Planck-Institute for Human Cognitive and Brain Sciences, Leipzig, Sachsen, Germany
}

\begin{abstract}
We investigated interactions between mothers and their children and specifically measured differences in the mothers' verbal and nonverbal communication as a function of their children's age.

Forty two-year-old children and forty five-year-old children and their mothers were video-recorded in two conversational settings. Measures were obtained for the mothers' speech complexity (mlu, use of verbs, complex sentences, and direct objects), their emotional prosody (pitch, pitch variability), and their pointing gestures.

Mothers of 5-year-olds used more complex speech than mothers of 2-year-olds, whereas mothers of 2-year-olds showed more emotional prosody, and pointed more often than mothers of five-year-olds. This is interpreted as an adaptation to their children's conversational abilities. As younger children do not understand very complex utterances, but might rely on more nonverbal communication (such as pointing gestures and emotional prosody) than older children, their mothers might use a less verbally complex, but rather emotionally rich and non-verbally sophisticated interaction style.
\end{abstract}

\title{
Do pictures facilitate mental imagery during text processing?
}

\author{
Anne Schüler \\ Knowledge Media Research Center \\ \section*{Katharina Scheiter} \\ Knowledge Media Research Center
}

\begin{abstract}
The aim of the reported study was to test the hypothesis that text-picture combinations aid learning because pictures reduce the learners' need to actively generate mental images on their own. This, in turn, should free up cognitive resources which can be used for other cognitive processes associated with learning, resulting in better performance compared to a textonly condition. This hypothesis was confirmed in an experiment based on a \(2 \times 2\) design with picture presentation prior to text (yes vs. no) and visuo-spatial secondary task (with vs. without) as independent variables: Learners without pictures showed a higher load of the visuo-spatial sketchpad (i.e., higher interference with the secondary task) during text processing than learners with pictures, presumably because the former generated mental images during reading. This interpretation is supported by the finding that pictures were especially helpful for learners with low imagery capacity. The implications of these results are discussed.
\end{abstract}

\title{
We never walk alone: The influence of social interaction on wayfinding behavior
}

\author{
Sarah Schwarzkopf \\ Center for Cognitive Science Freiburg \\ Rul von Stülpnagel \\ Center for Cognitive Science Freiburg \\ Christoph Hölscher \\ ETH Zurich Cognitive Science
}

\begin{abstract}
When people move through large-scale environments, they use multiple strategies to find their ways. While many studies have investigated individual wayfinding strategies, in naturalistic settings people usually don't navigate alone, but search for their destinations in pairs or small groups. Having a shared goal can have an impact on the perception of the scene, the attentional focus and the behavior of the individual participant. We investigate how social interaction influences navigation behavior and focus on a cooperative scenario. We developed a joint wayfinding paradigm to measure walking trajectories, walking speed, gaze behavior and speech data in a naturalistic indoor setting. We use two mobile eyetracking devices to analyse the behavior of pairs of participants solving wayfinding tasks. We'll present data on the impact of participants' cooperation behavior on perceptual and attentional processes and wayfinding strategies.
\end{abstract}

\title{
Does the listener keeps spatial information from the speaker's cohesive gestures to comprehend subsequent sentences without gestures?
}

\author{
Kazuki Sekine \\ University of Birmingham \\ Sotaro Kita \\ University of Birmingham
}

\begin{abstract}
This study examined whether listeners keep spatial story representation created by speaker's cohesive gestures beyond the concurrent sentence. Participants were presented with three-sentence discourse with two protagonists, in the first and second sentences, the gestures consistently assigned the two protagonists in either right or left of the gesture space. The third sentence (without gestures) referred to one of the protagonists, and the participants responded with one of the two keys to indicate the relevant protagonist. The response keys were either spatially congruent or incongruent with the gesturally established locations for the two participants. Experiments 1 and 2 showed that the performance in the congruent condition was better than that in the incongruent condition. Thus, listeners make a spatial story representation based on the gestures, and the spatial representation persists beyond the concurrent sentence, and the information is still activated in a subsequent sentence without a gesture.
\end{abstract}

School of CIS \& Center for Neural and Cognitive Sciences, University of Hyderabad Hyderabad-500046, India

\begin{abstract}
In this study we manipulated colors and shapes in different blocks in order to investigate the differential effect of stable spatial cues on color and shape recall. The task involves recency judgment where two items from the stream of serially presented stimuli are shown and the subjects have to respond by indicating which of them came later in the sequence. Our studies show a clear dissociation between color and shape recall. While spatial cues seem to facilitate shape recall, they seem to degrade the color recall performance. This effect becomes significant for shape-location trials beyond the working memory capacity limit of 4 items. The results can be interpreted as if individuation of colored objects draws from the same attentional resources as spatial attention and the resulting competition degrades performance in serial order judgment involving color whereas shape recall does not seem to be subject such competition.
\end{abstract}

\title{
Physical Skill and Idea Interaction in the Creation of New Dance Movements
}

\author{
Daichi Shimizu \\ University of Tokyo, Bunkyoku, Tokyo, Japan \\ Takeshi Okada \\ University of Tokyo, Bunkyoku, Tokyo, Japan
}

\begin{abstract}
It has been suggested that in creative activities, cognition and physical action are related to each other. This study focuses on this relationship in breakdance, which is a creative activity of artistic and acrobatic movements. For four months, we conducted field observations of practice sessions of three expert breakdancers, and held interviews with them to investigate the creation process of new and original movements. The video records of the 34 practices and the interview data were analyzed with respect to two aspects: 1) Whether or not the dancers performed important movements appropriately; and 2) What the dancers were thinking when generating new aspects of the movements. The results show an interactive process between the development of dance movements and the generation of ideas. The dancers gradually became able to perform the movements appropriately by generating new ideas, and they generated new ideas using the somatic sensation of the new movements.

\author{
Kwangsu Cho \\ Sungkyunkwan University
}

\begin{abstract}
A peer-based reviewing on writing often leads to improving learners' writing quality. Particularly, reviewing by writing comments lifted writing quality more greatly than reviewing without writing comments. This implies that learners' hard working on peers' writing engenders benefits on their own writing. This study attempted to explore which cognitive mechanism underlies in this cooperative learning system. We questioned whether learners' use of metacognitive strategies during reviewing might facilitate learners' self-learning. In a preliminary study, participants were asked to categorize their comments on peers' reports. Results from the study revealed that learners who categorized comments used metacognitive strategies more increasingly than those who did not. Controlling for the amount of using metacognitive strategies, writing quality was improved numerically more when learners were engaged in the categorization task than when they were not. With further data, we will examine to what degree learners' metacognitive learning during reviewing contribute to writing improvement.
\end{abstract}

\title{
Foot Movement for Walking Biases the Visual Attention Allocation
}

\author{
Marie Shoda \\ The university of Tokyo, Bunkyo-ku, Tokyo, Japan
}

Kazuhiko Yokosawa
The University of Tokyo

\begin{abstract}
Precise walking requires ample cognitive resource to control balance in the single leg stance while head moves periodically in the vertical axis within each stride cycle. Because visual information is a key factor in motor control, we hypothesize that walking alters the allocation of visual attention, thereby affecting the selective intake of visual information. Participants localized a peripheral dot while identifying the central letter in a display during treadmill walking, stepping in place, and standing still. Vertical head movement occurred only in the walking condition. Results show that visual attention was skewed in the single leg stance during walking and stepping in place. Vertical head movement affected the allocation of visual attention because only in the walking condition was attention oriented downward without skewing during the double leg stance. Cognitive resources and head vertical movement appear to work differently in adaptation of visual attention to walking.

CLEARPOND: Phonological and orthographic neighborhood information for multiple languages
}

\author{
Anthony Shook \\ Northwestern University
}

\author{
Sarah Chabal \\ Northwestern University
}

\author{
James Bartolotti
}

Northwestern University
Viorica Marian
Northwestern University

\begin{abstract}
Past research has demonstrated that neighborhood variables (e.g., neighborhood density) influence lexical processing (Andrews, 1989; Vitevitch \& Luce, 1999), but can have distinct effects for different languages (Vitevitch and Stamer, 2006). To explore how neighborhoods can vary both within and across multiple languages, we have developed CLEARPOND (the CrossLinguistic Easy-Access Resource for Phonological and Orthographic Neighborhood Densities), a database of phonological and orthographic neighborhood information for five languages: Dutch, English, French, German, and Spanish. Analyses using the CLEARPOND database revealed consistent effects of lexical frequency and word-length on neighborhood size across languages, while also highlighting how the languages differed in the distribution of neighbor-types (phonological/orthographic). CLEARPOND not only provides a tool that can be used to study differences between languages but also provides detailed information about characteristics of individual words in multiple languages. The CLEARPOND database is freely-available online and can be accessed at http://clearpond.northwestern.edu.
\end{abstract}

\title{
Thematic Music and Context Interact to Affect Inclusion of Schematic Elements During Story Generation
}

\author{
Cynthia Sifonis
}

Oakland University

\begin{abstract}
Listening to a \(90-\mathrm{sec}\) excerpt of thematic music (e.g., baby music) affects performance in a subsequent generation task by increasing the likelihood that concepts associated with the thematic music (e.g., "Sleep," "Baby") will be incorporated into the novel product (Sifonis \& Fuss, 2012). The generation task theme (e.g., writing a story about a visit to an alien planet versus writing about a visit to an undiscovered, foreign land) also interacts with the music theme to affect the degree to which concepts associated with the music are incorporated into the generated product.

The current study tested and supported the hypothesis that listening to thematic music activates complex schematic structures. The generation task theme provides context, thus affecting the specific manifestation of the thematic elements in the generation task (e.g., including concepts associated with a foreign land with many children versus those associated with an alien planet with many children).
\end{abstract}

\title{
Embodied Mental Imagery
}

\author{
Jan Frederik Sima \\ University of Bremen
}

\begin{abstract}
A new theory of visuo-spatial mental imagery and a computational model of the theory are presented. The theory assumes (visual) perception to be an active and guided process comprising of several low-level perceptual actions. Mental concepts are grounded in sets of such actions. Imagery comprises the "offline" employment of these actions providing concrete instances of the mental concepts through bodily feedback such as proprioception. The theory is compared to the contemporary theories and evaluated against a set of well established phenomena, i.e., mental scanning, mental reinterpretation, eye movements, unilateral neglect. It is argued that the theory provides explanations that go beyond those offered by the contemporary theories. The results provide support for the explanatory power of an embodied approach to cognition in which sensorimotor interaction constitutes conceptual knowledge in that it provides grounding and concrete manifestation of the semantics of mental concepts in the domain of visuo-spatial mental imagery.
\end{abstract}

\title{
Collaborative Recall and Extended identity in Twitter communication
}

\author{
Jurǵis Šķilters \\ University of Latvia \\ Līva Brice \\ University of Latvia \\ Krista Bērziņa \\ University of Latvia \\ Uldis Bojārs \\ University of Latvia \\ Monika Kreile \\ University of Oxford \\ Marta Selecka \\ University of Latvia
}

\begin{abstract}
The aims of the current study are to analyze research evidence of the ways in which collective recall exhibits extended social identity effects . Our core hypothesis was that the use of Twitter as a recall tool significantly contributes to social identity generation in general and self-categorization in particular. Based on a study of a representative sample of Latvian-language Twittersphere, we argue that a social network serves a two-fold role: (a) it extends the individual self as part of a distributed social reality and as part of a distributed on-line social network. The core results of our study show that Twitter functions as an extended distributive linguistic cognitive system supporting different kinds of recall tasks while at the same time exhibiting strong categorization effects through eliminating redundant information and reducing the descriptive complexity of the environment in recall.
\end{abstract}

\title{
Probing the neural dynamics of visual working memory with dynamic fields and fMRI

\begin{abstract}
Efficient visually-guided behavior depends on our ability to form, retain, and compare visual representations that may be separated in space and time. This ability relies on visual working memory (VWM). Here, we describe a layered neural architecture that captures the cortical population dynamics that underlie VWM. We then test this model using functional neuroimaging. Recent work has shown that the BOLD response is strongly correlated with local field potentials (LFPs). An analog of LFPs can be estimated from dynamic neural field (DNF) models. This estimate can be convolved with an impulse response function to yield time-dependent hemodynamic predictions. Using this approach, we show that the DFN model quantitatively captures fMRI data from recent studies probing changes in the BOLD response in the intraparietal sulcus (IPS) as set size increases in change detection. We also test a novel prediction of the model that BOLD responses should be greater on false alarms versus misses. These data run counter to common explanations of the origin of errors in change detection.

\title{
Looking at an empty side of the world. Hemispheric specialisation in directing language-mediated eye movements.
}

\author{
Sara Spotorno \\ University of Dundee, Dundee, Scotland, United Kingdom and University of Aix-Marseille, Marseille, France \\ Jens Apel \\ University of Wuppertal, Germany \\ \section*{Bérengère Plaza} \\ University of Nice-Sophia Antipolis, Nice, France \\ Sylvane Faure \\ University of Nice-Sophia Antipolis, Nice, France
}

\begin{abstract}
We investigated the relationship between linguistic and visual information, combining divided visual field and blank screen paradigms. In an eye-tracking experiment, two objects appeared for 180 ms , one in the right (rvf) and one in the left visual field (lvf), while participants maintained central fixation. After the objects disappeared, a word was presented auditorily. In matching trails ( \(50 \%\) ), it indicated one of the objects previously shown. Participants had to decide whether the word named a man-made or a natural entity. Findings revealed that they were more likely to saccade toward the side of the referent object when it had been presented in the lvf than in the rvf. Moreover, saccades in the lvf targeted more precisely the object's empty location. This suggests a crucial role of the right hemisphere in activating visual representations during language processing, indicating its greater ability in using spatial indexes to retrieve useful visual information.
\end{abstract}

\title{
How common ground affects the use of gesture space
}

\author{
Kashmiri Stec \\ University of Groningen \\ Mike Huiskes \\ University of Groningen
}

\begin{abstract}
Recent work has started to ask to what degree common ground, i.e. shared background knowledge, may affect the articulation of co-speech gestures, specifically as regards viewpoint. We extend that work by asking how gesture articulation is affected, and how the spatial location of those gestures changes as a result of common ground. Using naturalistic data, we find that with quotes grounded in past interactions, co-speech gestures are fewer and smaller, whereas with quotes ungrounded in past interactions (UGPI), co-speech gestures are more numerous and larger. Moreover, when speakers repeatedly reference the same entity, the co-speech gestures used become smaller with each repeated reference, thereby suggesting a kind of 'online' grounding. We also find that the use of gestural space is more consistent for UGPI utterances. This suggests that common ground affects both the articulation of gestures, and the way that gesture space is used.
\end{abstract}

\title{
The impact of Individual and Instructional Difference on Learning Measurement Concepts
}

\author{
Nancy L Stein \\ University of Chicago ( U of C) \\ Yuhtsuen Tzeng \\ National Chung Cheng University \\ Linda Siegel \\ University of British Columbia
}

\begin{abstract}
Abstract: This study compared 4th grade children in the U.S. and Taiwan on understanding (linearity, area, and volume. Taiwanese and American children were both under \(50 \%\) correct for the concepts of area and volume in October. By May, Taiwanese children learned \(90 \%\) of the targeted concepts. American children were still under \(50 \%\) correct.

During the following year, U.S. children received five weeks of instruction on linear, square, and cubic measure, or they received no instruction. Results showed significant increases on accurate knowledge of all measurement concepts, average score \(=89 \%\). Improvement was related, at the .72 level, to memory for forward going digit span. The control group did not improve on any type of measurement concept, despite their similar scores on memory for digit span. A third study showed that repeated practice on multiplication lowered the effects that digit span memory has on learning measurement concepts.
\end{abstract}

\title{
Eye motion along a static concrete object: Why "fictive motion" is not a figurative mental phenomenon
}

\author{
Kurt Stocker
}

University of Zurich

\begin{abstract}
Fictive motion (specifically the co-extension path type: "The road runs through the desert") is widely considered a specific class of figurative language. However, cognitive-linguistic and conceptual-metaphoric evidence is presented which suggests that linguistically expressed motion in fictive motion implicitly refers to the processing of a concrete action: to eye motion that occurs while scanning along a static visual percept (or mental image). As such, fictive motion differs principally from genuinely figurative expressions like ARGUMENT IS WAR - the figurative element of the latter cannot be interpreted as referring directly to a physically existing action or object. Also demonstrated is how a "non-figurative" theoretical approach to fictive motion can explain and predict so-called "non-fictive motion"; fictive motion-like temporal cognition; and fictivemotion types other than co-extension path. It is also shown how the various experimental cognitive and neurocognitive findings on fictive motion can be (re)interpreted in the new framework.
\end{abstract}

\title{
No adaptive strategy selection without outcome feedback
}

\author{
Hrvoje Stojic \\ Universitat Pompeu Fabra, Barcelona, Catalunya, Spain \\ Henrik Olsson \\ Max Planck Institute for Human Development, Berlin, Germany
}

\begin{abstract}
A common view in the judgment and decision making literature is that humans posses a repertoire of decision strategies, from which we choose adaptively when dealing with decision situations. Modeling this adaptive strategy selection process has proved to be difficult, but advances were recently made by modeling it as a reinforcement learning process. Dieckmann and Rieskamp (2007) investigated the influence of information redundancy in a multiple-cue learning setting and found surprising evidence for adaptive strategy selection in situations without outcome feedback, which is difficult to explain by a pure reinforcement learning model. We challenge these findings by pointing out problems in their experimental design. We replicate their experiment, add conditions with stricter experimental controls, and investigate possible underlying mechanisms. In conditions with stricter controls we find no evidence that participants manage to incorporate information redundancy into strategy selection and conclude there is no adaptive strategy selection without outcome feedback.
\end{abstract}

\title{
Judgments under Uncertainty: Bias, Experience, and Expectations
}

\author{
Chris N.H. Street
}

University College London

\author{
Daniel C. Richardson \\ University College London
}

\begin{abstract}
We are poor lie detectors, with accuracy only marginally better than guessing. Raters in social situations such as these must battle with their own uncertainty if they are to make a judgment, yet lie detection research has given little attention to the effects of uncertainty. We present evidence suggesting prior knowledge and expectations have an early influence on the judgment process, but only when forced into judgment. If able to abstain, raters do not rely on prior knowledge but rather indicate their uncertainty by withholding judgment until all the available information has been presented. After the speaker has presented their statement, and when no additional new information is available, we provide evidence from a number of experiments that lie detectors integrate their pre-existing biases and experience about deception in general with more specific information about the statement at hand.
\end{abstract}

\title{
An Attentionally Constrained Model of Statistical Word Learning
}

\author{
Sumarga Suanda \\ Indiana University \\ Seth Foster \\ Indiana University
}

\author{
Linda Smith \\ Indiana University
}

\author{
Chen Yu
}

Indiana University

\begin{abstract}
Recent research supports the notion that word learning can be conceptualized as a statistical learning process. As many have noted however, statistical learning is constrained by processes such as attention and memory. Here we tested an attentionally constrained framework of statistical word learning. We observed, through infant-perspective head cameras, infants' visual input as parents labeled novel objects during an infant-parent object-play session. We then constructed statistical learning models that aggregate word-to-object associations. We fed a baseline model the word-to-object co-occurrence patterns obtained from parent-infant observations. We fed an attentionally constrained model weighted co-occurrence patterns based on the perceptual properties of the objects (i.e., object sizes from the infant's view) at the time words were uttered. Models' learning was compared to children's forced-choice test results. Of interest is which of the two models best approximates children's learning. Implications of these results for statistical learning accounts of word learning will be discussed.
\end{abstract}

\title{
The time course of structural and number interference in sentence processing
}

\author{
Katja Suckow \\ School of Psychology, University of Dundee \\ Roger van Gompel \\ School of Psychology, University of Dundee
}

\begin{abstract}
In sentence processing, retrieval cue parsing accounts predict that processing difficulty occurs due to interference between similar noun phrases at verb integration (Van Dyke \& Lewis, 2003; Van Dyke, 2007). An important factor is number marking of the nouns because the number of the verb and the subject has to agree. According to Lewis and Vasishth (2005), different types of retrieval cue overlap (e.g., verb subcategorisation, semantics, number) should all cause interference simultaneously during processing. However, Van Dyke (2007) reported that interference due to subcategorisation overlap preceded semantic interference, suggesting that syntactic interference may occur before interference due to other cues. We investigated whether interference due to number overlap also occurs later than interference due to subcategorisation overlap. Interestingly, using eye-tracking, we found that the number congruency effect occurred early and no later than the subcategorisation interference effect, indicating that number interference has a very rapid effect on sentence processing.
\end{abstract}

\title{
Imagining emotions: An ERP study on mental imagery of facial expressions
}

\author{
Franziska Suess \\ Humboldt-University of Berlin \\ Rasha Abdel Rahman \\ Humboldt-University of Berlin
}

\begin{abstract}
Affective stimuli encountered in everyday life - such as emotional words, scenes or facial expressions - can elicit well-investigated emotional experiences. For instance, two distinct event-related brain potentials (ERPs) have been reported in response to emotional facial expressions, an early posterior negativity (EPN), associated with enhanced attention and perception of affective stimuli, and a later centro-parietal positivity (LPP), assumed to reflect processing of the intrinsic relevance of emotional stimuli. Other rich sources of emotions that have yet received little attention in EEG research are internal mental events such as thoughts, memories and imagination.

Here we investigated mental imagery of emotional facial expressions and its time course using ERPs. We presented participants with neutral faces and asked them to imagine the faces with an emotional or neutral expression. Early ERP modulations during imagery resemble the effects frequently reported for emotional facial expressions, suggesting shared early processes underlying emotion perception and imagination.
\end{abstract}

\title{
Perspective preference and spatial learning: An eye movement investigation
}

\author{
Masashi Sugimoto \\ Kyoto University \\ Takatsugu Kojima \\ Shiga University of Medical Science \\ Hiroyuki Tsuda \\ Kyoto University \\ Shogo Kajimura \\ Kyoto University \\ \(\underset{\text { Kyoto University }}{\text { Ayae Iwamoto }}\) \\ Kyoto University \\ Yuki Sato \\ Kyoto University \\ Takashi Kusumi \\ Kyoto University
}

\begin{abstract}
The current study investigated the effect of perspective preference on spatial learning. Previous studies revealed that certain factors, such as strategies and goals, affect wayfinding behavior and map learning. We focused on perspective preference as analyzed through measurement of eye movements, which enables us examine potential differences in spatial learning. We divided university students into a survey or route preference group through a map-learning questionnaire. While participants studied the maps, we measured participants' eye movements to each map element (landmarks, streets, and compass rose). After studying a map, participants completed verification tasks and wrote their own map of the learned environment. In contrast to our prediction, the survey and route groups did not show the difference in regard to their gaze to most of the map elements. Although results did not emerge as expected, we discuss the effect of perspective preference on map learning and memory.
\end{abstract}

\title{
Finding Structure in Space and Time: Active Trace of Patterns
}

\author{
Yanlong Sun \\ University of Texas Health Science Center at Houston \\ Hongbin Wang \\ University of Texas Health Science Center at Houston
}

\begin{abstract}
In extracting statistical regularities from the seemingly random environment, our minds grow special interests in patterns. To account for such a behavior, much research has been focusing on top-down influences such as the representativeness heuristic and Bayesian belief updating. Here we take a reverse-engineering approach by first examining the waiting time statistics and the self-overlap property of patterns and revealing a normative basis for people's special attention to patterns. With a unsupervised neural network simulation, we show that different patterns may leave different traces in mind corresponding to the waiting time statistics, indicating an early pattern dissociation without any top-down guidance. We argue that the sense of randomness could have started locally with short sequences and emerged early at the perceptual level, and, the process of spatial-temporal association may be the early driving force towards a structured hypothesis space.
\end{abstract}

\title{
Cognitive inhibition and the unbelievability of supernatural ideas
}

\author{
Annika Svedholm \\ University of Helsinki, Helsinki, Finland \\ Marjaana Lindeman \\ University of Helsinki, Helsinki, Finland \\ Miika Leminen \\ University of Helsinki, Helsinki, Finland
}

\begin{abstract}
After decades of research, the reason why people are attracted to the supernatural (paranormal, magical, superstitions) is poorly understood. It is possible that the question has been approached from the wrong angle and that it is skepticism that needs to be explained, not the beliefs. Taking this as a starting point, we examined \((\mathrm{N}=40)\) whether skeptics have stronger cognitive inhibition than believers. Because cognitive load disrupts inhibition and reveals intuitive thinking, we hypothesized that working memory load increases ontological confusions less among skeptics than among believers. Ontological confusions, such as conceiving of lifeless objects as having mental states, are known to be central to supernatural beliefs. The results supported the hypothesis. Strong cognitive inhibition may thus partly explain why supernatural beliefs, albeit based on natural information processing, seem so unbelievable to millions of people. An ongoing study examines skeptics' and believers' cognitive inhibition in more detail.
\end{abstract}

\title{
Collaborative Memory Foraging in Categorical Recall Tasks
}

\author{
Janelle Szary \\ University of California, Merced \\ Christopher Kello \\ University of California, Merced \\ Theo Rhodes \\ State University of New York at Oswego
}

\begin{abstract}
A classic paradigm for investigating memory is the category recall task, where participants recall as many items as possible from a given category, within some time window. Category recall tasks have been used to investigate memory as a search process, where memory is conceptualized as a landscape with distributed resources (resources being the target items of memory recall). Rhodes and Turvey (2007) show that the dynamics of memory search are akin to animal foraging behavior. Specifically, patterns of recall exhibited Lévy processes, which have been observed in many species and at many scales, and are hypothesized to be optimal under certain conditions. Here, we investigate the effects of social context on Lévy processes using a collaborative category recall task. Although the processes of collaborative recall may differ from individual recall, our results suggest that the products of that recall are similar.
\end{abstract}

\title{
Is Dishonesty an Automatic Tendency?
}

\author{
Maryam Tabatabaeian \\ University of California Merced, merced, California, United States \\ Rick Dale \\ University of California Merced, merced, California, United States
}

Nicholas D Duran
University of California Merced, merced, California, United States

\begin{abstract}
The present study utilizes a novel task to test two competing hypotheses concerning the automaticity of dishonesty. The traditional hypothesis claims that in order to act dishonestly one has to first overcome the truth bias, which results in more time and effort. The opposing hypothesis indicates that lying in order to serve self-interest is an automatic tendency, and therefore takes less time than refraining from lying.

The goal is to look at the action dynamics of dishonesty in order to investigate its underlying cognitive processes. Subjects were asked to privately predict the outcome of a virtual coin-flip. After observing the actual outcome they reported whether their prediction was correct or wrong. The movements of the mouse towards the target answer were recorded and used for action dynamic analysis. Our results support the latter hypothesis indicating that dishonest people take less time and experience less hesitation while choosing the deceptive answer.
\end{abstract}

\title{
The searching effect of metaphor on text rereading: Difference by familiarity
}

\author{
Tomohiro Taira \\ Osaka City University
}

\begin{abstract}
Text comprehension is the process of searching and uniting information. In this process, some pragmatic triggers such as metaphorical expressions can help select important sentences from the text. In this regard, Taira and Kusumi's (2008) demonstration of the effect of metaphor comprehension on the text rereading process is controversial and lacking in persuasive data. This study comprises two aspects: a reanalysis of Taira and Kusumi and an additional experiment examining how the effect of metaphor comprehension on text rereading works. The results of this study showed the effect of metaphor, and indicated two points: (1) the effect of metaphor provide a meaning-searching process that showed a delayed reading time of sentences that describe important information regarding a text topic, and (2) this effect was shown in the case of unfamiliar metaphors, and not familiar metaphors.
\end{abstract}

\title{
Formation of an art concept: How is visual information from photography utilized by the artist in concept formation?
}

\author{
Kikuko Takagi \\ The University of Tokyo
}

Takeshi Okada
The University of Tokyo

\section*{Sawako Yokochi}

Tokyo Future University

\begin{abstract}
The art concept plays an essential part in the creation of contemporary art. In order to capture the progress of the formation process of an art concept, we conducted a case study of a contemporary artist. We interviewed a professional artist about his creation process once every three weeks for about ten months. This report focuses on an early phase of the search for ideas, in which he took many photographs to collect visual information to form the core part of the art concept. Using both the photographs he took and the interview data collected during this phase, we identify when and how features of his art concept emerged. The results show that his art concept was formed through cycles of two types of search for visual information: an active, explorative search to find the unexpected, and more a focused search to interpret it.
\end{abstract}

\title{
Bounded rationality leads to optimal decision-making and learning under uncertainty: Satisficing, prospect theory, and comparative valuation breaking the speed-accuracy tradeoff
}

\author{
Tatsuji Takahashi \\ Graduate School of Science and Engineering, Tokyo Denki University \\ Kuratomo Oyo \\ Graduate School of Science and Engineering, Tokyo Denki University \\ Yu Kohno \\ Graduate School of Science and Engineering, Tokyo Denki University
}

\begin{abstract}
Some classically rational standards for actions such as optimization are simply intractable. We often instead satisfice a certain reference level that is good enough for us. We can use some heuristics but they may lead to biases. Though rational analysis by Anderson (1990) can argue the adaptive rationality of biases in relation to the environmental structure, heuristics and biases have been mostly studied in isolation from other factors in conformity with the tradition in psychology. To show the efficacy of the subrational heuristics in union, we execute computer simulations adopting the framework of reinforcement learning that models iterative decision-making under uncertainty. We implement three characteristics representative of human behavior: Satisficing (Simon, 1952), risk attitudes and reflection (Tversky \& Kahneman, 1981), and comparative valuation (Kahneman \& Tversky, 1979). We show that they, combined together, exhibit an adaptively optimal behavior with an extremely easy parameter tuning.
\end{abstract}

\title{
Source-target mapping strategy in displaced communication: Communication strategy to represent absent objects
}

\author{
Kaori Tamura \\ Japan Advanced Institute of Science and Technology, Nomi, Ishikawa, Japan \\ Takashi Hashimoto \\ Japan Advanced Institute of Science and Technology, Nomi, Ishikawa, Japan
}

\begin{abstract}
Displacement, which is to express absent objects, is one of the important design features of human language. It has not been well considered in the context of communication. We conducted a graphical communication experiment to investigate displacement in communication. In this experiment, two adults are paired, and a sender drew an absent object expressed by an unconventional combination of two words, adjective and noun, while a receiver answered what the drawing represented. This process was repeated 8 times for one object in each pair. The senders usually drew two pictures corresponding to two words, respectively. The analysis of results indicated that nouns should be understood in advance for understanding adjectives which are difficult to represent by drawings. This suggested that in displaced communication source-target mapping strategy was used to compose expressions like metaphors, and that identifying which expression represents a target was important in order to understand absent objects.
\end{abstract}

\title{
Conceptual Transformation in Origami
}

\author{
Thora Tenbrink \\ Bangor University, Wales, UK \\ Holly A. Taylor \\ Tufts University, Medford, MA
}

\begin{abstract}
Origami paper folding involves challenging spatial problem solving, including a number of complex cognitive processes that have not been extensively explored. To gain insights into the nature of these processes, we had participants think aloud while following Origami instructions (verbal and pictorial). Our analysis of participants' verbalizations revealed recurring patterns that reflect the underlying cognitive processes. Namely it showed evidence of reading and reformulating the task description, considering actions and task status, comparing task status to instructional pictures, evaluating progress, referring to previous experience, recognizing problems, and adding ideas about the current instructional step. The last two categories highlight how participants conceptualized this spatial task. The verbalizations also reflect a typical order that the cognitive processes follow: reading - reformulating - reconceptualizing - evaluating. The recurring pattern in this ordering suggests that participants gradually moved away from the original instruction towards a broader conceptualization for action in the current context.
\end{abstract}

\title{
The contribution of frequency, phonological and semantic factors in the development of the English past tense.
}

\author{
Anna Theakston \\ University of Manchester, United Kingdom \\ Grzegorz Krajewski \\ University of Warsaw, Poland \\ Sarah Keeble \\ University of Manchester, United Kingdom \\ Anna Woollams \\ University of Manchester, United Kingdom
}

\begin{abstract}
Despite a vast amount of research, debate continues concerning the mechanisms underlying correct use of morphological systems such as the English past tense. Relatively little is known about precisely what, when, and how children acquire aspects of inflectional morphology due to the paucity of studies examining the earliest stages of development, and the generally narrow focus on a small number of items and predictors. To address these problems, we provide comprehensive evidence concerning the earliest stages of development. 543 English-speaking children (196 2-year-olds, 176 3-year-olds, 1714 -yearolds) took part in a past tense elicitation task. Responses were elicited for 300 verbs ( 200 for 2 -yr-olds) and measures derived (largely from child-directed-speech) for a wide range of frequency, phonological and semantic predictor variables. We present the outcomes of analyses relating these novel predictor variables to the unique behavioural dataset, revealing the cognitive and linguistic underpinnings of children's early past tense development.
\end{abstract}

\title{
Accommodating talker-specific phonetic detail: Influences on internal category structure
}

\author{
Rachel Theodore \\ University of Connecticut
}

\author{
Emily Myers \\ University of Connecticut \\ Janice Lomibao \\ University of Connecticut
}

\begin{abstract}
Listeners customize speech processing to accommodate talker-specific phonetic variation. For example, listeners modify established phonetic boundaries to incorporate a talker's idiosyncratic productions. In addition to being marked by boundaries, phonetic categories exhibit a graded internal structure, with some members of the category considered better members than others. Here we examined whether sensitivity to talker-specific phonetic variation influences internal category structure. Two groups of listeners heard a talker produce \(/ \mathrm{k} /\). Word-initial voice-onset-time (VOT) was manipulated such that one group heard the talker produce \(/ \mathrm{k} /\) with shorter VOTs relative to the other. Listeners were then presented with a range of VOTs and asked to rate each for goodness as \(/ \mathrm{k} /\). Results to date indicate that exposure during training robustly influences the range of VOTs considered the best exemplars of \(/ \mathrm{k} /\), suggesting that accommodating talker-specific phonetic variation results in a comprehensive re-mapping of acoustic-phonetic space and is not limited to the boundary region.
\end{abstract}

\title{
A Neuro-Computational Approach to Equivalence Formation in Arbitrary Categories
}

\author{
Angel E. Tovar \\ Facultad de Psicología, Universidad Nacional Autónoma de México \\ Gert Westermann \\ Department of Psychology, Lancaster University
}

\begin{abstract}
The Stimulus Equivalence paradigm studies the learning of stimulus classes (categories) composed of functionally equivalent stimuli with or without perceptual similarities. The relations between stimuli in a class can either be learned or be derived from other stimulus relations: if stimulus \(A\) is equivalent to \(B\), and \(B\) to \(C\), then the equivalence between \(A\) and \(C\) can be derived without explicit training. There has been little work on the mechanisms underlying equivalence class formation. Here we present a neurobiologically plausible neural network model of stimulus class learning. The network successfully models three classic studies on stimulus equivalence. The Hebbian weights in the model describe the formed equivalences and the levels of association between class members, and resulting activation patterns are correlated with the response accuracy and response latencies in the original studies. The model predicts that stimulus equivalence formation depends on the environmental regularities of stimuli occurrence and co-occurrence.
\end{abstract}

\title{
Coordination among edge team members during crisis management
}

\author{
Sebastien Tremblay \\ Universite Laval \\ Isabelle Turcotte \\ Universite Laval \\ Alexandre Labrecque \\ Universite Laval \\ Jessica Desrochers-Pare \\ Universite Laval \\ Vincent Rousseau \\ University of Montreal
}

\begin{abstract}
Crisis management (CM) situations are most-often complex and dynamic, and require team members to make optimal decisions under constraints of high risk, uncertainty, high workload, and time pressure (see, e.g., Brehmer, 2007). An Edge Organization (EO) is an adaptive, rapidly reconfigurable, and distributed team structure in which no roles are previously assigned, and resources are not distributed in advance. Such a team structure is assumed to be able to improvise and respond quickly to emerging problems. We used the C3Fire CM simulation to measure the coordination (of units and resources) efficiency amongst edge team members. Twenty-four teams of four participants completed four C3Fire scenarios, each lasting 10 minutes. Results revealed that team members achieved better coordination as they progressed through the scenarios. This learning effect suggests that it could be beneficial to train team members to coordinate their actions efficiently and fully exploit the potential agility provided by EO.
\end{abstract}

\title{
Visual landmarks and the visual impedance effect
}

\author{
Kai Hamburger \\ Justus Liebig University Giessen; Experimental Psychology and Cognitive Science \\ Florian Roeser \\ Justus Liebig University Giessen; Experimental Psychology and Cognitive Science \\ Cate Marie Trillmich \\ Justus Liebig University Giessen; Experimental Psychology and Cognitive Science
}

\begin{abstract}
According to Lynch (1960; p. 83) "the sequence [of landmarks] facilitates recognition and memorization". Thus, under which circumstances do landmarks facilitate wayfinding? We therefore investigated the helpfulness of landmarks during route knowledge and survey knowledge retrieval from long-term memory. A field study with citizens of a street festival in a mid-size German town (Giessen) was performed. Sixty-three participants had to draw the shortest possible route between two given locations in the town. Within this experiment, two different conditions were tested respectively: drawing the route without landmarks and with additionally presented landmarks. A comparison of conditions revealed different performance groups: perfect performance ( \(8 \%\) ); performance improvement with additional landmarks ( \(32 \%\) ); equal performance in both conditions ( \(36 \%\) ); and performance decrement with additional landmarks ( \(23 \%\) ). These results were confirmed in two further experiments. We demonstrate that the decremental findings may be a result of the so-called visual impedance effect (Knauff \& Johnson-Laird, 2002).
\end{abstract}

\title{
Automatic and controlled processes of reasoning: insight from the matching hypothesis of syllogisms
}

\author{
Ping Ping Tse \\ Universidad de Granada \\ Sergio Moreno-Rios \\ Universidad de Granada \\ Juan Antonio Garcia-Madruga \\ Universidad Nacional de Educación a Distancia \\ Maria Teresa Bajo \\ Universidad de Granada
}

\begin{abstract}
The study aimed to study the inhibitory mechanism in syllogistic reasoning when the outputs of the heuristic strategy and analytic reasoning disagree. We manipulated the congruency of the quantifier of the conclusion with those of the two premises according to the matching strategy and the validity of the syllogism. After each syllogistic evaluation task, a lexical decision task was used to check if the semantic content of the conclusions was inhibited. The results suggested that after correctly solved conflict problems (match-invalid or mismatch-valid), the semantic priming effect of the words related to the two terms in the conclusion diminished. For no-conflict problems, the recognition time of the related words was faster than that of the unrelated words. The results suggested that inhibition on the content of a syllogism may not only be triggered by the conflict induced by the believability but also by the surface structure of the syllogisms.
\end{abstract}

\title{
Framing effects in perceptual decision-making
}

\author{
Konstantinos Tsetsos \\ Experimental Psychology, Oxford University \\ Christopher Summerfield \\ Experimental Psychology, Oxford University
}

\begin{abstract}
Research on the psychology of simple, perceptual choices has led to an impressive progress in capturing the underlying mental processes as optimal mechanisms. Within this theoretical framework, perceptual decisions arise from a feed-forward process involving the sampling and accumulation of momentary evidence up to a decision boundary. According to this view, the stage where the information is accumulated is automatic and decision makers can exert strategic control on the decision boundary only, in order to adapt their performance to the task demands (e.g. speed-accuracy trade-offs). We present new behavioural and eye-tracking data challenging this view and suggesting that the way information is accumulated in perceptual decisions, is subject to differential weighing that depends on the task framing (e.g. select the brightest or the darkest spot). We conclude that choices are mostly influenced by extreme values, and whether positive or negative peaks are more pivotal is frame-dependent and subject to top-down control.
\end{abstract}

\title{
Differences between maximizers and satisficers in regret and counterfactual thinking during repeated versus switching decisions
}

\author{
Takashi Tsuzuki \\ Rikkyo University
}

Manabu Kikuchi
Rikkyo University

\author{
Itsuki Chiba
}

Rikkyo University

\begin{abstract}
Recent research has demonstrated that with a positive prior experience, an actor who decides to switch decisions should feel more regret than one who decides to repeat (the status quo effect). Conversely, with a negative prior experience, the switcher should feel less regret than the repeater (reversal of the status quo). We tested the influence of a maximizing tendency on the strength of these two effects, measured using the Japanese version of the Regret and Maximization Scale. In the positive prior experience scenario, the maximizer group scored higher on presumed regret and counterfactual thinking than the satisficer group. In the status quo scenario, the maximizer group scored higher on counterfactual happiness than the satisficer group. Our results indicate that maximizers show a reversal of the status quo effect in some settings.
\end{abstract}

\title{
The effects of self-explanation on science concept learning for sixth grade students: Misconceptions matter
}

\author{
Yuhtsuen Tzeng \\ National Chung Cheng University \\ Yu-Ping Huang \\ National Chung Cheng University \\ Nancy Stein \\ University of Chicago
}

\begin{abstract}
Self-explanation (SE) is an effective strategy for improving understanding and it relied on learners' proper deployment of prior knowledge. Surprisingly, there is limited research on how might misconceptions affects learning despite they are inherent part of learners' knowledge system. We examine the influence of SE on processes and outcomes of science learning for 36 sixth grade students by varying degrees of prior knowledge and relevant misconceptions. The SE group read and selfexplained a text describing state changes of water requiring proper notions of molecules while the control group read twice and think aloud. The results indicated that there are no effects of SE, prior knowledge for learning outcomes. However there is significant effect of SE by misconception interaction. Low misconception students benefit from SE but not for high misconception counterparts. SE did influence amounts and types of verbal protocol students generated. The results indicated that the influence of SE heavily modulated by learners' misconceptions.
\end{abstract}

Do Japanese junior high school pupils really dislike mathematics? -Discrepancies between explicit and implicit assessment measures-
}

\author{
Akitoshi Uchida \\ Togakushi Junior High School
}

\author{
Kazuo Mori \\ Institute of Engineering, Tokyo University of Agriculture and Technology
}

\begin{abstract}
The purpose of this study is to examine whether Japanese junior high school pupils really dislike mathematics. In addition to questionnaires to inquire explicitly of the likings of school subjects, we administered the FUMIE Tests (Mori et al., 2008) to 512 junior high school pupils to assess the implicit evaluative association to the school subjects. We found a considerable proportion of pupils answered negatively to the target school subjects in the questionnaire while their implicit association scores showed somewhat positive valences. The discrepancies were larger for "mathematics" than "science". One hundred of 512 pupils answered negatively to mathematics while their implicit measures were positive. In contrast, only five of 102 showed the same discrepancy for science. These results imply that there may exist a tendency to pretend to be a math-dislike in pupils. We discussed this tendency that may eventually lead them to real math-dislikes.
\end{abstract}

\title{
Are you human? The engagement in real-time social interactions recruits the reward system
}

\author{
Ulrich Pfeiffer \\ University Hospital Cologne, Department of Psychiatry, Cologne, Germany \\ Leonhard Schilbach \\ University Hospital Cologne, Department of Psychiatry, Cologne, Germany \\ Bert Timmermans \\ University of Aberdeen, School of Psychology, Aberdeen, UK \\ Bojana Kuzmanovic \\ Research Center Jülich, Institute of Neuroscience and Medicine (INM-8), Ethics in the Neurosciences \\ Alexandra Georgescu \\ University Hospital Cologne, Department of Psychiatry, Cologne, Germany \\ Gary Bente \\ University of Cologne, Department of Psychology, Institute for Social and Media Psychology \\ Kai Vogeley \\ University Hospital Cologne, Department of Psychiatry, Cologne, Germany
}

\begin{abstract}
An intrinsic motivation for social interaction has often been proposed and is thought to be unique to the human species. However, little is known about underlying neural mechanisms. Here, we investigated whether experiencing engagement in social interaction recruits the reward system of the brain. A combined eye-tracking and fMRI paradigm was used in which participants interacted with a virtual agent in a series of gaze-based interactions in real-time. To create situations in which they experience the interaction as social or as non-social, they were made believe that during each block the agent's gaze behavior could either be controlled by another human participant or a computer algorithm. The other participant was a confederate of the experimenter, which enabled experimental control of the agent's gaze reactions. After each block participants had to indicate whether they experienced the interaction as social or not. Results demonstrated that gaze-based interactions with a perceived human partner is associated with activity in the ventral striatum, a core component of reward-related neurocircuitry, while interactions with a computer-driven agent activate attention networks. In addition, the nature of the interaction with a human partner (naive vs. cooperative) differentially modulates striatal activity.
\end{abstract}

\title{
Differences in Interactional Attitudes in Second Language Conversations: From the Perspective of Expertise
}

\author{
Ichiro Umata \\ National Institute of Information and Communications Technology, Seika-cho, Soraku-gun,, Kyoto, Japan
}

Seiichi Yamamoto
Doshisha University, Kyotanabe-shi, Kyoto, Japan
Kosuke Kabashima
Doshisha University, Kyotanabe-shi, Kyoto, Japan
Masafumi Nishida
Doshisha University, Kyotanabe-shi, Kyoto, Japan

\begin{abstract}
We examined the effects of participants' linguistic expertise on their communicative behaviors and their interactional attitudes in conversations in their second language. Quantitative analyses of eye-gazes during utterances showed that the speakers with lower linguistic expertise were observed more by the listeners in the second language conversations, whereas, the listeners' expertise level did not affect the amount of their gazes to the speakers. The analyses of a questionnaire suggested that the participants with lower expertise were not conscious of their own gazing activities; they self-evaluated the amount of their gazes to the speakers' eyes much lower in conversations in their second language than those in their native language. The participants with lower expertise evaluated the pressure they felt higher than those with higher expertise. It is likely that they were too occupied with conducting conversations to maintain enough control over their interaction activities.

\title{
Effects of Cultural Knowledge on Parallel Language Activation in German-English Bilinguals
}

\author{
Sebnem Uzuner \\ San Diego State University \\ Henrike Blumenfeld \\ San Diego State University \\ Marcel Giezen \\ San Diego State University
}

\begin{abstract}
Bilinguals have been shown to activate their two languages simultaneously during spoken word recognition (e.g., Blumenfeld \& Marian, 2007). We investigated whether top-down conceptual processing influences parallel language activation using the visual world eye-tracking paradigm. Cultural knowledge was used to manipulate semantic activation in L1 during L2 word processing. Critical trials contained target items that were culturally meaningful to individuals who grew up in Germany, alongside German competitor items that had word-initial phonological overlap with the target word. We hypothesized that German-English bilinguals would fixate the German competitor items more in the culturally salient condition than in the culturally neutral condition. Preliminary data from seven German-English bilinguals and 10 English monolinguals revealed a competitor effect in the culturally salient condition only for bilinguals ( \(\mathrm{p}=.03\) ), with no effect in the culturally-neural condition ( \(\mathrm{p}>.1\) ). Results suggest that activation of cultural knowledge in bilinguals exerts a conceptual top-down influence on parallel language activation.

Stimulating Retrieval During Reading to Improve Word Learning and Memory
}

\author{
Gesa S. E. van den Broek
}

Radboud University Nijmegen, Behavioural Science Institute

\author{
Atsuko Takashima \\ Radboud University Nijmegen, Donders Institute for Brain, Cognition and Behaviour; Radboud University Nijmegen, Behavioural Science Institute \\ \section*{Eliane Segers} \\ Radboud University Nijmegen, Behavioural Science Institute \\ \section*{Ludo Verhoeven} \\ Radboud University Nijmegen, Behavioural Science Institute
}

\begin{abstract}
Retrieving information from memory improves the long-term retention of that information more than continued restudying (e.g., Karpicke \& Roediger, 2008). We investigate if this testing-effect can be applied to word learning during reading by manipulating the sentence context in which words are presented. In a within-subject experiment, adult learners without prior knowledge of Swahili studied 80 Swahili words and then repeatedly read the words either in an L1-context that was uninformative and required the retrieval of word meanings from memory to be understood (e.g., "I use the =funguo=") or in a rich context that enabled the readers to derive word meanings (e.g., "I use the \(=\) funguo \(=\) to unlock the door"). Recall-accuracy and speed for the newly learned words were measured during reading as well as immediately and seven days after practice to evaluate effects of sentence context and retrieval success during reading on the retention of word form and meaning.
\end{abstract}

\title{
When do PDP neural networks learn localist representations?
}

\author{
Ivan Vankov \\ University of Bristol \\ Jeffrey Bowers \\ University of Bristol
}

\begin{abstract}
One of the most distinctive characteristics of the Parallel Distributed Processing (PDP) approach to cognitive modeling is that representations are distributed across a large set of units. However, this is not always the case. In a series of simulations we show that PDP neural networks tend to form localist representations under certain conditions. First, localist representations are developed when the mapping between the input and output patterns is arbitrary. A second pressure to learn localist codes comes from having to keep multiple representations active at the same time. Introducing biologically plausible constraints on the network architecture also fosters developing local codes. Taken together, these findings suggest that the widespread assumption that PDP neural networks learn distributed representations is often wrong. Moreover, exploring the computational reasons for which PDP learn localist representations provides insight into why selective neurons are often found in the brain.

\title{
Cognitive Improvement after Surgical Treatment of Moyamoya Disease
}

\author{
Thais Varzoni \\ University of North Florida \\ \section*{C. Dominik Güss} \\ University of North Florida \\ Ricardo A. Hanel \\ Mayo Clinic
}

\begin{abstract}
Moyamoya disease is a rare entity characterized by progressive narrowing of intracranial blood vessels. Moyamoya in most cases does not respond well to medical therapy and often leads to surgical revascularization. The physiological benefits of the surgery for Moyamoya patients have been well documented, yet the effects of surgery on cognitive skills are far less studied. Participants in the current study were 30 patients, 24 to 85 years of age, who underwent surgery and were all treated at Mayo Clinic in Jacksonville, Florida. All patients underwent a physical and cognitive preoperative evaluation, where speech, memory, and intellectual processes were measured. After the surgical intervention, patients returned for 3 follow-up assessments over a period of 6 months. All patients experienced stabilization or improvement of physiological symptoms. Regarding cognitive functions, speech, memory, and intellectual processes improved significantly after surgery. Further prospective studies are needed to better assess cognitive outcomes after revascularization for Moyamoya.

\title{
Measuring the Degrees of Separation of a group of Minds
}

\author{
Tomas Veloz \\ University of British Columbia
}

\begin{abstract}
The degrees of separation are essential in the study of social networks. We develop a graph theoretical methodology inspired in this concept to study behavioral data. Having a similarity measure appropriate to the data, we propose to build a graph connecting each agent its nearest \(n\) neighbors, having that their similarity exceeds a threshold p. From here, graph theoretical indicators such as connectivity and clustering can be studied as functions of p and n .

We apply this methodology to a psychological experiment where 97 participants estimate the typicality of 8 objects with respect to the concept "Hat", in 2 contexts. Using correlation distance as a similarity function, we compute clustering properties, and average path length as functions of \(n\) and \(p\). Interestingly, only \(n=20\) connections are required to keep the similarity structure of the system, having an average path length near 2.
\end{abstract}

\title{
Synchronizing to Learn and Like
}

\author{
Roy Vink \\ Behavioural Science Institute, Radboud University, Nijmegen, The Netherlands \\ Anna Bosman \\ Behavioural Science Institute, Radboud University, Nijmegen, The Netherlands \\ Toon Cillessen \\ Behavioural Science Institute, Radboud University, Nijmegen, The Netherlands
}

\begin{abstract}
Ever seen two people walking down the street in the exact same pace? This kind of interpersonal synchrony has been observed in both humans, as well as in animals (e.g., large groups of fireflies flash at the same time, schools of fish and flocks of birds synchronize their movement). For animals it appears to be beneficial (for survival) to synchronize their behavior, but what are the benefits for humans to do so? There are indications that interpersonal synchrony supports social bonding. Previous studies have shown that interpersonal synchrony can have both an effect on (e.g., increases memory), and can be affected by social factors (e.g., higher likeability ratings, more interpersonal synchrony). The goal of the present study was to examine whether social factors (e.g., popularity, friendship) affect interpersonal synchrony when working together. Furthermore, we looked at the relation between interpersonal synchrony and learning and likeability.
\end{abstract}

\title{
The Influence of Motion Language and Gaze Orientation on Spatial Memory
}

\author{
David Vinson \\ University of California, Merced, Merced, California, United States \\ Drew Abney \\ University of California, Merced, Merced, California, United States \\ Teenie Matlock \\ University of California, Merced, Merced, California, United States \\ Rick Dale \\ University of California, Merced, Merced, California, United States
}

\begin{abstract}
When participants observe a man who looks to have fallen or jumped off of a cliff, spatial memories of the man's location are further down a gravitational trajectory compared to his actual location (Freyd, 1985). Previous research has repeatedly observed that inferring gravity - a top-down process - modulates spatial memory. The present study found that differences in the eye gaze orientation of the man by a cliff such as facing up or facing down, and linguistic information such as 'Jumped' or 'Fell', independently influence the spatial memory of the man's location. A brief discussion is presented regarding the influences of top-down and bottom-up processes in spatial memory.
\end{abstract}

\title{
Social gaze orientation influences decision making
}

\author{
David Vinson \\ University of California, Merced, Merced, California, United States \\ Rick Dale \\ University of California, Merced, Merced, California, United States
}

\begin{abstract}
Richardson, Spivey and Hoover (2009) observed that attending to one of two choices in a decision making task increases the likelihood of that response by ten percent. Reflexive gaze orientation, attending to the same area as others, has also been shown to influence reaction times on simple dual choice tasks. The current study addressed how the eye gaze direction of a highly simplified face influences decisions made regarding questions with no obvious answer. Observed results indicate that the appearance of eyes looking toward one answer over another significantly impacts the decision making process. Similar to past work on the impact of social stimuli on orienting, we show that social stimuli can also impact decision making under uncertainty.
\end{abstract}

\title{
Recognition Memory Processes in Novel Noun Generalization
}

\author{
Haley Vlach \\ University of Wisconsin, Madison, Madison, Wisconsin, United States
}

\begin{abstract}
Previous research on word \& category learning has hypothesized that memory processes may be critical to the longterm ability to generalize information. The current experiment was designed to elucidate the recognition memory processes occurring during children and adults' category learning. Participants were presented with a novel noun generalization task and five recognition memory tasks. The results revealed that there were developmental differences in (a) the retention for information presented during category exemplar presentations, and, (b) the sub-categories of recognition memory that were significantly related to category learning performance. These findings suggest the relationship between recognition memory and category learning processes may change across development.
\end{abstract}

\title{
Visitors from outer space: On picking up relevance in inductive reasoning
}

\author{
Wouter Voorspoels \\ University of Leuven, Belgium \\ Gert Storms \\ University of Leuven, Leuven, Belgium
}

\begin{abstract}
In the last decade, numerous studies in inductive reasoning have shown that people are remarkably quick at picking up the relevant features that allow generalizations. One formal account of (some instances of) cases where this ability emerges, relies on the assumptions people make about the manner in which the observations are sampled from the world. According to a weak sampling scheme, observations are randomly drawn from the environment. However, a reasoner can also assume that the observations are sampled deliberately from the intended hypothesis (strong sampling). In the present contribution, we compare these assumptions in a inductive reasoning task using semantic stimuli from 4 superordinate concepts (animals, clothes, vehicles,musical instruments). Model analyses are performed to examine the sampling assumptions of reasoners in this context. We find that people generally assume a strong sampling scheme. However, the model seems to underestimate the relevance sensitivity of the participants.
\end{abstract}

\title{
New methods for assessing ontological and representational changes in the conceptual system of children and adults
}

\author{
Stella Vosniadou \\ National and Kapodistrian University of Athens \\ Despoina Lepenioti \\ National and Kapodistrian University of Athens \\ Anna Choundala \\ National and Kapodistrian University of Athens \\ Kalliopi Eikospendaki \\ National and Kapodistrian University of Athens \\ Petros Papavasiliou \\ National and Kapodistrian University of Athens \\ Emiliana Thanou \\ National and Kapodistrian University of Athens
}

\begin{abstract}
Cognitive developmental research has documented that children acquire rich knowledge about the physical and psychological world before they are exposed to science, and that learning science requires substantial ontological, epistemological and representational changes to happen in the conceptual system of the child. For example, Vosniadou \& Skopeliti (2005) showed that while the majority of third grade children categorized the earth as a physical object distinct from solar objects like the sun and the moon, \(90 \%\) percent of 5 th graders categorized the earth as an astronomical object, belonging to the same category as the sun and the moon. In the present research we will present two novel, chronometric, tasks for assessing the conceptual re-organizations that take place as children are exposed to systematic science instruction and for further exploring the question of whether naive theories are overwritten or survive and continue to exist together with the scientific theories.

\title{
Feeling Guilt vs. Regret about Own Decisions: What are the Psychological and Neurobiological Differences?
}

\author{
Ullrich Wagner \\ Charité - Universitätsmedizin Berlin, Department of Psychiatry and Psychotherapy, Division of Mind and Brain Research, Charitéplatz 1, 10117 Berlin, Germany \\ \section*{Lisa Handke} \\ Charité - Universitätsmedizin Berlin, Department of Psychiatry and Psychotherapy, Division of Mind and Brain Research, Charitéplatz 1, 10117 Berlin, Germany \\ Henrik Walter \\ Charité - Universitätsmedizin Berlin, Department of Psychiatry and Psychotherapy, Division of Mind and Brain Research, Charitéplatz 1, 10117 Berlin, Germany
}

\begin{abstract}
Humans use counterfactual thinking in order to evaluate their previous choices, comparing the actual outcome of a choice with what would have happened if they had chosen another action option. Two prototypical emotions resulting from such counterfactual evaluations are guilt and regret, both of which play an important role in regulating human choice behavior. Guilt is thought to refer specifically to social choices, while regret occurs for both individual and social choices. Here, we introduce an fMRI compatible new experimental paradigm to differentially induce guilt and regret under controlled conditions as a result of real decision. Behavioral data confirm that guilt but not regret specifically occurs in a social context (i.e. after harm for another person caused by own choices). On the neural level, initial results point to a critical involvement of different sub-regions within the prefrontal cortex in the processing of guilt vs. regret.
\end{abstract}

\title{
Word Segmentation Without Statistics
}

\author{
Felix Wang \\ University of Southern California \\ Toben Mintz \\ University of Southern California
}

\begin{abstract}
A critical step in language acquisition is segmenting speech into words. Prior cross-linguistic research demonstrates the importance of language specific segmentation strategies (Gervain \& Erra, 2012). English-learning infants can use statistical information to segment words in laboratory experiments (Saffran et al., 1996), but its informativeness in segmenting English is unclear (Yang \& Gambell, 2004; Swingley, 2005). We analyzed one corpus of 611,837 child-directed utterances (Theakston et al, 2000; MacWhinney, 2000), and one corpus of 50,776 adult-directed utterances (Pitt et al., 2007) and found that, in both corpora, a simple strategy that assumes that each syllable is a word would be highly effective in segmenting words. Accuracy was \(69.68 \%\) and \(61.7 \%\) in the child and adult corpora, respectively, segmenting \(87.44 \%\) and \(87.90 \%\) of the corpora. These findings should guide further investigations into the processes infants actually use to segment speech, and more broadly how they learn appropriate language-specific word segmentation strategies.
\end{abstract}

Statistical Learning in Non-Chinese Speakers Exposed to a Sequence of Words without Spaces
}

\author{
Tsanyu Wang \\ National Taiwan Normal University
}

Adam Li
National Taiwan Normal University
Yeou-Teh Liu
National Taiwan Normal University
Jenn-Yeu Chen
National Taiwan Normal University

\begin{abstract}
A Chinese sentence contains no extra spaces between words. We hypothesize that implicit word segmentation by Chinese readers is developed via the statistical learning mechanism that is universal. Twenty non-Chinese speakers were exposed to a sequence of 3600 characters constructed from six disyllabic words with 6 different characters. The transitional probabilities between any two characters were .46 to 1 within words, and 0 to .29 between words. The sequence was presented one character every half a second. Occasionally, the presentation rate doubled. The participants' task was to detect the instances of double presentation. Upon completing the task, a surprise test followed that consisted of a word and a nonword (reversals of the characters in a word) from the sequence. The participants had to decide which one had appeared before. The averaged accuracy rate was greater than chance (.53). This suggests the statistical learning mechanism is available to all language learners.
\end{abstract}

\title{
Closer than you think?: Options for efficiently approximating optimal analogies under Structure Mapping Theory
}

\author{
Todd Wareham \\ Memorial University of Newfoundland, St. John's, NL, Canada \\ Tijl Grootswagers \\ Radboud University, Nijmegen, The Netherlands \\ Iris van Rooij \\ Radboud University, Nijmegen, The Netherlands
}

\begin{abstract}
Structure Mapping Theory (SMT) is an important and influential theory in cognitive science. One unresolved issue is this theory's intractability. It is known that finding optimally systematic analogies under SMT is NP-hard, making it unrealistic that human analogizing is characterized by optimality. Yet, experimental studies suggest that the optimality assumption gives the best fit to human performance data. A solution to this paradox may be that SMT can be efficiently approximated to such a degree that, for practical intents and purposes, human analogies appear to be optimal. However, outside of a limited empirical evaluation of the commonly-used greedy SME heuristic given in Forbus and Oblinger (1990), no analyses of the approximability of SMT have been done to date. We fill this void by providing both the first theoretical analyses of the types of efficient approximability available for SMT and the first systematic empirical evaluation of the greedy SME heuristic.
\end{abstract}

\title{
Robust social learning to babble in a spiking neural network model
}

\author{
Anne S. Warlaumont \\ University of California, Merced \\ Sophia R. Hyatt \\ University of California, Merced
}

\begin{abstract}
Three humans interacted with a spiking neural network model that controls the lip and jaw muscles of a speech synthesizer. The model learns using spike-timing dependent plasticity that is greater when reinforcement is received. First the humans each selectively reinforced the model, encouraging it to more frequently produce vocalizations with speech-like syllabic elements. Afterwards, for each human-reinforced simulation a yoked control simulation was generated. All the sounds produced during the course of learning for all human-reinforced and all yoked control simulations were then judged on a four-point syllable quality scale by all three listeners (sounds were presented in random order). In all cases, these judgments indicated that the human-reinforced models produced more sophisticated babbling over the course of learning whereas the yoked control simulations did not. The results support this model of how canonical babbling, a major developmental milestone, may develop.
\end{abstract}

\title{
Emotion and Decision-Making: Modeling Strategy Selection
}

\author{
Szymon Wichary \\ Interdisciplinary Center for Applied Cognitive Studies, Warsaw University of Social Sciences and Humanities \\ Tomasz Smolen \\ Department of Psychology, Krakow Pedagogical University
}

\begin{abstract}
Models of decision making neglect the impact of emotions on information processing. Here we present a model of decision strategy selection that can account for the differences in the use of two strategies, the take-the-best heuristic (TTB) and the Weighted Additive rule (WADD) in a probabilistic inference task. How can such a model incorporate emotions? Our model assumes attentional weighting of cues, controlled by the activity of locus coeruleus - a brainstem nucleus associated with physiological arousal. Using hierarchical Bayesian modeling, the model was evaluated on data from a study where participants performed a probabilistic inference task and emotional stress was manipulated with highly aversive slides. For each participant we estimated the parameter that controls cue weighting. This parameter correlated positively with the proportion of choices consistent with TTB and negatively with the proportion of choices consistent with WADD. Moreover, this parameter was sensitive to the emotional stress manipulation.
\end{abstract}

\title{
Television network attitudes toward political candidates implicit in lexical statistics
}

\author{
Jon Willits \\ Indiana University \\ Mark Seidenberg \\ University of Wisconsin Madison
}

\begin{abstract}
Languages exhibit statistical regularities concerning the frequencies and co-occurrences of words. Language users learn from such patterns without being consciously aware of them. We investigated statistical properties of the language used on television news in discussing politicians. We compiled corpora consisting of language used on four networks (MSNBC, ABCNews, CNN, FOXNews) from 2007-2012. We analyzed the frequencies with which 500 affectively-valenced words cooccurred with politicians' names (Obama, McCain, Romney) during the run-ups to the 2008 and 2012 elections. We used these co-occurrences to derive a summary measure, their net positivity score. Positivity scores for candidates changed over time in ways that reflect real-world events. Positivity towards candidates differed across networks. Net positivity toward President Obama during his first term was strongly correlated with approval ratings. The results show that statistical aspects of language, of which people are not consciously aware, convey varying attitudes on network news.

\begin{abstract}
Spoken words are phonologically reduced through various processes (e.g., assimilation) in fluent speech. The reduced forms of words give rise to perceptual difficulties for nonnative speakers. This study examined whether accent types (General American and Received Pronunciation (PR) British Englishes) of native English fluent speech affect fluent speech perception in Chinese speakers. A representative sample of sixty undergraduate students were tested with listening comprehension tests (recordings produced by American and British English speakers), reduced forms dictation test (with Americanand British-accented speech as stimuli) and fluent speech production task. Based on correlational analyses, it is shown that listening comprehension was significantly correlated with both fluent speech perception and production skills among the Chinese speakers. Importantly, these correlations were observed within the same accent type and across the two accents. However, our regression analyses showed that speech perception rather than production significantly predicted the outcome of listening comprehension.
\end{abstract}

The deficits of visual encoding processes in Chinese Dyslexics
}

\author{
Orieta H. Y. Wong
}

Department of Psychological Studies, The Hong Kong Institute of Education, HKSAR
Michael C. W. Yip
Department of Psychological Studies, The Hong Kong Institute of Education, HKSAR

\begin{abstract}
The present research aimed at identifying cognitive processing that works at the initial stage of letter identification. First, we used the word superiority effect task to set the baseline of visual detection rate and then we used the letter matching task to evaluate the phonemic transference rate of the particpants. It was hypothesized that physically-different letters required longer processing time as the judgment depended not only on visual detection, but also on a process of phonemic transference. Our results found that the control group had a higher letter identification rate than the dyslexic group, showing that visual detection rate was a good predictor of reading disability. However, phonemic transference rate was not a good predictor of dyslexia. One of the reasons may be that the process of letter identification involved cognitive skills other than that of phonemic transference alone.

\title{
Inflection from form versus meaning: Developmental and computational evidence
}

\author{
Anna Woollams \\ School of Psychological Sciences, University of Manchester \\ Joanna Moy \\ School of Psychological Sciences, University of Manchester \\ Sarah Keeble \\ School of Psychological Sciences, University of Manchester \\ Grzegorz Krajewski \\ Faculty of Psychology, University of Warsaw \\ Anna Theakston \\ School of Psychological Sciences, University of Manchester
}

\begin{abstract}
Inflectional morphology has proven a test case for evaluating theoretical approaches to language processing. The bulk of empirical data has been acquired using the inflection from stem task, which approximates more naturalistic speech production only if mandatory stem retrieval is assumed. Yet work with adults reveals quite different results when inflection proceeds instead from meaning. Connectionist computational models of inflection have simulated these task differences, but the extent to which they accurately reflect development remains unknown. For the first time, we consider the impact of task type upon inflectional development of 908 children aged between 2 and 4 years. We then present a revised version of a connectionist model of inflection, which has been trained in a manner consistent with child directed speech in order to capture the children's performance. Taken together, this work demonstrates the progression of the field to more ecologically and developmentally valid approaches to inflection.

\title{
Mnemonic convergence in a social network:
}

\author{
Jeremy Yamashiro \\ New School for Social Research, New York, NY, United States \\ William Hirst \\ New School for Social Research, New York, NY, United States
}

\begin{abstract}
Selective rehearsal of memories through conversation shapes subsequent recall for both speakers and listeners. Interactional memory acts have typically been studied in dyadic conversation or small groups; however, as Christakis and Fowler (2009) point out, humans don't just belong to groups, we are more precisely enmeshed in social networks. This study extends Coman and Hirst's (2012) work on propagation of socially-shared retrieval-induced forgetting (Cuc, Koppel, and Hirst, 2007) and social contagion (Roediger, Meade, \& Bergman, 2001) across a series of conversations. We move from dyadic networks to a dynamically self-assembling social network of 46 undergraduates over a nine-week period. Using a framework derived from Kauffman's (1994) models of adaptive fitness landscapes in evolution, we trace mnemonic convergence as it emerges from the interplay of "internal" cognitive factors and dynamics attributable to network connectivity. Contributions to the cognitive psychology of collective memory are discussed.
\end{abstract}

\title{
How to rectify the confirmation bias in Wason(1960)'s 2-4-6 task
}

\author{
Tomohito Yamazaki \\ Keio University \\ Mutsumi Imai \\ Keio University
}

\begin{abstract}
People have a strong confirmatory bias, which is remarkably difficult to overcome. In this research, we investigated how we could help people rectify the confirmatory bias, using Wason(1960)'s 2-4-6 task. 195 University and middle school students participated in our study, in which they were to find out the rule "increasing 3 numbers," starting from the 2-4-6 number sequence. Prior to the task, the participants were assigned to one of the four training conditions: (1)"Counter-Examples", in which participants were instructed to create the positive and counter-examples for the current hypothesis; (2) "Two-Hypotheses", in which participants were instructed to create examples for two different hypotheses; (3) "Counter-Examples-AND-TwoHypotheses; (4) Control, in which participants were told to think about examples consistent with their hypothesis. We found that the training to think counter-examples facilitates attempts to falsify the current hypothesis and subsequent hypothesis change, but creating examples for two different hypothesis did not.
\end{abstract}

\title{
Computational modeling of inference generation during reading comprehension
}

\author{
Meni Yeari \\ Bar-Ilan Univeristy, Ramat-Gan, Israel \\ Paul van den Broek \\ Leiden University
}

\begin{abstract}
This research presents a computational model that simulates inference generation during reading comprehension. Inferences refer to information that readers generate from their background knowledge in order to clarify, connect, and elaborate textual information. The computational model integrates Latent Semantic Analysis (LSA), which simulates general knowledge by computing the strength of semantic association between concepts (Landauer \& Dumais, 1997), with the Landscape Model, a dynamic model of reading comprehension that simulates fluctuations of concepts' activation and the emergence of episodic connections between them (Yeari and van den Broek, 2011). The extended model was used to simulate behavioral data from a large number of studies on inference generation. Successful simulations of the various findings demonstrate the unique roles of semantic associations, episodic inter-textual relations, and working memory (limitation of concepts' activation sum) in the activation of different types of inferences (i.e., elaborative and bridging inferences).
\end{abstract}

\title{
Argument order as an expectation trigger in Korean
}

\author{
Hongoak Yun \\ Konkuk University \\ Uphong Hong \\ Konkuk University \\ Yun-Ju Nam \\ Konkuk University \\ Hyunjung Kim \\ Konkuk University
}

\begin{abstract}
Expected words/constituents are often processed faster than unexpected words/constituents. In languages like English that verbs are placed before arguments that they encode, the occurrence of verbs pre-activates upcoming arguments, suggesting that verbs' arguments are expected upon the recognition of verbs. However, this is not the case for languages like Korean that verbs are placed after the arguments associated with verbs. This study investigated whether argument order might play a role in cuing upcoming arguments. Using Hong et al.'s materials, we conducted a completion study. We found that patients were expected when recipients were introduced before, whereas recipients were not expected when patients were introduced before, suggesting that comprehenders might expect encountering patients after recipients but not vice versa. The probability of patients/recipients was correlated with the frequency of regressions that Hong et al. observed. We will further examine the role of probability and uncertainty in processing in terms of expectation.
\end{abstract}

\title{
Social interaction and cognition: from L. Vygotsky and M. Bakhtin tradition to computer agents' interactivity

\begin{abstract}
Social-interactive cognition in Russia builds on the ideas of cultural-historical psychology by L. Vygotsky, A. Leontyev, A. Luria, as well as communicative aspect of cognition introduced by M. Bakhtin in his theory of dialogism which, in its turn, laid the ground for the studies of social and situated cognition. Since 1980-s cognitive-discursive paradigm in Russia, introduced by E. Kubryakova, has attracted attention of cognitive science scholars. Within this paradigm cognitive approaches to pragmatics of communication and agentivity have been developed (V.Zabotkina, E. Pozdnyakova).

The given study introduces further development of the field, based on a multi-modal corpus built with recorded live communication data. Presently it's the biggest multi-modal corpus of emotional communication, so it ensures completeness and accuracy of research, conducted on its basis. Two- and three-dimensional computer agents (A. Kotov) operate a set of speech patterns in a complex of restricted communication situations, simulating real-life emotional social interaction.
\end{abstract}

\title{
Metacognitive Judgments in Category Learning
}

\author{
Valnea Zauhar \\ University of Rijeka \\ Igor Bajšanski \\ University of Rijeka \\ \section*{Drazen Domijan} \\ University of Rijeka
}

\begin{abstract}
The aim of the study was to investigate confidence in classification accuracy during category learning with three levels of categorization difficulty based on a simple logical, conjunctive or complex rule. Twenty five psychology students participated in the study. Stimuli were geometrical figures that varied on three dimensions: shape, colour, and size. We analysed differences in absolute accuracy of confidence judgments with respect to task difficulty (three levels), learning phase (early, late) and performance groups (slow and fast learners). For the simple logical task, we obtained a significant main effect of phase and a significant interaction between phase and group, suggesting that fast learners achieved higher accuracy earlier. For the conjunctive task, the significant main effect of the group showed higher accuracy of fast learners. For the complex task, there was a significant interaction between phase and group showing that judgment accuracy in slow learners did not improve during learning.
\end{abstract}

\title{
Effects of Strategy and Rule Complexity on Multivariable Inductive Judgments
}

\author{
Corinne Zimmerman \\ Illinois State University
}

\author{
Steve Croker
}

Illinois State University

\begin{abstract}
We investigated the effects of strategy use and rule complexity on multivariable inductive judgments. Participants \((\mathrm{N}=274)\) made judgments about which of two cars presented on a computer screen was faster. Participants were randomly assigned to a complex rule or a simple rule. For the complex rule, three of five variables affected speed; for the simple rule one variable affected speed. Participants were instructed to make explicit (try to discover the rules governing speed) or implicit (speeded intuitive) judgments for 300 trials with feedback.

A 2 (complexity) x 2 (strategy instruction) ANOVA revealed main effects of complexity, \(\mathrm{F}(1,270)=6.17, \mathrm{p}=.014\), and task instruction, \(\mathrm{F}(1,270)=11.69\), \(\mathrm{p}=.001\), and a significant interaction, \(\mathrm{F}(1,270)=7.38, \mathrm{p}=.007\). The explicit strategy led to better performance for the simple rule only, but no differences were found for the implicit strategy. These findings run counter to recent work showing an advantage for implicit processing of complex rules (Zimmerman \& Pretz, 2012).
\end{abstract}

\title{
Difference in Single vs. Pair judgements on Deception Detection, Confidence and Bias based on the Level of Communication
}

\author{
Mircea Zloteanu \\ University College London, London, United Kingdom \\ Daniel Richardson \\ University College London
}

\begin{abstract}
When people judge whether others are telling the truth, they act differently if they are working alone or in a group. The current experiment explored this finding. Participants (working alone or in pairs) provided either a binary truth/lie decision, or a binary decision and a set of reasons chosen from a list, or an open ended discussion/explanation. Being alone or in a pair had no significant effect on accuracy, but confidence was higher in pairs. A truth bias was found in the single condition but was eliminated for pairs when they specified a reason or had a discussion. Accuracy was highest when stating a reason chosen from a list, while confidence increased with the amount of information provided. These findings improve our understanding of the effect of pair decision making, illustrating how varying levels of information can have different effect on decision making and deception detection.
\end{abstract}

\title{
Progressive Development of the Number Sense in a Deep Neural Network
}

\author{
Will Y. Zou \\ Stanford University \\ James L. McClelland \\ Stanford University
}

\begin{abstract}
What are the developmental bases of the number sense? This ability could arise through evolution or experience. Stoianov \& Zorzi (2012, Nature Neuroscience, 8, 194-196) showed that a neural network could learn number sense from visual examples containing varying numbers of elements. However, the layer-wise training regime is unrealistic from a developmental standpoint. A key observation is that number acuity progressively develops from infancy to adulthood (as reflected by a decreasing Weber fraction). This development involves accumulation of single examples, each of which updates the connection weights in a hierarchical system. We present an unsupervised deep network that learns all weights as it observes one 'number example' at a time. As on-line training progresses, neurons representing numerosity start to emerge in the deeper layers, and the Weber fraction progressively sharpens. These results establish that a generic learning algorithm in a deep network gives rise to a clear developmental trajectory of the number sense.
\end{abstract}

\title{
On the different types of information stored in the lexicon and their neural bases
}

\author{
Camila Zugarramurdi \\ Facultad de Psicología, Universidad de la República, Uruguay.
}

\author{
Álvaro Cabana \\ Facultad de Ciencias, Universidad de la República, Uruguay. \\ Juan Valle-Lisboa \\ Facultad de Ciencias, Universidad de la República, Uruguay.
}

\begin{abstract}
We explore the idea that the neuropsychological organization of memory explains contradictory results about the lexicon. We believe that a semantic component stores the prototypic information and an 'episodic' component stores both the exceptions to the prototypes and the exceptionally common stimuli. With this theoretical insight we studied the different types of information that are accessed when a word is presented to a subject. To this end we first reproduced some results from Hare and coworkers showing that the presentation of a word for a noun facilitates the recognition of words related to the context of the word usage more than what could count as a semantic definition. The same pattern is observed for the neurophysiologically determined facilitation of the N400 component. Some of the results can be explained by corpus linguistic tools such as LSA. We present evidence from bimodal priming experiments supporting part of our theoretical proposition.
\end{abstract}

[^10]:    ${ }^{1}$ Inflectional markers that are overtly distinct from the other plural or singular forms of the same declension class and hence clearly identify the surface form as case marked.

[^11]:    ${ }^{2}$ Online: http://celex.mpi.nl/
    ${ }^{3}$ Surface frequency denotes the token frequency of a word form (such as table) (Schreuder \& Baayen, 1997: 119). Stem frequency (Schreuder \& Baayen, 1997: 120) is derived by cumulating frequencies of inflectional variants of a word, which have also

[^12]:    ${ }^{4}$ Fries (frieze), Schahs (shahs), Gemischen (mixtures.DAT)

[^13]:    ${ }^{5}$ Family size had to be excluded because it was highly correlated with family frequency $(\mathrm{r}=-0.82)$. Type frequency cannot be considered in the same model as group because type frequencies are tied with group membership (their correlation is 1 ).

[^14]:    ${ }^{1}$ Point-only trials were not included given that such trials would pit gaze and point against each other; moreover, pointing one place and looking another is rarer in day-to-do life.

[^15]:    ${ }^{2}$ For details on how subject means were computed, please see Bergelson \& Swingley, 2012.
    ${ }^{3}$ All subsequent tests are two-talked Wilcoxon tests unless noted otherwise; all " $\mathrm{X} / \mathrm{X}$ infants" results indicate the number of infants with positive performance. M is mean; Mdn is the pseudo-median estimate of the Wilcoxon test.

[^16]:    ${ }^{4}$ In a linear model pointing behavior is significantly predicted by both age, and by vocabulary residualized by age, suggesting that vocabulary predicts behavior above and beyond age alone.

[^17]:    ${ }^{5}$ Within each corpus's frequency counts, we did not constrain word class; 'kiss' occurring as a noun or verb was counted for 'kiss', just as 'apple blueberry sauce' was counted for 'apple'.

[^18]:    ${ }^{6}$ Separate analysis of non-nouns as verbs and performatives showed the same overall pattern as non-nouns combined.

[^19]:    ${ }^{1}$ This is specifically the case for decisions about where within a word to target the eyes. The control of decisions about which word to target is known to reflect cognitive processing.

[^20]:    ${ }^{2}$ As the target word moved to different absolute positions on the screen depending on the shift condition, for the purposes of blink exclusion, we used a target word region defined as the union of the locations occupied by the target word across all shift conditions.

[^21]:    ${ }^{3}$ The space prior to the word (position 0 ) was thus excluded.
    ${ }^{4}$ These probabilities come with a caveat: on the standard oculomotor account, many attempts to refixate a short word and many attempts to skip a long word will fail. Thus, on the standard account, these probabilities underestimate the true rate of unintentional target word fixations, which may be a substantial portion of trials. We return to this point in the Conclusion.

[^22]:    ${ }^{1}$ The 6-state solution for new foils effectively splits up two of the stages into shorter stages. Although this might explain the new foils in themselves better, our interest is explaining associative recognition.

[^23]:    ${ }^{1}$ Three additional tasks were performed on days 1 and 5 . To measure trait motivational tendencies, participants completed the Behavioral Activation System / Behavioral Inhibition System scales (BIS/BAS; Carver \& White, 1994). Participants also completed a finger-tapping task as a performance-based measure of manual motor asymmetries. Finally, an N-back task was performed as a measure of working memory. Results from these tasks do not bear on mood, and have not been analyzed.

[^24]:    ${ }^{1}$ The subject is marked by nominative case whereas the object is marked by accusative case at the determiner and noun, respectively. For masculine but not for feminine nouns, the subject and object status can be unambiguously differentiated via case marking (e.g., der Uhu/the ${ }_{[\text {NOм }} \operatorname{owl}_{[\text {[NOM] }}$ (subject) vs. den Uhu/the ${ }_{[A C C]} \mathrm{owl}_{[\mathrm{ACC}]}$ (object)).

[^25]:    ${ }^{1}$ See Appendix for formal definitions of the two filters.

[^26]:    ${ }^{2}$ See Appendix for the set of phonetic features.

[^27]:    ${ }^{3}$ See Appendix for the full set of feature values.

[^28]:    ${ }^{1}$ Kay and McDaniel (1978) actually proposed two closely related hierarchies, one of which is shown here for illustration. Boster's analyses considered both.

[^29]:    ${ }^{2}$ Levinson et al. (2003) were careful to note that their proposal is based on synchronic, not diachronic, data; they therefore advanced their proposal as a hypothesis concerning possible patterns of historical language change, not as a firm claim about such patterns.
    ${ }^{3}$ As in the case of color, our interpretation of Levinson et al.'s (2003) proposal, based on their Figures 16 and 18, reduces to two distinct hierarchies, one of which is shown here for illustration, but both of which we use in our analyses. Both of these hierarchies are specified further in the analyses below.

[^30]:    ${ }^{4}$ This model is most clearly articulated in Levinson et al.'s (2003) Figure 18, but where the order of divisions is underspecified in this diagram (e.g. the relative order of IN/INSIDE vs. NEAR/AT categorical splitting), we rely on the ordering of the implicational scale presented in Figure 16 for clarification.

[^31]:    ${ }^{5}$ The two alternative versions of the model that we considered differ in whether more specific ON or UNDER categories form first. In addition to these two alternatives, the model also varies in whether OVER or NEAR categories are distinguished earlier. However, these distinctions are made with respect to the category AT, which is not included in our analysis because as a residual category, it does not appear to have a meaningful cross-linguistic focus. Thus, the NEAR/AT distinction is not available to our participants, which in turn prevents variability in whether OVER or NEAR is distinguished first.

[^32]:    ${ }^{1}$ Cf. Snedeker \& Yuan, 2008 for more on children's sentence processing.

[^33]:    ${ }^{2}$ The 27 bilingual children heard and used English at least 50\% of the time, as reported by parents. This proportion is representative of the area where we collected data, which has a large population of fully- or partially-bilingual speakers. We replicated all analyses below, excluding bilingual speakers and saw essentially no difference in the qualitative or quantitative pattern of results reported below.

[^34]:    ${ }^{3}$ We excluded occasional emphatically lengthened monosyllabic words like [wav:] 'woooow!' from the calculation of the average and the resulting length manipulation.

[^35]:    ${ }^{4}$ See a sample of the final videos and data from all conditions in one version at: http://langcog.stanford.edu/materials/anticip.html

[^36]:    ${ }^{5} \mathrm{We}$ assume here that it takes children $\sim 333 \mathrm{~ms}$ to plan an eye movement, following Fernald and colleagues (2008). A significant shift in gaze to the next speaker before 333 ms of speech indicates that the eye movement was planned before the response began. We saw anticipation in all conditions, so below we compare anticipation across conditions by analyzing looks to the upcoming speaker at the onset of the response turn.

[^37]:    ${ }^{6}$ Longer gaps give more time for gaze shift.
    ${ }^{7}$ There were also marginal effects of Age and Condition overall ( $t=-1.85$ ). There were not enough non-question switches under 200 ms to test for effects of switch type in this model.

[^38]:    ${ }^{1}$ In all our experiments, the categories are novel and equally probable, so we omit the prior probability component of Bayesian reasoning. We continue to use the term Bayesian because of the common feature of Bayesian models of induction that predictions are integrated across multiple categories, weighted by their likelihood.

[^39]:    ${ }^{1}$ We decided to restrict the correct and wrong HMMs to two hidden states because there was not enough data to train three hidden states in the wrong HMMs.

[^40]:    ${ }^{1}$ We in fact verified this through simulations using their model.

[^41]:    ${ }^{2}$ This may be due to the need to compress brain size for successful birthing, and lower compressability of grey matter.

[^42]:    ${ }^{3}$ Lewis and Elman used 10 hidden units and 2 interhemispheric units; we increased these numbers to facilitate task-learning. Select simulations run with their parameters showed similar effects.
    ${ }^{4}$ We used a gradient $\left((y-t)^{3}\right)$ that penalized local minima where a many patterns were learned quickly by sacrificing a few patterns which were not learned at all.
    ${ }^{5}$ Parameters: $T=5, \alpha=10^{-3}, \kappa=10^{-2}$

[^43]:    ${ }^{6}$ noise $=\mathcal{N}\left(2 * 10^{-4} *\right.$ delay, $\left.1 * 10^{-4}\right) ;$ constant chosen such that $\mu$ is $\approx 2 \%$ of average activity over all units.

[^44]:    ${ }^{1}$ An obvious exception to this are species capable of vocal learning - particularly song-birds and cetaceans. We suspect it is no coincidence that these species (a) have combinatorial signalling systems, and (b) make use of cultural transmission. See Feher et al. (2009) for an example of the important role culture has in bird-song.
    ${ }^{2}$ This refers to a particular type of learning where a behaviour is acquired by observing another who also acquired that behaviour the same way (Kirby \& Hurford, 2002).

[^45]:    ${ }^{3}$ The same metric was used to give feedback to participants, but was first recast into a similarity score by computing 1-error, and then given as accuracy by percentage. An error score of 0.17 translates to a similarity score of 0.83 , and appeared to participants as $83 \%$ correct.

[^46]:    ${ }^{4}$ To do this, we used tools from the Zlib library: www.zlib.net

[^47]:    ${ }^{5}$ This analysis is intended to be illustrative rather than definitive, and is based on the sample of 6 sequences shown here, not the whole set. As we can see in Figure 2 the sequence sets are not fully stable and are still undergoing change, making a more detailed structural analysis difficult.

[^48]:    ${ }^{1}$ The same noise process applies to context features; we simply assume that all context features are sampled at once at the beginning of the trial, rather than over time.

[^49]:    ${ }^{2}$ The effect of the logarithm is simply to put positive and negative changes on the same scale.

[^50]:    ${ }^{1}$ Ability estimates were generated using expected a posteriori scoring.

[^51]:    ${ }^{1}$ Joint first authorship

[^52]:    ${ }^{1}$ Many factors have been identified as contributing to production preferences (see e.g. Jaeger \& Tily, 2011). Here we take participants' empirically estimated (Exp. 3) relative preference for shorter over longer messages as a measure of subjective production cost.

[^53]:    ${ }^{2}$ Exps. 1 and 2 here were identical to Exps. 1 and 2 in Degen and Franke (2012) with the difference that we use linguistic instead of pictorial messages.

[^54]:    ${ }^{3}$ Normally one would specify prior probabilities of states, but we assume that all referents are (believed to be) equiprobable. One would also normally specify utilities, but since we assume interlocutors want to cooperatively identify the referent, utilities are given by identity matrices that cancel out where normally they'd be relevant.
    ${ }^{4}$ As for notation, if $A$ is a matrix, let $\mathbf{T}(A)$ be its transpose, and $\mathbf{N}(A)$ its row-normalization. If $A$ and $C$ are matrices, $A C$ is their matrix product. We will also use a non-standard operation on matrix $A$, namely $\max \operatorname{row}(A)$ which returns a binary matrix with the same dimensions as $A$, such that max $\operatorname{row}(A)_{i j}=1$ if $A_{i j}=\max _{k} A_{i k}$ and 0 otherwise. We abuse notation by assuming that vectors are implicitly coerced if combined with matrices in standard arithmetic operations. So, for instance, $B-c$ is obtained by subtracting $c$ in each row.

[^55]:    ${ }^{5}$ The quantal response function is also known as logit choice rule, as soft-max function (Sutton \& Barto, 1998) or, if $\lambda=1$ as Luce's choice rule (Luce, 1959).

[^56]:    ${ }^{6}$ This is because $x=\log \frac{P(\text { costly })}{P(\text { cheap })}-\log \frac{P(\text { cheap })}{P(\text { costly })}$ reduces to $x=$ $\log (\exp (-\lambda c))-\log \frac{1}{\exp (-\lambda c)}=-2 \lambda c$.

[^57]:    ${ }^{1} \mathrm{http}: / / \mathrm{www}$. eecs.berkeley.edu/Research/Projects/CS/vision/gro uping/segbench/

[^58]:    ${ }^{1}$ This explanation may still warrant further investigation, as unlike our position presented here, people might not use the cue time for a slow removal process, but only to find the to-be-removed items. However, this explanation cannot easily account for the reduction of the repetition/ similarity effects observed in Experiments 1 and 2.

[^59]:    ${ }^{1}$ These were determined with a non-parametric $t$-test, the Whitney-Mann U-test, since the distributions of entropy scores are non-normal.
    ${ }^{2}$ After correction for multiple comparisons, this is not approaching significance.

[^60]:    ${ }^{3}$ marble $1\left(m_{1}\right)$ refers to the blue marble in the one-item task, and to the blue, brown, black, red, olive, and purple marbles in the six-item task.
    ${ }^{4}$ The raw log likelihoods should not be compared between tasks, because there are a different number of observations per task. This is corrected for in the prediction percentages, which are comparable between tasks.

[^61]:    ${ }^{5}$ This bootstrap model, which defines the dynamics of evolutionary drift, is equivalent to a Bayesian MAP model with $\alpha=0$. See Reali \& Griffiths (2010) for the proof.

[^62]:    ${ }^{6}$ Both of the empirical transition matrices are ergodic.

[^63]:    ${ }^{1}$ Previous studies have shown that children's head movements in the horizontal dimension are approximated by (though are slightly lagged by) their head movements (Yoshida \& Smith, 2008). Our own experience with the current apparatus ratifies these conclusions for the horizontal field but suggests that head movements in the ver-

[^64]:    tical field are less reliable. Hence, these studies may run the risk of underestimating the proportion of faces actually seen by children.

[^65]:    ${ }^{2}$ Since orientation was coded via body posture, faces seen while the caregiver was behind the child were due to children looking over their shoulder.

[^66]:    ${ }^{1}$ It is worth noting that the Greedy heuristic is not the only model that seeks to account for Olson's theoretical stance. A possible alternative is not to proceed incrementally, but to compare entire descriptions of increasing length, starting from those consisting of a single property, until the target is distinguishing. This would ensure a description that contains no more information than is absolutely required, something the Greedy heuristic can in fact only approximate. However, this 'Full Brevity' model, also discussed by Dale (1989), is unlikely to be psycholinguistically realistic, for three reasons: (i) it is computationally extremely expensive, since it potentially involves search through all available combinations of properties (Reiter, 1990); (ii) speakers tend to overspecify, as we discuss below; (iii) an implementation of Dale's Full Brevity model has been shown to produce output that does not match that of human speakers, compared to algorithms that are incremental in nature (van Deemter, Gatt, van der Sluis, \& Power, 2012).

[^67]:    ${ }^{2}$ Frank and Goodman (2012)'s discussion employs the term word rather than property; however, little hinges on the difference for present purposes.

[^68]:    ${ }^{1}$ This representation assumes that basic perceptual preprocessing has taken place (e.g., the correspondence problem has been solved).

[^69]:    ${ }^{2}$ As described in Blei et al. (2010), trees drawn from the nCRP can be infinitely deep, but we impose a maximal depth for simplicity.

[^70]:    ${ }^{3}$ The latent motion components can be marginalized analytically using properties of Gaussian processes.

[^71]:    ${ }^{4}$ Note that the model does not explicitly represent rotation but instead represents the tangential motion component in each time step.

[^72]:    $5_{\text {http: }} / /$ mocap.cs.cmu.edu/

[^73]:    ${ }^{1}$ The data from one participant were excluded due to excessively low within-dimension performance on both tasks (both slopes were two standard deviations below group averages).

[^74]:    ${ }^{1}$ The probabilism is intended to capture all factors that contribute to the imperfect measurement value of a specific post at a randomly chosen time. This includes both limits in the precision of measurement as such and exogenous factors that affect the cost but are unknown to the consumers.

[^75]:    ${ }^{2}$ In the multiple-comparisons, we report raw $p$-values assuming $\alpha=.05$. The Bonferroni corrected $\alpha$-level is app. . 008 . The same is true for the multiple-comparisons reported below.

[^76]:    ${ }^{1}$ The reason for testing their combined effect was that these two factors are highly interrelated (i.e., repeated encounters with the same partner, by default, bring along the opportunity of RB as each player would know what the other player has done so far).

[^77]:    ${ }^{2}$ The rejection rates for the alternative distributions (5/5), (2/8), and (10/0) were $2 \%, 6 \%$ and $82 \%$ respectively in Experiment 1.
    ${ }^{3}$ The rejection rates of the alternative distributions in the (5/5), (2/8) and (10/0) games were as follows: Nobody rejected the $(2 / 8)$ distribution and only one participant rejected the $(5 / 5)$ distribution. Almost $96 \%$ rejected the (10/0) distribution.

[^78]:    ${ }^{1}$ Geoffrey Bird is now at Institute of Psychiatry, King's College London.

[^79]:    ${ }^{\text {a }}$ Des $=$ Desirable information; Undes = Undesirable information

[^80]:    ${ }^{2}$ This enables a more appropriate normative analysis of the data (see Shah et al., 2013), which we do not elaborate on here.
    ${ }^{3}$ Controlling for these factors did not change the results.

[^81]:    ${ }^{1}$ The two previous ERP studies investigated sentences of the form some elephants have trunks - literally true but rendered infelicitous by scalar implicature (Nieuwland, Ditman, \& Kuperberg, 2010; Noveck \& Posada, 2003). The final word evokes an N 400 relative to the final word in felicitous sentences (some dogs have spots), at least if the sentences are carefully matched.
    ${ }_{2}$ Panizza, Chierchia, and Clifton Jr. (2009) report an eyetracking-while-reading study with a similar manipulation, but involving number. The relationship between number and scalar implicature is complex, unclear, and controversial.

[^82]:    ${ }^{3}$ The choice of threshold (e.g., 1.96) affects the type of clusters found - low thresholds are better at detecting broadly extended but weak effects - but does not affect robustness to multiple comparisons. Other threshold resulted in similar findings.

[^83]:    ${ }^{4}$ Breheny, Katsos, and Williams (2006) report longer reading times for scalar triggers in contexts expected to promote scalar implicature calculation. However, the contextual manipulations are uncontrolled, making its results difficult to interpret. In the case of Exp. 3, the manipulation is fully confounded with a repeated name penalty, sufficient to explain their results.

[^84]:    ${ }^{1}$ Specifically, each time the simulate button was clicked a random number between 1 and 10000 was generated. If the number was less than 511 then the woman had cancer.

[^85]:    ${ }^{2}$ These qualitative results remained unchanged when deviation scores in the sampling condition were recomputed against a normative solution that replaced the stated base rate of $1 \%$ with the base rate implied by the sample drawn by each participant (i.e. the observed proportion of positive cancer trials).

[^86]:    ${ }^{3}$ These qualitative results remained unchanged when deviation scores were recalculated using individual cancer base rates implied by the sampling information instead of the stated rate of $1 \%$.

[^87]:    ${ }^{1}$ Notwithstanding a body of theoretical work (see e.g. Markman and Stilwell, 2001).

[^88]:    ${ }^{2}$ Although concreteness is well understood intuitively, it lacks a universally accepted definition. It is often described in terms of reference to sensory experience (Paivio et al., 1968), but also connected to specificity; rose is often considered more concrete than flora. The present work does not address this ambiguity.

[^89]:    ${ }^{3}$ E.g. she states "What is important to this view is not how abstract words come to have weaker connections [to associated information]...only that they generally do" (1991, p. 243).

[^90]:    ${ }^{4}$ Subjects were asked to consider their idea of synonymy and then rate the "similarity of meaning" of word pairs (1965, p. 628).

[^91]:    ${ }^{1}$ The 3-dimensional solution (stress $=.17$ ) provided little additional information. The third dimension could be interpreted as reflecting a distinction between metric (e.g., far from, near) and nonmetric (e.g., above, to the left of) prepositions, but this dimension also distinguished the four clusters in Figure 1 reasonably well.

[^92]:    ${ }^{2}$ Other dimensionality reduction techniques (hierarchical clustering and principal components analysis) yielded similar results, suggesting that the clusters are not an artifact of MDS (Holmes, 2012).
    ${ }^{3}$ In addition to identifying clusters within the 2-dimensional similarity space, the dimensions themselves may also be interpreted. These dimensions seem to capture broad distinctions among spatial relations in the world. The $y$-axis reflects a distinction between topological and projective relations (Levinson et al., 2003); most of the prepositions in the above-below and in clusters refer to relations between contiguous objects, whereas those in the front-back and leftright clusters specify a frame of reference. The x -axis is less easily interpreted. Several researchers have noted that the above-below and front-back axes are perceptually asymmetric with respect to canonical body position, whereas the left-right axis is perceptually symmetric (e.g., Clark, 1973). However, the in cluster is not well captured by this distinction; relations of containment and proximity are not readily characterized in terms of symmetry.
    ${ }^{4}$ The in category was not included because it was the only category that did not contain terms with opposite meanings, making CP more difficult to assess than for the other categories.

[^93]:    ${ }^{1}$ These concerns do not necessarily undermine the distinction between personal and impersonal dilemmas, for which there is independent evidence (Moore, Clark \& Kane, 2008). The two claims are independent; one can accept the personal-impersonal distinction without thinking that people's moral judgments in these cases are driven by differences in the emotions the situations evoke.

[^94]:    ${ }^{1}$ Participants in the study of Feldman et al. (2010) were prompted to give an answer immediately after the presentation of the stimulus.
    ${ }^{2}$ Tohill and Holyoak (2000) used a serial subtraction task, while Feldman et al. (2010) - a "public speech" procedure.
    ${ }^{3}$ STAI for Tohill and Holyoak (2000) and a self-assesment 5point scale for the Feldman et al. (2010).
    ${ }^{4}$ The Feldman et al. (2010) study used geometric figures and the relations between them, while the Tohil and Holyoak (2000) study, used much more complex everyday situations, depicted in two pictures, which usually involved more than 3 actors and a number of diverse relations between them.
    ${ }^{5}$ Match-to-sample task (Feldman et al. (2010)) - one sample and two distinct targets (one superficially similar and one relationally similar) vs. a cross-mapping task, where participants should choose which option in the bottom picture "goes with" the object, pointed from the experimenter. Both the target object and the options were embedded in complex relational structures. The number of options varied between 3 and 6 alternatives for answer, etc.

[^95]:    ${ }^{6}$ Seven of them were devised by Markman and Gentner (1993) for a study of structural alignment; two were created later and used in the experiments on how anxiety influences analogical mapping by Tohill and Holyoak (2000). Both research groups kindly provided their stimuli for our study. All original stimuli were drawn again, carefully preserving the key relations between the objects.

[^96]:    ${ }^{7}$ State anxiety in the control condition of our experiment is 2.65 higher than in the Tohill and Holyoak's study, and 2.01 lower in the anxiety condition.

[^97]:    ${ }^{1}$ Concepts here are denoted by the name of their referent typed in upper case letters.

[^98]:    ${ }^{2}$ For example, learning the idea of MOVING THE KING TWO SQUARES TOWARDS A ROOK ON THE PLAYER'S FIRST RANK, FOLLOWED BY MOVING THE ROOK ONTO THE SQUARE OVER WHICH THE KING CROSSED (i.e., CASTLING in chess) may strike one as a case of bona fide concept learning.
    ${ }^{3}$ Many examples support this generalization from the formation of perceptual prototypes to the construction of schemas, scripts, mental models, and propositional representations. As Carey (2009) says, it is a truism that all learning involves building new representations from antecedently available ones.
    ${ }^{4}$ I.e., adding new operators, predicates, etc. with content that no combination of the earlier set of primitives could represent. One example is adding the modal operators 'possibly' and 'necessarily' to classical propositional logic.

[^99]:    ${ }^{5}$ Fodor's circularity problem has been described above. In specifying the meaning of some concept via a hypothesis, we must understand and use the very concept of which we formulate the hypothesis (Fodor, 1990, 1998). Goodman's problem of induction is that given a body of empirical data, there are infinitely many ways to inductively generalize from it, and learning theories need to explain how we choose our preferred ones (Goodman \& Putnam, 1983).

[^100]:    ${ }^{6}$ Note also that actions like coupling, or noticing what takes minimum effort are pretty close to a sensorimotor vocabulary. I suggest no return to empiricism, still it is worth noticing that sensorimotor activity might play some mediating role in bootstrapping mathematical concepts. To this extent Piaget's view of development may be correct.

[^101]:    ${ }^{1}$ The value of relational language and comparison might in some cases be related because using the same term for different examples can invite comparison of these examples (e.g., Gentner, 2003, 2010; Gentner \& Medina, 1998; Gentner \& Namy, 1999). However, our focus here will be on the individual effects of relational language and comparison.

[^102]:    ${ }^{2}$ All of the post-hoc tests were Tukey HSD tests.

[^103]:    ${ }^{1} 12$ additional toddlers were recruited but never included in the study because they declined to participate in a warm-up task, in which the child was asked to choose between two stuffed elephants.

[^104]:    ${ }^{2} 4$ additional two-year-olds and 3 three-year-olds were recruited but never included in the study because they declined to participate in a warm-up task, in which the child was asked to choose between two stuffed elephants.

[^105]:    ${ }^{1}$ phasespace.com/impulse_motion_capture.html

[^106]:    ${ }^{2}$ The first frame was dropped from each dataset to match the number of frames of data with the number of frames of derivative.

[^107]:    ${ }^{1}$ http://github.com/lmjohns3/driving-simulator

[^108]:    ${ }^{1}$ Note that parts of the empirical research reported in this paper have been published in Gerjets, Kammerer, and Werner (2011) who compared the two thinking-aloud groups (irrespective of prior knowledge). The data of the silent group were gathered at the same time as the data of the two thinking-aloud groups.

[^109]:    ${ }^{1}$ See Taylor, Devereux, Acres, Randall, and Tyler (2011) for details.

[^110]:    ${ }^{2}$ We generated 50 and 150 clusters for the concepts and features respectively using hierarchical clustering on WordNet.
    ${ }^{3}$ The multi-class implementation, SVM Multiclass (v. 2.20).
    ${ }^{4}$ Potential features were defined as all adjectives and singular/plural nouns in a sentence.
    ${ }^{5}$ Due to memory constraints associated with the very large number of training instances, we were only able to train our UKWAC models on one third of the UKWAC corpus; we selected every third learning pattern for training.

[^111]:    ${ }^{6}$ Only a small proportion of our triples derived their relations in this way; at this point, in our training sets we had assigned relations to over $94 \%$ of triples from our Wikipedia corpus, and $97 \%$ from the UKWAC corpus.

[^112]:    ${ }^{7} 300$ factors, using the TASA corpus at 1 sa.colorado.edu.
    ${ }^{8}$ The correlation confidence intervals, calculated using Fisher transformations (Fisher, 1915), are given at the $95 \%$ level of confidence, and two-tailed $p<0.05$.

[^113]:    ${ }^{9}$ i.e. both 'correct' and 'plausible' triples were counted as correct, while 'related' or 'wrong' triples were considered incorrect.

[^114]:    ${ }^{1}$ Khetarpal et al. (2009) used a slightly different formalization of these ideas. We use this one because it maps cleanly onto the communicative scenario sketched above, in which a listener tries to understand a speaker's meaning. The results reported below remain qualitatively unchanged if the original formalization is used instead.

[^115]:    ${ }^{2}$ Regier et al. (in press) presented slightly different extensions of English categories against this map, one of which was not connected. We have chosen these extensions instead because (1) they allow English categories to be connected in this map, (2) that connectedness allows us to include English in our upcoming analyses, and (3) these extensions agree well with our linguistic intuitions.

[^116]:    ${ }^{3}$ A followup study found that these pile-sorts were broadly similar across the two languages, although they did reflect the sorter's native language to some extent (Khetarpal et al., 2010).

[^117]:    ${ }^{1}$ Some work, e.g. Griffiths and Kalish (2007), has also considered models of type (1b), but only for the discrete parameter case.

[^118]:    ${ }^{2}$ This is equivalent to sampling from $\pi_{t}(p)$ and generating an example from the distribution implied by the value of $p$ chosen.
    ${ }^{3}$ These models are equivalent to special cases of 'blending inheritance' models of cultural evolution of a quantitative character (Boyd and Richerson, 1985: 71ff).

[^119]:    ${ }^{4}$ This contrasts with the common statement that 'blending inheritance' reduces variance of a quantitative trait over time (Boyd and Richerson, 1985: 75). However, stable or increasing variance are possible for particular cases of Boyd and Richerson's model, such as the case considered here where each learner has a single 'cultural parent' and there is noise in estimating the parent's cultural model.

[^120]:    ${ }^{5}$ The ML estimate of $\hat{p}$ in the no-prior case above, $\mu_{a}-\bar{y}$, can thus be thought of as the Gaussian-prior estimate when the prior is very flat relative to the dispersion of the phonetic category $\left(\tau \gg \sigma_{a}\right)$.

[^121]:    ${ }^{6}$ A additional extension to be explored is horizontal transmission. In the present models, learners do not receive input from members of their own generation, but this could impact the dynamics as well.

[^122]:    ${ }^{1}$ Voice onset time (VOT) is defined as the time between the release of a stop consonant and the start of vowel phonation.

[^123]:    ${ }^{2}$ It is typical of the cue-distractor task that the distractor is not itself a valid output, and so effectively has zero prior and posterior probability.

[^124]:    ${ }^{1}$ The first two authors contributed equally to this work

[^125]:    ${ }^{1}$ All t-tests are two-tailed.

[^126]:    ${ }^{1}$ "But first" was ambiguous because it could refer either to the time period before the first or the second movement. Thus, we also performed analyses only on target referents that were mentioned second, for whom the ambiguity did not apply, which showed a similar pattern of results.

[^127]:    ${ }^{1}$ The authors are listed in alphabetical order. This paper is based

[^128]:    ${ }^{2}$ See, e.g.,Woodward 2003, 362-364.

[^129]:    ${ }^{3}$ Code obtainable on request.

[^130]:    ${ }^{1}$ Logistic regression models of response choices were fit by the Laplace approximation, whereas linear regression models of response times and fixation proportions were fit using restricted maximum likelihood estimation. Fixed effects included prosody condition (Noun- vs. Verb-focus), display type (one- vs. two sets of related pictures), and standardized trial number. Analyses of fixation proportions additionally included picture type. We also included random by-subject and item intercepts as well as slopes for the interaction between prosody condition and picture type. To minimize the risk of over-fitting the data, fixed effects were removed stepwise and each smaller model was compared to the more complex model using the likelihood ratio test (Baayen, Davidson, \& Bates, 2008).

[^131]:    ${ }^{1}$ Hereafter: double-quotation marks are used for quoting speech, with phonetic and prosodic specification. Capital letters represent prosodic emphasis. Square brackets ([ ]) are used for example words or sentences abstracted away from acoustic detail, e.g., [It is raining outside] can be said as, "It's RAINING outside!", "It IS raining outside!", et cetera.)

[^132]:    ${ }^{1}$ The plotted numerical values change very little with the inclusion of incorrect trials and the pattern of statistical results remains identical.

[^133]:    ${ }^{2}$ Please see Davelaar et al. (2005) for computational details.

[^134]:    ${ }^{1}$ For whole body motion considered here, we simply integrated the motion energy over the entire ROI without subdividing the image region. An analysis at smaller scales might necessitate an integration over smaller overlapping patches.

[^135]:    ${ }^{1}$ In this analysis, we focus only on situations where a single referring word is used.
    ${ }^{2}$ This assumption is made for purposes of simplicity only, as a variety of our previous work has explored the use of social and pragmatic information in biasing the distribution over intended referents (Frank \& Goodman, 2012).

[^136]:    ${ }^{3}$ The 1-many constraint is related to the concept learning model proposed by Goodman, Tenenbaum, Feldman, and Griffiths (2010) using a disjunctive normal form grammar.

[^137]:    ${ }^{1}$ Small capital letters are used to distinguish concepts from objects.

[^138]:    ${ }^{2}$ This manipulation was motivated by the observation that different types of ambiguity license different inferences. To illustrate this, imagine a learner in a confounded across context. The learner observes a situation with two apples and a situation with two oranges. In each situation, she hears "dax bren nes". The referent is clear in each individual situation - apple and orange, respectively - and the learner might infer that this phrase corresponds to a superordinate category, such as FRUIT. In the confounded within context, the learner observes two situations, both containing an apple and an orange, and again hears "dax bren nes" in each. Unlike in the across case, a learner in this context would have no information about how to correctly map the meaning of this phrase, since the context is consistent with both a subordinate and superordinate interpretation. Different generalization patterns are thus predicted in the confounded across and within conditions.

[^139]:    ${ }^{1}$ The absolute value of this slope is not meaningful because of the relatively large scale of the items (1 to 36 ) compared to the range of the itemwise correlation.

[^140]:    ${ }^{2}$ We could rearrange the items in order of difficulty, but this would bias the analysis towards the result we observe. Instead, we present the items in the order they were presented for parity with Unsworth and Engle (2005).
    ${ }^{3}$ These random effects models allow the decrease in accuracy across items to begin at a different level of accuracy or, in addition, decrease at a different rate for each participant, respectively

[^141]:    ${ }^{1}$ In a way, it can be argued that, thanks to material culture, human beings have managed somehow to take advantage of most environments on Earth (and outside of it), but it is a partial success which requires a continuous implementation of resources and knowledge in order to maintain those achievements as persistent.
    ${ }^{2}$ It is important to note recent research based on Schrödinger's focusing on energy, matter and thermodynamic imbalances provided by the environment, draws the attention to the fact that all organisms, including bacteria, are able to perform elementary cognitive functions because they "sense" the environment and process internal information for "thriving on latent information embedded in the complexity of their environment" (Ben Jacob, Shapira, and Tauber (Ben Jacob, Shapira, \& Tauber, 2006, p. 496)). Indeed Schrödinger maintained that life requires the consumption of negative entropy, i.e. the use of thermodynamic imbalances in the environment.

[^142]:    ${ }^{3}$ Attention is drawn for the first time to the idea of niche construction by important researchers like Schrödinger, Mayr, Lewontin, Dawkins, and Waddington. Firstly in the field of physics and subsequently in the field of the theory of evolution itself. Waddington particularly stressed the influence of organism development.

[^143]:    ${ }^{4}$ This perspective has generated some controversies, since the extent to which modifications count as niche-construction is not clear, thus entering the evolutionary scene. The main objection regards how far individual or even collective actions can really have ecological effects, whether they are integrated or merely aggregated changes. On this point, see (Sterelny, 2005) and the more critical view held by (Dawkins, 2004). For a reply to these objections, see (Laland, Odling-Smee, \& Feldman, 2005).

[^144]:    ${ }^{5}$ The regulatory dimension of structural violence is often diluted in the pervasive form of narratives conveying "moral templates": the fairytales that are told to children from early youth, novels, plays, dramas and - more recently - motion pictures are all involved in the dissemination of some moral, economic or spiritual teaching, but they also circulate via gossip (Baumeister, Zhang, \& Vohs, 2004).

[^145]:    *JK and TM contributed equally to this work.

[^146]:    ${ }^{2}$ Initial analyses found no effects of participants' handedness (Dehaene et al, 1993); it was thus removed from further analyses.

[^147]:    1 This is assuming categorization at the same level in a categorization hierarchy and within the same domain. Presumably, any given object can belong to multiple categories along a subordinate to superordinate spectrum (e.g., robin, bird, animal) and can be categorized in different ways depending on the intention of the categorizer (e.g., parakeet versus pet animal). We are discussing here categorization decisions that are equated across these dimensions (e.g., robin versus blue jay).

[^148]:    ${ }^{2}$ It should be noted that this explanation does not account for differences between the ambivalent and uncertain conditions.

[^149]:    ${ }^{1}$ Numbers in angled brackets indicate the utterance number in the original corpus.

[^150]:    ${ }^{1}$ Note that both measures are not independent of each other; selection and error rates add up to 1 .

[^151]:    ${ }^{1}$ New York University, Department of Psychology, 6 Washington Place, New York, NY 10003 USA
    ${ }^{2}$ Massachusetts Institute of Technology, Department of Brain and Cognitive Sciences, 77 Massachussetts Ave., Cambridge, MA 02139 USA

[^152]:    ${ }^{1}$ Because our study was conducted in Germany we used the corresponding German words "selten", "gelegentlich", "häufig", and "fast immer". Note that Bocklisch et al.'s (2012) study was also conducted in Germany with estimates given for the very same (German) terms.

[^153]:    ${ }^{2}$ Note, all symptoms does not mean that subjects were presented with all symptoms of a trial at each time, but with all symptoms that were relevant to the current judgment. Thus, in the all-symptoms condition subjects saw the sequence $\left\{S_{1}\right\},\left\{S_{1}, S_{2}\right\},\left\{S_{1}, S_{2}, S_{3}\right\}$, whereas in the single-symptom condition subjects were presented with the sequence $\left\{S_{1}\right\},\left\{S_{2}\right\},\left\{S_{3}\right\}$.

[^154]:    ${ }^{3}$ For this purpose, we used a grid search over a plausible set of values for $\delta$ between $1 \mathrm{e}-10$ and $1 \mathrm{e}+10$.

[^155]:    ${ }^{4}$ Remember that in the limit, if $\delta=\infty$ there is no decay; if $\delta=0$ the posterior probability depends on only the most recent symptom.
    ${ }^{5}$ More specifically, the algorithm proceeds as follows: (i) Given the current assignments of participants to clusters, find the $\delta$ parameter for each cluster

[^156]:    that minimizes the $M S E$ of the model predictions with respect to the average response profile of the subjects within the cluster. (For this purpose, we used a grid search over a plausible set of value for $\delta$.) (ii) Given the model predictions for the different clusters, reassign subjects to a cluster such that the correlation between the individual response profile and the model prediction is maximized. Then, iterate through (i) and (ii) until no participant changes cluster anymore.

[^157]:    ${ }^{1}$ The general validity of the PME is demonstrated using simple combinatorics (cf., Jaynes, 2003).

[^158]:    ${ }^{2}$ The general form of the solution is due to L. E. Boltzmann. For a sketch ot the derivation, see, e.g., Moscoso del Prado (2011).

[^159]:    ${ }^{3}$ The same effects reported here were also replicated for other corpora of English and French. These additional analyses are not reported here for brevity reasons.
    ${ }^{4}$ Piantadosi et al. (2012) report effects on length in syllables. I use phoneme-based lengths instead as these are more sensitive, but I also replicated the same effects using syllable-based lengths. Conversely, Piantadosi and colleagues also report that their effects also held when measuring length in phonemes.
    ${ }^{5}$ The log number of senses provides a better approximation to the psychologically relevant magnitude than does the raw count (cf., Moscoso del Prado, 2007). Note however that doing the calculation on raw counts of word senses did not result on different results.

[^160]:    ${ }^{6}$ http://www. speech.cs.cmu.edu/cgi-bin/cmudict

[^161]:    ${ }^{1}$ For a complete list of the property clusters of S1 and S2, sometimes called the 'Standard Menu', see Evans and Frankish (2009). I take the two-system hypothesis to be stronger than the existential claim that there are two systems of reasoning. The thesis is that cognition is divided into two systems and that each system has a certain set of properties associated with it-the properties on the Standard Menu.

[^162]:    ${ }^{2}$ Response toggle would be behavioral evidence for SCB rather than phenomenological evidence (as in the 'belief that p ', 'feels that not-p' cases).

[^163]:    ${ }^{3}$ The Monty Hall case is as follows. A subject is invited to a game show at which he or she may win a new car. The car is behind one of three doors. Behind the other two is nothing. The subject is told to pick a door. Monty, the game show host, opens one of the doors which the subject did not pick. The subject is then asked if he or she would like to change his or her answer. While it might at first seem that it does not matter, in fact there is a $2 / 3$ chance that the car is behind the door that the subject had not picked.

[^164]:    ${ }^{4}$ Parallel as opposed to sequential. In the former the two systems operate at the same time, in the later S1 operates first, then may shut down while S 2 performs its computations. Almost all two-system advocates endorse a form of the parallel view.
    ${ }^{5}$ On most accounts the S1 level of belief is the same as the implicit level of belief.
    ${ }^{6}$ This need not be a conscious suppression.

[^165]:    ${ }^{7}$ This well-known test involves the subject being shown the names of colors written in various colored prints. The subject is asked to give the name of the print-color. The faster and more accurately the participant gives the color of the print (rather than the word), the higher executive functioning and less cognitively depleted that participant, while the slower and less accurately the participant gives the name of the color of print, the lower the participant's executive functioning and more cognitively depleted the participant.

[^166]:    ${ }^{1}$ I will focus on the 3D Ebbinghaus illiusion because of the simplicity of the results, but it needs to be noted that the experimental conditions of this experiment have been criticized recently (Pavani et al. 1999, Franz 2001, 2003, Franz et al. 2000, 2003, Gillam 1998, Vishton 2004 and Vishton \& Fabre 2003, but see Haffenden \& Goodale 1998 and Haffenden et al. 2001 for a response and Briscoe 2008 for an overview. I focus on the 3D Ebbinghaus experiment in spite of these worries, but those who are moved by Franz et al. style considerations can substitute some other visual illusion, namely, the Müller-Lyer illusion, the Ponzo illusion, the hollow face illusion or the Kanizsa compression illusion, where there is evidence that the illusion influences our perceptual judgments, but not our perceptually-guided actions.

[^167]:    ${ }^{2}$ The distinction between the anatomical and the functional level also works in the other direction. The McIntosh and Lashleya experiment can be and has been taken to show that the dorsal stream is not informationally encapsulated (see Brogaard 2011 for analysis). But the experiments are not about the dorsal stream; they are about action-guiding vision. Interpreting them as having damning implications for the dorsal/ventral distinction is based on the equivocation of dorsal vision and action-guiding vision.

[^168]:    ${ }^{1}$ Throughout this paper, the term "rules" is used informally, and in this context refers to any regularity that people rely upon to guide inference. It is not intended to imply that the regularities in question correspond to explicitly represented, verbalizable rules.

[^169]:    ${ }^{2}$ The responses for these 6 rose monotonically across trials. This pattern makes sense if one assumes the bags are constrained to contain the same set of types. One participant spontaneously reported having made this assumption. This was not the intended interpretation of the task, but it is not an unreasonable one.

[^170]:    ${ }^{3}$ One reviewer noted that the gap between skewed and uniform does not increase across trials, and took this to imply that participants were not learning across trials. This is not correct: the trials differ systematically in tems of the number of types and tokens, making it difficult to draw any such inference. The key test of whether cross-trial learning takes place is to look at bag 7: if no cross-trial learning occurs, then responses should be identical for this bag in both conditions, because this stimulus was identical in the two conditions.
    ${ }^{4}$ Bag was coded as a categorical variable, and the random effect of bag-by-subject subsumes the random effect of subject.
    ${ }^{5}$ Analyses were run in $R$ version 2.15 .2 using the lme 4 package version 0.999999-0. Several other model specifications were

[^171]:    tried: none had lower BIC. Inspection of residuals suggests this model provides a good fit to the data. Nevertheless, it is important to note that the effect of condition is robust: it was significant in all model specifications tried, including several that analyzed only the binary version of the response variable (i.e., extrapolative vs nonextrapolative).
    ${ }^{6}$ The coin package (version 1.0-21) in R was used to compute an exact $p$ value in the presence of ties.

[^172]:    ${ }^{7}$ Strictly speaking, the samples should be constrained such that each type appears at least once among the $n$ observed marbles or the $100-n$ unobserved ones. For simplicity I have avoided introducing this additional constraint in this paper.

[^173]:    ${ }^{8}$ In principle there is no reason why a model with individual differences should be avoided: in practice, the computational difficulties in estimating such a model are somewhat severe.

[^174]:    ${ }^{1}$ We note that this lexicon is only used in input generation and evaluation, and not in the learning of the model.

[^175]:    ${ }^{1}$ However, for some emotion concepts, some features are indeed necessary (e.g. test anxiety involves thinking that an exam is going to take place) while others are merely characteristic.
    ${ }^{2}$ Prinz (2004) argues that some emotions are individuated by a calibration file, i.e. a mental file which includes different judgments that are unified because they all bear on the person's well-being in the same way. Prinz' strategy is to officially claim that the calibration file is part of the cause of the emotion but not constitutive for it. Since he at the same time describes the calibration file as being the essential feature for individuating an emotion, this is finally not a consistent position to hold.

[^176]:    ${ }^{3}$ Although the intentional object is crucial for distinguishing emotions from each other, it does not follow that the object is the bearer of the emotion (as an extended mind theorist might want to claim). While we remain neutral about the extended mind hypothesis in general, it is worth noting that our account does not

[^177]:    ${ }^{5}$ If someone is trained to inhibit any expressive sign of his emotion, we may still be able to recognize the emotion by inference, e.g. by noticing the force that someone uses to inhibit the expressions in the given context.
    ${ }^{6}$ We want to clarify the relation of our pattern account of emotion to earlier philosophical component theories of emotions by excluding a main deficit we do not inherit. Some component theories have analyzed emotions as beliefs plus desires plus (often) feelings (e.g. Lyons, 1980; Robinson, 1983). Whatever the relevant components are, Döring (2009) presents the following principle criticism: component accounts cannot explain why an emotion is (usually) experienced as a unitary conscious state. We fully acknowledge that an emotion is experienced as a unitary conscious state, but we will not provide an explanation of why and how this experience came about. Providing such an explanation is not necessary for a plausible philosophical account of emotions. Otherwise the problem would also affect Döring's account - she merely emphasize the unity of emotional experience but do not provide an explanation for it, either.
    ${ }^{7}$ This is at least true if we presuppose an identity theory of mental and physical states. We tend to do so but at the same time presuppose that the relevant physical state involves more than just a neural state, i.e. the whole body and maybe part of the environment.

[^178]:    ${ }^{8}$ Fear is fear no matter whether the observer knows that he deals with an anxious person or a courageous person but it is much easier to recognize knowing this and we can recognize it easier in an obviously dangerous setting than in a (seemingly) save setting.
    ${ }^{9}$ We allow for the case of emotion recognition without ascribing it to the other, i.e. without conceptualization but this case will not be the focus of this paper.
    ${ }^{10}$ For the sake of argument we can identify conceptual and linguistic abilities. For a fine-grained distinction between linguistic and non-linguistic concepts in the context of animal cognition, see Newen and Bartels, 2007.
    ${ }^{11}$ We are not discussing here what it means to possess concepts since it is sufficient to account for top-down influences to establish a general picture of perceiving emotions.

[^179]:    ${ }^{1}$ It must be acknowledged that this sentence contains an ambiguity with respect to the attachment of the adjunct during the meeting but as it occurs after the resolution of the filler gap dependency it should not have any affect on the results.

[^180]:    ${ }^{1}$ These specific terminologies are laid out here for the purpose of the present paper, rather than trying to resolve the emerging terminological debate within the field.

[^181]:    ${ }^{2}$ Due to experimenter error, one dyad's affiliative prompt was based on a sociopolitical topic on which both agreed. However, close inspection of the data confirmed the affiliative nature of the conversation.

[^182]:    ${ }^{3}$ The experimenter sat beside the camcorder, outside of the participants' immediate range of vision, in order to monitor the equipment unobtrusively and to ensure the participants did not stray from the assigned topic.

[^183]:    ${ }^{4}$ One dyad included in the present analyses was excluded from analyses in Paxton and Dale (under revision), due to incomplete data for other analyses.

[^184]:    ${ }^{5}$ The automated speech analysis produces off states frequently, as it prioritizes ignoring non-target speech. This can minimize the magnitude of the negative correlations, since there are frequent off states that match in time during an interaction (e.g., pauses).

[^185]:    ${ }^{1}$ In actual discourse, $2^{\text {nd }}$ person reference is achieved by pointing to the physical location of the addressee.
    ${ }^{2}$ This is a highly simplified description (for a more in-depth treatment see Sandler \& Lillo-Martin 2006), but is adequate for the present purposes.

[^186]:    ${ }^{3}$ We focused on selecting BSL verbs that clearly encoded motion of transfer semantics of the kind needed for the ACE, and did not control for other factors like sentence length. The challenge of finding enough non-directional BSL verbs, in particular, meant that we were not able to achieve an exact balance between the verb types and required use of the same verbs in sensible and nonsense versions of the sentences.

[^187]:    ${ }^{4}$ The marginal three-way interaction in Experiment 1 b arises due to a tendency for congruent trials to be particularly slower than incongruent trials, only in non-directional verbs encoding events moving away from the body. As a result, this provides no evidence compatible with the ACE effect previously reported for English.

[^188]:    ${ }^{5}$ Note that the signers recruited for Experiment 1 were also BSL-English bilinguals, a status which holds true of most users of sign language, as they must also be able to communicate in the spoken/written language of the surrounding hearing community.

[^189]:    ${ }^{6}$ Because Experiments 1a and 2a used the same pool of items, varying only in whether the events were $1^{\text {st }} / 2^{\text {nd }}$ person (Exp. 1a) $2^{\text {nd }} / 3^{\text {rd }}$ person (Exp. 2a) we also conducted an analysis combining both experiments ( $\mathrm{N}=32$ ) with Experiment as an additional factor. The main effect of congruence was not significant in this analysis ( $F<1$ ) nor any other interactions involving congruence (all $F<1$ ).

[^190]:    ${ }^{1}$ Note that we have not considered the symmetry of the smile since this characteristic is difficult to perceive by a user when watching a face to face interaction between virtual agents

[^191]:    ${ }^{2}$ Other interpersonal stances may influence the mapping between perceptive space and motor space, such as warm or polite. However, a model of the effect of the different stances on the perceptive and motor space is out of the scope of this paper.

[^192]:    ${ }^{3}$ http://www.iis.fraunhofer.de/en/bf/bsy/produkte/shore.html

[^193]:    ${ }^{1}$ The terms used in this paper are compatible with standard terminology used by chemists in technical writing. Items such as soap, coconut, or sugar are a mixture of substances and are not considered pure 'substances' by chemists. Instead, chemists refer to these items as 'materials'. For simplicity, the term 'materials' is used here to refer to all items rather than having to distinguish between materials and substances. This terminology does not fit squarely within the typical cognitive science framework where 'substances' might be used to indicate different categories and 'materials' used to refer to the stimuli and props used in an experiment. In addition, when materials are added to water there may or may not be a chemical reaction, depending on the makeup of the materials involved. Therefore, we use the term 'mixing' to capture the process for all items, regardless of the chemical outcome of the mixing process.

[^194]:    ${ }^{2}$ Antacid became 'meds', bath bomb and washing powder became 'stuff for the bath' and 'Stuff for the Wash' respectively. Peppercorn was shortened to 'pepper', and stock cube was 'stock'. 'lolly' was a short stick of candy.

[^195]:    ${ }^{1}$ These purported tempi only partially overlap with those commonly used in human music. The slowest recorded value would correspond to a Lento, while the majority of chimpanzee inter-beat intervals would translate to tempi such as Allegrissimo or Prestissimo.

[^196]:    ${ }^{2}$ The software processing part has four key tasks: data filtering, data transformation to extract meaningful parameters, logging specific variations of these parameters and play particular sounds in correspondence of these variations. Parameters and settings can be changed in order to vary the sensitivity of the device. The mapping between raw data, parameters and sound output can be altered depending on the experiment.

[^197]:    ${ }^{3}$ www.arduino.cc
    ${ }_{5}^{4}$ www.python.org
    5 www.nintendo.com
    ${ }^{6}$ cycling74.com/products/max/

[^198]:    ${ }^{1}$ We have also coded every gesture for its formal components (e.g., handshape, location, movement), but this coding does not bear on the current analysis, and so we do not discuss it further.

[^199]:    ${ }^{2}$ CC's used more frequently offer more opportunities for convergence, and so should arguably be weighted more heavily in calculating distance.

[^200]:    ${ }^{3}$ We are in the process of collecting data to verify convergence in NSL, though of course this data will be 20 years after the point of convergence we argue for.

[^201]:    ${ }^{1}$ The variable values used were: $\tau=150$ and $h=-3.25$. The noise term added/subtracted a random amount of activation averaging approximately 1.25 activation units to every $x$ value at each time step in the evolution. The resting level of an activation field was therefore about -2 activation units, equal to the resting level $h$ plus noise. The response input weight $(r)$ was 2.7 , and was the same for inputs to both the articulator and Voicing field of the required response. $d$ was 4.5 . The cross-field inhibition threshold $(\chi)$ was 0 . The amount of cross-field inhibition subtracted on each step from other fields when an articulator field was above $(\chi)$ was 0.75 . The values for the interaction term were the same in all four

[^202]:    ${ }^{1}$ To circumvent the discussion on lexical categories (noun/verb distinction) in Tagalog (e.g., Himmelmann, 2008), we will use the term "predicate" throughout this paper to refer to voice-marked words and the term "argument" to refer to heads of case-marked (non-oblique) phrases.

[^203]:    ${ }^{2}$ In English the syntactic subject is the PSA: it triggers agreement with the verb and it is the target of many syntactic operations (to the exclusion of the syntactic object). In Tagalog, however, we refrain from using the term "subject" for the ang-marked argument phrase in order to underscore the fact that the Tagalog PSA is different from the syntactic subject in an accusatively aligned language (such as English).
    ${ }^{3}$ In this paper, we adhere to the Leipzig Glossing Rules (http://www.eva.mpg.de/lingua/resources/glossing-rules.php); the following abbreviations are used: $\mathrm{AV}=$ actor voice, $\mathrm{NPSA}=$ nonprivileged syntactic argument, PSA = privileged syntactic argument, UV = undergoer voice. The first line of a glossed example shows the sentence in Tagalog with the relevant morphemes separated, the second line provides a word-by-word translation of the words and morphemes, the third line shows the word order of the sentence again in terms of semantic roles, the last line gives an English translation.
    ${ }^{4}$ For the sake of brevity, we waive glossing aspect-mood morphology because it is irrelevant for the morphosyntactic issues discussed in this paper.
    ${ }^{5}$ We use Foley and Van Valin's (1984) notions of "actor" and "undergoer" to refer to semantic relations between predicates and arguments.

[^204]:    ${ }^{6}$ More precisely, the predicate in (3) and (4) takes patient voice marking because the PSA denotes the patient of the action. Predicates may also take series of other voices. Following Himmelmann (2005), we subsume patient voice and these other voices under the label "undergoer voice" because they share a couple of semantic and formal characteristics in contrast to actor voice.

[^205]:    ${ }^{7}$ The Tobii Fixation Filter as implemented in Tobii Studio 2.3 was used to determine fixations.

[^206]:    ${ }^{8}$ By-item analyses showed analogous patterns; the full set of byparticipant and by-item results is available from the first author on request.

    Linear mixed models were run in R using the $\operatorname{lmer}()$ function of the lme 4 package. pMCMC values were calculated with the pvals.fnc() function of the languageR package. Figures were created using the ggplot2 package in R.

[^207]:    ${ }^{1}$ Some may also consider this a strong point of the methods, since the methods make explicit if too little information is available for a reliable decision. Yet, assuming that modelers often need to take a decision based on a set of available data, an equivocal comparison outcome is disadvantageous.

[^208]:    ${ }^{2}$ Given this procedure, BSSE and PED sometimes show both high performance and high percentages of situations where no model was recovered. Such a pattern indicates that the method in question only rarely recovered any model, but if it did, it was accurate

[^209]:    ${ }^{1}$ We excluded one participant for holding down a single key through the entirety of the second half of the experiment.

[^210]:    ${ }^{2}$ Individual responses were corrected in swapped trials to allow for consistent analysis.

[^211]:    ${ }^{3}$ We used 500 simulations to estimate the aggregate distribution of predictions over all individuals. We suspect that each individual used far fewer simulations, but aggregate across-subject behavior is consistent with many simulated paths over the full set of subjects (see Teglas et al. for a related discussion).
    ${ }^{4}$ Due to computational limitations, these parameters could not be easily fit to this data. However, because they were fit to aggregate behavior in the prior model, we assumed that they would capture aggregate performance in this similar task as well.
    ${ }_{5}$ This was an upper bound nearly equivalent to the longest trial.

[^212]:    ${ }^{6}$ Although the model only simulated once every tenth of a second, this parameter could take on continuous values. If it fell between two simulation times, the model decision would be a weighted average of each of those two decisions.

[^213]:    ${ }^{1}$ We use the term structure as a shorthand for combinatoriality and/or compositionality.

[^214]:    ${ }^{2} \mathrm{We}$ assume that the first meaning feature is expressed in the first form character. Without this constraint, it is impossible to specify holistic languages given this small form space: e.g. the holistic language in Table 1 is compositional if we allow the first meaning feature to map to the second form character. It would be possible to distinguish between holistic and compositional systems without this constraint given $|\Sigma|>2$, but to minimise runtimes we opted for $|\Sigma|=2$ and a constrained definition of compositionality.
    ${ }^{3}$ Inferring a distribution over languages, rather than a single language, allows learners to track changes in their partners' linguistic behaviour over time.

[^215]:    ${ }^{4}$ Training dyads on their own productions ensures that the configuration of the model is identical for dyads and chains. We ran an additional set of dyad simulations with a modified transmission regime, such that pairs are trained on the initial target language and go on to interact repeatedly but are not retrained on their productions from the last round of interaction (i.e. there is no training phase after generation 1): this produces results which are highly similar to dyads with transmission at every generation, showing that the retraining step does not introduce some additional conservative tendency.

[^216]:    ${ }^{5}$ In accordance with an ongoing set of human experiments based on these models, the context is stripped from these observations: in other words they contain only form-meaning pairs, with a context consisting solely of the topic.

[^217]:    ${ }^{1}$ Awareness of a 'double-negation elimination' logical rule (Rips, 1994) was proposed as important for reaching the normative answer for the problems used by Stupple et al. (2013).

[^218]:    ${ }^{2}$ The average reported by Frederick was $1.24, \mathrm{~N}=3428$.

[^219]:    ${ }^{3}$ A reviewer suggested that high WMC individuals might solve problems more rapidly and thus not show the anticipated correlation. However, when WMC is controlled for there is still no reliable correlation between CRT scores and reasoning task response times (Exp. 1, p=.64; Exp. 2, p=.22). However, this possibility warrants a fine-grained examination in future.
    ${ }^{4}$ It was also suggested - based on Kuhl (2000) - that some 'high logic' participants prematurely inhibit alternative construals of CRT questions to avoid ambiguity, and this explains some variance in CRT scores - again, this warrants further investigation.

[^220]:    ${ }^{1}$ Capital letters indicate stressed syllable.

[^221]:    ${ }^{2}$ The remaining $2 \%$ of three-syllabic words bears stress on the final syllable, and in this case stress it is graphically marked (e.g., coliBRİ, hummingbird).

[^222]:    ${ }^{1}$ We set $\alpha=\beta$, as Nilsson, Rieskamp, and Wagenmakers (2011) have shown that estimating separate exponents of the value function for gains and losses (i.e., $\alpha$ and $\beta$ ) can lead to unreliable estimates of $\lambda$ (see also Wakker, 2010). We set $\gamma^{+}=\gamma^{-}$, as the priority heuristic treats probabilities equally across gains and losses.

[^223]:    ${ }^{1}$ Infants also viewed preferential looking pre- and post-tests of the two faces side by side; however, as no differences in looking to the faces emerged, perhaps due to their novel 'out of context' presentation, this data is not reported.

[^224]:    ${ }^{2}$ One out of 24 infants did not search in any boxes during test trials, and thus was omitted from this analysis.
    ${ }^{3}$ Two out of 24 infants did not search in any boxes during generalization trials, and thus were omitted from this analysis.

[^225]:    ${ }^{1}$ Backward induction is a generalization of the minimax algorithm for extensive form games; the subgame-perfect equilibrium is a refinement of the Nash equilibrium, introduced to exclude equilibria with implausible threats (Osborne and Rubinstein, 1994).
    ${ }^{2}$ The term 'strategy' is used here more broadly than in game theory, where it is just a partial function from the set of histories (sequences of events) at each stage of the game to the set of actions of the player when it is supposed to make a move. We are interested in human reasoning strategies that can be used to solve the cognitive problems posed by the game.

[^226]:    ${ }^{3}$ From the computational complexity theory perspective, this corresponds to a hierarchy of computational problems of increasing complexity (see, e.g., Arora and Barak, 2009).

[^227]:    ${ }^{4}$ Thus, we did not use a generic implementation of forward reasoning with backtracking that would work for any possible game tree.

[^228]:    ${ }^{5} \mathrm{~A}$ similar phenomenon is well-recognized in natural language semantics. People often shift the meaning of sentence $\varphi$ from $\llbracket \varphi \rrbracket$ to a more restricted meaning $\llbracket \psi \rrbracket \subseteq \llbracket \varphi \rrbracket$. And again, one of the factors triggering such meaning-shifts might be related to the computational complexity of $\varphi$ (see, e.g., Szymanik, 2010).

[^229]:    ${ }^{1}$ The average fragment length necessary to predict the whole sequence correctly was $77.4 \%$ ( $\mathrm{SD}=0.7 \%$ ).

[^230]:    ${ }^{2}$ Candidates were determined by top-down reconstruction, i.e.

[^231]:    replayed as a temporal sequence in the aggregate SM signal layer.

[^232]:    1 Reduced df is due to empty cells for some participant/condition combinations in this analysis.

[^233]:    ${ }^{2}$ We fit separate models for the different phonological relatedness conditions because a combined model revealed a significant interaction between relatedness, time period and type of phonological relation. Using location-movement as a reference condition, the $95 \%$ CI of the change in relatedness $\times$ time period interaction coefficient was ( $11.8,103.8$ ) for handshape-movement $\left(p_{M C M C}=.040\right)$, and ( $-1.7,94.3$ ) for handshape-location ( $p_{M C M C}$ $=.064)$.

[^234]:    ${ }^{1}$ In fact, the selective modification model involves modification of both typicality 'votes' and dimension diagnosticities, the latter being required to explain reverse conjunction effects.

[^235]:    ${ }^{2}$ As Ran and Duimerang note, a problem with this is that the nature of outside knowledge is 'not clearly defined and is treated as a kind of black box in which the cognitive mechanisms that guide its function are unknown' (Ran and Duimerang, 2009, p. 57).

[^236]:    ${ }^{3}$ The statement that two sets intersect is taken to mean that they have a non-empty intersection.

[^237]:    ${ }^{4}$ Most of the subtleties of schema-update proposals are ignored, here. Conjunction and reverse-conjunction effects (Smith et al., 1988) are potentially explained, however, assuming typicality attributions are increased by conceptual specificity, and decreased by conceptual contradiction. This has the effect of making red apples more typical, and brown apples less typical of the red apple conception than either apples or red things taken separately.

[^238]:    ${ }^{1}$ To examine whether their difference in holistic processing was due to their difference in writing or reading abilities, we analyzed Holistic $A^{\prime}$ with their reading and writing performance measures put as covariates (ANCOVA). The difference in holistic processing between Writers and Limited Writers was still significant even when word naming accuracy, $F(1,38)=9.744, p<.01$, or word naming response time, $F(1,38)=7.916, p<.01$, was used as a covariate. However, when dictation accuracy was used as a covariate, the effect became insignificant, $F(1,38)=2.235$., n.s. These results suggest that the difference in holistic processing between Writers and Limited-writers was largely due to their writing performance, as reflected in the dictation task (i.e., the ability to recall and write down words). We also put all the reading variables simultaneously as covariates and the group difference of HP was still significant, $F(1,38)=5.365, p<.05$. Similar effects were obtained using RT.

[^239]:    1 Note that objectively, in each risky choice, $S$ is the better choice as soon as the sure loss of $S$ is lower than the expected value of $R$, while $R$ is the better choice as soon as the expected value of $R$ becomes lower than the sure loss of $S$.

[^240]:    2 This is an independent publication and has not been authorized, sponsored, or otherwise approved by Apple Inc.

[^241]:    3 A fluctuation is defined as each choice that is different from the previous choice.
    4 A switch-point is defined as the closest fluctuation to the middle choice for which; in case of an $I D$ sequence, the number of $R$ choices in between this fluctuation and the first $S$ choice in a continuous stretch of $S$ choices spanning the middle, is less than the number of $S$ in between. In case of a $D I$ sequence, it is the other way around.

[^242]:    ${ }^{1}$ The Bonferroni correction was calculated by dividing the alpha level (one-tailed) by the number of comparisons (i.e. six). Hence, adjusted alpha levels were 0.008 for significance values of $p<.05$ and 0.017 for marginal significance values of $p<.1$.

[^243]:    ${ }^{1}$ During individual baselines, only the first two criteria generated negative feedback.

[^244]:    ${ }^{2}$ For every pair and condition, half the trials were used to calculate ASYNC for one person and the remaining trials for calculating ASYNC for the other person (randomly distributed). This allowed us to perform all analyses with the full degrees of freedom.

[^245]:    ${ }^{1}$ Kousta et al (2009) modelled nonlinearity using restricted cubic splines; here we report a measure including linear and quadratic terms because they map directly onto the theoretical alternatives described in previous literature. We also tested models based on restricted cubic splines; they perform comparably to the polynomial models described above.

[^246]:    ${ }^{2}$ Some previous studies of this nature only report analyses on average response times for single words, averaged across multiple subjects but treated as point estimates (e.g. Estes \& Adelman, 2008a,b; Kousta et al., 2009; Larsen et al., 2008). Such approaches may overestimate the quality of any predictor as an essential component of variability has been discarded. In the present study we conduct analyses of trial-level data (nearly 50,000 observations) as well as item averages, allowing us to test whether emotional variables still play a role when individual variability is taken into account.

[^247]:    ${ }^{3}$ Non-significant predictors were kept in the baseline model in case their absence may have altered the effects of emotional valence in subsequent models.

[^248]:    ${ }^{4}$ We also tested 3-order polynomial measure of valence, but the cubic term was never a significant predictor in any of our analyses.

[^249]:    ${ }^{1} \mathrm{An}$ object displaying the property.
    ${ }^{2}$ An object that does not display the property

[^250]:    ${ }^{3}$ For the model formulation, we follow (Baayen, Davidson, \& Bates, 2008) in their discussion of mixed models for split plot designs. The analyses were carried out in R , using the lme4 package (Bates \& Sarkar, 2007).

[^251]:    ${ }^{4}$ Note that the model estimate for posAnegB is negative, contrary to what you would expect on the basis of Figure 3 due to addition of list as a factor.

[^252]:    ${ }^{5}$ The criterion for classifying was the literal appearance of the intended terms in the rule (and, obviously, in an unambiguous way).

[^253]:    ${ }^{6}$ More specifically, in a weak sampling scheme, hypotheses are not reweighted. In a strong sampling scheme hypotheses with a smaller extension are given more weight

[^254]:    ${ }^{1}$ In the interest of space, we do not report the full qualitative analyses of children's explanations in this paper. Instead, we provide a brief summary of these data Experiments 1-2.

[^255]:    ${ }^{1}$ The AUC is equivalent to a Wilcoxon test of ranks.

[^256]:    ${ }^{2}$ The discontinuities were interpolated by plotting linear segments between end points of the ROC curve.

[^257]:    ${ }^{1}$ Target categories for Experiment 1: bird, bee, toilet, scissors, dog, chainsaw, bowling ball, cat, car, keyboard, river, baby.
    ${ }_{2}$ Portions of Experiment 1 were presented at the Vision Sciences Society Meeting, May 2011.

[^258]:    ${ }^{3}$ All $p$-values were generated using Markov chain Monte Carlo sampling ( 10,000 simulations).

[^259]:    4 This increase in response validity compared to Exp. 1 allowed us to fully counterbalance all trial variables on matching trials while keeping the length of the experiment manageable.
    ${ }^{5}$ It is possible some of the natural sound cues were simply harder for participants to identify. To ensure unambiguous recognition of the remaining natural sounds used in Experiment 2, we enlisted 29 additional participants (mTurk) to report the source of each auditory cue in a free response task. Participants correctly identified the source of the natural sound $78 \%$ of the time. There was no relationship between cue identification (percentage correct by cue category) and response latencies on the sound cued trials (Pearson $r=-0.025$ ).

[^260]:    ${ }^{6}$ There is intriguing evidence that sometimes, speakers do modulate pronunciations of words in a graded fashion and that listeners are sensitive to these modulations (Nuckolls, 1999; Parise \& Pavani, 2011), e.g., speaking faster or slower to describe a faster or slower moving object (Shintel, Nusbaum, \& Okrent, 2006). Language can be easily stripped of these features however (e.g., in written form) while still being perfectly understandable.

[^261]:    ${ }^{1}$ Easy: reference bar maximum speed $=1 \mathrm{~m} / \mathrm{s}$, controllable bar $=$ $2 \mathrm{~m} / \mathrm{s}$. Difficult: reference bar $=2.5 \mathrm{~m} / \mathrm{s}$, controllable bar $=4 \mathrm{~m} / \mathrm{s}$.

[^262]:    ${ }^{2}$ Best model according to standard comparison with AIC and $\chi^{2}$.

[^263]:    ${ }^{1}$ We use the term processing in a generic sense to include both perception and cognition. To distinguish both, we use the terms perceptual and conceptual processing, respectively.

[^264]:    ${ }^{1}$ The formula in R was the following: scalest $\sim 1+$ dur * asp $+(1+$ dur $\mid$ subject $)+(1 \mid$ nes.item $)$ ).
    ${ }^{2}$ We calculated $p$ values on the basis of the $t$-values, using the following code in R :
    tvalues <- fixef(model) / sqrt(diag(vcov(model))) pvalues <- 2*(1-pnorm(abs(tvalues)))

[^265]:    ${ }^{1}$ We use the term "surprising outcome" in this paper to denote the target surprising event because traditional terminology is too theory-laden; for instance, "unexpected event" suggests one had expectations about the event when this is not always the case, and "abnormal event" presupposes some unspecified normative standard.

[^266]:    ${ }^{2}$ The only plausible explanation we could garner was leaving your belt at the security area in an airport.

[^267]:    ${ }^{3}$ Unreported in this paper for space reasons.

[^268]:    ${ }^{1}$ The actual threshold levels were chosen to result in accuracy levels close to $90 \%$ on the basis of a pilot study and were set at .95 for raw cosine similarity, .70 for sqrt cosine similarity, and .50 for rank order correlation. The same thresholds were used throughout the analyses reported in this paper. Pilot work furthermore suggested that the accuracy of the different measures was similarly affected by proportional threshold variations.

[^269]:    ${ }^{1}$ The term mimetic is derived from "mime," which means "to act out."

[^270]:    ${ }^{2}$ In neural net terms, CF amounts to the capacity to spontaneously and subconsciously vary the shape of the activation function, flat for divergent thought and spiky for analytical
    ${ }^{3}$ The approach can thus be contrasted with computer models of how individual learning affects biological evolution (e.g., Higgs, 2000; Hinton \& Nowlan, 1987; Hutchins \& Hazelhurst, 1991).

[^271]:    ${ }^{1}$ We also considered using partitioning clustering methods such as k-means or PAM. However these methods yielded an optimal number of two clusters for eyes data. This result was not realistic from a human observer analysis. We finally preferred to keep the four eyes clusters found by human analysis.

[^272]:    ${ }^{1}$ Analyses that included random slopes for the factor of interest (Partner), for both items and subjects, yielded the same pattern of results as the ones reported here.

[^273]:    ${ }^{2}$ Size refers to the Size of the first named picture. Pictures were either relatively big (e.g., apple in Figure 1) or small (e.g., blouse in Figure 1). Size did not interact with any other factors in the analyses reported in this paper.

[^274]:    ${ }^{1}$ Because of technical problems, two of the 32 items had to be eliminated from all computations.

[^275]:    ${ }^{2}$ In five exceptional cases people were also accepted, whose scores between the corresponding scale and the other scales differed around one scale unity.

[^276]:    ${ }^{1}$ We follow Rips's (2010) terminology.

[^277]:    ${ }^{2}$ Demos of the different experimental conditions can be accessed
    here: http://www.ucl.ac.uk/lagnado-lab/experiments/ demos/backtracking_demo.html

[^278]:    ${ }^{1}$ All the examples discussed can be found in Fauconnier, Turner 1998 as well as in Fauconnier, Turner 2002.

[^279]:    ${ }^{2}$ This point can be illustrated with a presentation at a conference. The quality of presentation is not directly connected with the quality of the idea. From time to time we encounter an attractive presentation representing a dull or controversial theory and vice versa.

[^280]:    ${ }^{3}$ A chain complex is one of the ways of complex thinking.

[^281]:    ${ }^{1}$ Both authors contributed equally to this work.

[^282]:    ${ }^{1}$ Note, however, that accent type (contrastive vs. unmarked) was not manipulated in this study.

[^283]:    ${ }^{2}$ The German translation equivalent of the sentences is felicitous even though also in the English example cannot occur in this syntactic position.

[^284]:    ${ }^{3}$ In our previous experiments, we tested the alternatives to the elements in object position. Yet Fraundorf et al. (2010) did not find any differences in the effects across syntactic position (subject vs. object).

[^285]:    ${ }^{1}$ Here and elsewhere we give English versions of Dutch originals.

[^286]:    ${ }^{2}$ "with" translates to the monosyllabic "met" and "without" to the bi-syllabic "zonder" in Dutch

[^287]:    ${ }^{1}$ We report $p$-values calculated using a MCMC simulation ( R code: pvals.fnc) for a mixed-effects model without random correlations. The R code is: lmer (distance $\sim$ conjunction + (1|participant) $+(0+$ conjunction | participant $)$, data $)$.

[^288]:    ${ }^{2}$ For instance, if the and + baseline schema was rated as a 4, and and + objects-contained was rated a 6 , the normalized rating for and + objects-contained was 6-4 $=2$.

[^289]:    ${ }^{1}$ Set theory has demonstrated that quantifiers can be derived from number, and vice versa (Van Heijenoort, 1977).
    ${ }^{2}$ Gamma-band oscillations have been advanced as a candidate for carrying binding information in object representations (Knowlton et al., 2012).

[^290]:    ${ }^{3}$ DORA binds representations of roles to fillers (e.g., objects) dynamically (i.e., the binding of a role to a filler is temporary so that the same role can be bound to different fillers in different contexts) via systematic asynchrony of firing (Doumas et al., 2008). In asynchronybased binding, roles are bound to their fillers by proximity of firing, with bound roles and fillers firing in direct sequence. For example, to bind searcher to cat, and sought to mouse, the units coding the searcher role fire, followed by the units coding cat. Next, the units coding the sought role fire followed by the units coding for mouse.

[^291]:    ${ }^{4}$ As well as non-overlaps, though not as quickly.

[^292]:    ${ }^{1}$ While familiar compounds like cheese knife have a conventional meaning, given a sufficiently rich context, they can take on an indefinite number of alternative meanings-such as a knife made of cheese, or the knife given as a trophy to the prize winning cheese maker. We are concerned here with the default meaning that first comes to mind in the absence of such a context.

[^293]:    Table 1: General categories of noun, and the semantic relations to which they are biased, together with examples of compounds used

[^294]:    (1) sort of long so they're usually about that long I think [0.17]

[^295]:    ${ }^{1}$ It would be more realistic to present only the NC pattern, and let the model discover an HC representation autonomously. This is the subject of a planned enhancement of the present model.

[^296]:    ${ }^{1}$ Contextual diversity is the log-transformed number of contexts in which a certain word occurs. This variable has been shown to be more informative than word frequency (Brysbaert \& New, 2009).

[^297]:    ${ }^{2}$ There were 304 trials in the experiment resulting in 303 pairs because of its continuous nature. Thus, the relatedness proportion is only $12.5 \%$ (i.e., $38 / 303$ ). Note that this number may be a little higher for some participants due to the random ordering of pairs (e.g., shower-chocolate followed by cake-vault).

[^298]:    ${ }^{1}$ The analysis of participants' error rates yielded a significant modality effect, with both types of recipients being more accurate in the bi-modal than in the uni-modal condition. No other effects were significant.

[^299]:    ${ }^{1}$ The previous model also represented informants' expressed confidence, overall knowledgeability, and tendency towards overconfidence. These are not included in the current work.

[^300]:    ${ }^{1}$ In this paper we maintain a distinction between 'models', which are analytically analysable descriptions of a system and 'simulations' which are individual numerical implementations of a model. While some results are derived analytically from models, others come from numerical simulation. Iterated learning experiments with human subjects can also be seen as simulations of the process of language evolution.

[^301]:    ${ }^{2}$ However, since the target of study is the cultural transmission process (how systems change by being repeatedly transmitted through a bottleneck) both computational and human simulations can arguably be seen as actual instantiations of this highly abstract generic phenomenon.

[^302]:    ${ }^{1}$ Using the dichotomous choice response as the dependent variable, logistic regression and likelihood ratio tests found similar results

[^303]:    ${ }^{1}$ For instance, applying the causal Markov condition to a causal chain $X \rightarrow Y \rightarrow Z$ entails that $Z$ is independent of $X$ given $Y$ (e.g., $P(z \mid y, x)=P(z \mid y, \neg x)$.

[^304]:    ${ }^{1}$ These are not the only models that have been proposed to characterize similarity, but they are the most widely used. Alternatives such as simplicity and transformation models (see Goldstone et al, 2010), are not discussed for the sake of brevity.

[^305]:    ${ }^{2}$ A popular classification (Walton, 1992) classifies slippery slope arguments into four types: Sorites, Causal, Precedent, and the Full. It is worth stressing that this classification does not aim to have psychological reality and it would not have any standing in the current proposal.

[^306]:    ${ }^{1}$ In fact, Mehrabian originally investigated just the contributions of the channels to a listener's attitude towards a message in emotional settings, but his figures have often been misinterpreted as accounting for any kind of communication, see e.g. http://www.speakingaboutpresenting.com/presentation-myths/mehrabian-nonverbal-communication-research/.

[^307]:    ${ }^{1}$ Dirac notation being used here, which was invented as a shorthand for quantum physics (Isham, 1995). It explicitly allows us to represent a vector $a$ using a ket, $|a\rangle$, with the transpose given as a $b r a\langle a|$. This allows for an immediate recognition of the inner product between two vectors $\langle a \mid b\rangle$ (a $b r a-k e t$ ) and of the outer product $|a\rangle\langle b|$. We use it here to make explicit the difference between our agent $A$ and her cognitive state $|A\rangle$, a distinction that will become important when the effects of social context are discussed. The vector space being used is a Hilbert space, which is a real or complex inner product space that is also a complete metric space with respect to the distance function induced by the inner product (Isham, 1995).

[^308]:    ${ }^{2}$ Available at http://www.per.marine.csiro.au/staff/ Fabio.Boschetti/quantumPeople.html .

[^309]:    ${ }^{1}$ E.g. Atance \& O'Neill (2001), Bischof-Koehler (2000), Moore \& Lemmon (2001), Povinelli (2001), Suddendorf \& Busby (2005), Levine et al. (2002), Addis, Wong \& Schacter (2008).
    ${ }^{2}$ E.g. Tulving, Hayman \& Macdonald (1991), Klein, Loftus \& Kihlstrom (2002).
    ${ }^{3}$ Hassabis et al. (2007).

[^310]:    ${ }^{4}$ Okuda et al. (2003), Szpunar, Watson \& McDermott (2007), Addis, Wong \& Schacter (2007), Buckner \& Carroll (2007).
    ${ }^{5}$ The core references are Wheeler, Stuss \& Tulving (1997) and Tulving (2002). An alternative, but similar account is proposed by Suddendorf \& Corballis (1997; 2007).

[^311]:    ${ }^{6}$ The proposal to define MTT wider than is commonly done is not revolutionary. A similar point of view is shared by D'Argembeau \& Van der Linden (2005), Hassabis (2007) and Buckner and Caroll (2007).

[^312]:    ${ }^{7}$ Cf. Tulving (2002), Wheeler, Stuss \& Tulving (1997), Suddendorf \& Corballis $(1997,2007)$.

[^313]:    ${ }^{8}$ The first conception of autonoetic consciousness is prevalent e.g. in D'Argembeau \& Van der Linden's (2004, 2006), Gardiner's (2001) and some of Tulving's work. Fink et al (1996), Gerrans and Tulving (2002:2) seem to opt rather for the second, whereas Wheeler, Stuss and Tulving (1997) seems to work strongly with the third conception of autonoetic consciousness.
    ${ }^{9}$ Cf. also Nagel (1975).

[^314]:    ${ }^{10}$ This observation seems to be well in line with Suddendorf \& Corballis' account of MTT: Drawing on a survey of episodic memory by Friedman (1993), they highlight that neither chronology nor a "sense of 'pastness'" are basic properties of memory traces. Nevertheless, and in contrast to our account, Suddendorf \& Corballis are convinced that experiences of episodic states always have such phenomenal properties concerning time.
    ${ }^{11}$ Gerrans \& Sander (MS) propose a radically different account in which MTT is conceived as a non-conscious, implicit phenomenon not involving explicit (overt) representation - and hence does not require (narrative) self-awareness.

[^315]:    ${ }^{12}$ The first two (and hence more basic) levels deal roughly with the ordering or representation of information and executive functions respectively.
    ${ }^{13}$ Furthermore, Suddendorf \& Corballis themselves seem to be skeptical about the requirement of linguistic abilities for MTT, so it is surprising that they opt for Mitchell's third level, rather than the second.

[^316]:    ${ }^{14}$ Dennett (1991), one of the most prominent proponents of the narrative self, is pessimistic about the inquiry into a self which is more than just an abstract, theoretical postulate in our models of the mind.

[^317]:    ${ }^{15}$ Macphail (2000) contents that MTT is dependent on language; Suddendorf \& Corballis (1997) disagree. Clayton et al. 2000 hold that it is impossible to investigate MTT in non-human animals, since language is the only agreed-upon medium to report it. Suddendory \& Busby $(2003,2005)$ challenge this opinion; they hold that MTT is also expressed in action through „pantominiming past events, practice rehearsal of anticipated events and in acts that only make sense in the light of anticipated future events" (2005: 114).

[^318]:    ${ }^{1}$ This is frequently done for short eye-tracking regions in visual world studies because 200 ms is known as the amount of time needed to program an eye-movement.

[^319]:    ${ }^{1}$ More specifically, participants answered additional questions about their internet use and their experience with sexual harassment on the internet. These questions were part of a larger project; the results will not be reported since they are irrelevant for our hypotheses.

[^320]:    ${ }^{1}$ Each of the first 24 problems on the SPM has 6 answer choices, and each of the latter 36 problems has 8 answer choices.

[^321]:    ${ }^{1}$ We acknowledge that using lying in one's taxes as the deception domain may have resulted in effects that we were unable to control. The reason we saw much less risk taking in deception scenarios may be that some participants did not base their decisions on the outcomes and associated probabilities, or moral considerations of deceiving in general, but were driven by a specific aversion to lying in their taxes or to the government.
    ${ }^{2}$ We also designed two additional questions with a medium probability of $55 \%$ and outcome of (-)\$1000, but they were excluded from the analysis for the purpose of this paper, since the focus here is the four-fold pattern of risk attitudes.

[^322]:    ${ }^{3}$ For each participant we calculated a risk taking score $(\in[0,16])$ as the number of times they chose the risky option in 16 questions.

[^323]:    ${ }^{1}$ We speculated that there may not be sufficient power to a detect a significant relationship in the present analysis. In Experiment 2, we report a follow-up analysis that pools the data from Experiment 1 and 2. This result is convergent with the present conclusion.

[^324]:    ${ }^{2}$ We did conduct a parallel set of analyzes to those reported using fixation number, saccadic amplitude, blinks, and saccadic duration. There was no effect of block or the critical block by break interaction on saccadic amplitude or saccadic duration. However, we did find an effect of block on fixation number such that fixation number decreased over the course of the task in both Experiment 1 and in both break conditions in Experiment 2. In Experiment 2, we did not find an interaction between Break and Block. Taken together, these data suggest that decreases in fixation frequency over time are not indexing the negative effect of fatigue, but rather may be indexing the positive effect of practice

[^325]:    ${ }^{1}$ Although audio was recorded, it was not analyzed in these experiments. Only visual information was examined.

[^326]:    ${ }^{2}$ Continuous was defined as a clip with no sections longer than 0.25 s where range of motion magnitude did not fall within motion criteria. This 0.25 s buffer was used to accommodate naturally oscillating motion magnitudes.

[^327]:    ${ }^{3}$ Mixed pairs were eliminated due to factors related to past relationship studies showing that they are not perceived in the same manner as same-gender dyads.

[^328]:    ${ }^{1}$ To see this, suppose that the adjacency relation has two positions Next and Nixt. Now let object $a$ occupy the position Next and object $b$ the position Nixt. Then switching the positions of the objects would yield another complex for the same state.

[^329]:    ${ }^{2}$ Views based on thematic roles are also objectionable; they cannot handle certain cyclic relations. (cf. Fine (2000, p. 17, note 10)).

[^330]:    ${ }^{3}$ An ordered pair $\langle a, b\rangle$, for example, may be coded in set theory as the set $\{\{a\},\{a, b\}\}$.

[^331]:    ${ }^{1}$ Although the task drew attention to meaning, it did not draw attention to the form-meaning connection which was the target of learning.

[^332]:    ${ }^{2}$ Since the Chinese language has no article system, Chinese participants were simply told that these were words that were used before the noun. The Chinese participants were however familiar with the concept of articles from their L2.

[^333]:    ${ }^{3}$ In both cases exceptions exist．For instance，zoeng1 is also associated with furniture items．Such exceptional items were not included in the experiment．
