Van Kleef and colleagues have argued that if partners in a social interaction lack information about the other's needs, desires, and goals, then emotional displays help people make sense of situations (Van Kleef, De Dreu, \& Manstead, 2010). It follows then that people will tend to look more at emotionally significant facial features when there is uncertainty in social interactions. Therefore, with respect to the eye tracking measure, the contextual emotion hypothesis predicts that individuals will fixate more on diagnostic facial features when the confederate's negotiation strategy is incongruent with his facial expression.

An alternative hypothesis suggests that emotion perception is driven purely by the structural features of a face alone. This hypothesis predicts that individuals will show heightened threat responses to angry faces compared to happy faces-regardless of the confederate's strategy with which they are coupled-and there should be more eye fixations on threatening faces (Mogg, Garner, \& Bradley, 2007; Tracy \& Robins, 2008).

## Method

## Participants, Design, Materials, Apparatus

Eighty participants were recruited from university undergraduate psychology courses. Participants played a multi-issue bargaining task (Van Kleef, De Dreu, \& Manstead, 2004). The task involves a scenario in which
participants act as mobile phone sellers and have to negotiate over three issues: a price, length of service contract, and warranty duration with the virtual human (see Figure 2, Payoffs). Each issue had a level that denoted its worth to the participants. Given that the participant was the seller, she would get the most points by selling the mobile phones for the highest price ( $\$ 150$, level 9 ) in order to gain 400 points; the shortest warranty period ( 1 month, level 9) corresponding to 120 points; and the shortest service contract (1 month, level 9) corresponding to 240 points. Participant's maximum score was therefore 760 points.

The confederate was an intelligent agent that displayed emotional facial expressions to convey anger or happiness. The study employed a 2 X 2 fully-crossed factorial betweensubjects experimental design. The two factors were the virtual human's emotional facial expression (happy or angry) crossed with his negotiation strategy (tough or soft). When the virtual human used a tough strategy (competitive), he made small concessions from his initial offer compared to the larger concessions he made using a soft (i.e., cooperative) strategy.

Both the soft and tough negotiating confederates made the initial offer to the participant, which was level 1 of price ( $\$ 110$, zero points to the participant), level 2 of warranty period ( 8 months, 15 points to the participant), and level 1 of length of service contract ( 9 months, zero points to the participant). From this 1-2-1 initial offer by the confederate, the soft and tough agent followed different counter offer policies. In both cases, the confederate's offer was not contingent on the participant's counter offers (see Table 1).

Table 1: Progression of Soft and Tough Negotiation offers through the six round task

| Round | Soft | Tough |
| :--- | :--- | :--- |
| 2 | $1-2-3$ | $1-2-2$ |
| 3 | $1-4-3$ | $1-3-2$ |
| 4 | $3-4-3$ | $2-3-2$ |
| 5 | $3-4-5$ | $2-3-3$ |
| 6 | $5-4-5$ | $3-3-3$ |

While participants interacted with the virtual character during the negotiation game, various measures related to their cardiovascular states were recorded. Electrocardiographic (EKG) and impedance cardiographic (ZKG) signals were recorded continuously with a Biopac MP150 system, using a standard lead II electrode configuration (for EKG) and a tetrapolar aluminum-mylar tape electrode system (for ZKG); blood pressure was continuously recorded using an automated blood pressure device. The automated blood pressure recorded readings via a cuff placed around the participants' wrists and fingers of their non-dominant left hand. The EKG and ZKG signals were scored using an interactive software program that produces ensemble-averaged values for heart rate (HR), pre-
ejection period (PEP). Additionally, cardiac output (CO) was calculated from stroke volume (SV) recordings via impedance and heart rate; and total peripheral resistance (TPR) was calculated using impedance and blood pressure readings as a measure of vascular activity.

An SMI RED eye tracker was used with 60 Hz sampling rate and a 17 " flat screen monitor. The eye tracking camera was positioned to the monitor and as such was unobtrusive to the participants during the task.

## Procedure

Participants completed a health screening questionnaire and informed consent was obtained prior to their participation. No one refused to participate. Female research assistants proceeded to apply the necessary sensors for physiological recording including impedance tape electrodes, EKG spot electrodes and blood pressure sensors. A five point calibration was used to ensure proper eye tracking measurement.

Next, the participant sat comfortably at rest for five minutes prior to receiving any task instructions. Finally, the participants were instructed to play 1 practice round to learn the user interface, during which the virtual human was not visible. Next, the criterion negotiation game commenced for 6 rounds. Afterwards, participants completed surveys that recorded their subjective and open-ended responses to the virtual human.

## Results

## Negotiation Task

Performance on the negotiation task was calculated based on how much the participants conceded to the virtual confederate over the six rounds. Each issue in the negotiation was summed at each round to compute a demand score. The best outcome for the participant would have been a demand score of 760 points. The final performance measure was the difference between the first and last round demand scores. If participants conceded more over the six rounds, this difference score would be higher. A univariate ANOVA with two factors (1. emotion: happy or angry; 2. strategy: tough or soft) showed no main effects or interactions (all $p$ 's $>0.5$, see Table 2 for means).

Table 2: Mean demand score difference from the first and last round (SD). A score of zero indicates no concession.

|  | Angry | Happy |  |
| :--- | :--- | :--- | :--- |
| Soft | $150.2(223)$ | $129.4(217)$ | $140.6(217)$ |
| Tough | $113.3(155)$ | $142.5(193)$ | $127.6(173)$ |
|  | $131.8(190)$ | $136.3(202)$ | 133 |

## Cardiovascular Physiological Indexes

We predicted that individuals interacting with the virtual confederate would exhibit task engagement, and that those interacting with an incongruent virtual confederate (e.g., soft strategy but angry face) would experience threat.

## Task Engagement

According to the Biopsychosocial Model, task engagement is indexed by increases from baseline in sympathetically driven cardiovascular responses. As is common in this research, we calculated changes from baseline in preejection period (PEP), a purely sympathetically driven cardiovascular measure (Tomaka, Blascovich, Kelsey, \& Leitten, 1993).

We established average baseline values of HR and PEP by averaging baseline minutes 4 and 5 for each of these measures. PEP decreased during the task ( $M=133.3 \mathrm{~ms}, S D$ $=15.76$ ) compared to the baseline $(M=135.8 \mathrm{~ms}, S D=$ 16.06), as predicted, two-tailed paired samples $t$-test, $t(78)=$ $3.31, p=.001$.

## Challenge and Threat

Total Peripheral Resistance (TPR) scores were computed by subtracting TPR during baseline from TPR during the negotiation task. A univariate ANOVA did not show a main effect of either strategy or emotion (both $F$ 's $<1$ ). There was also no interaction, $F(1,62)=1.47, p=.23$.

Cardiac output (CO) reactivity scores were computed by subtracting CO during baseline from CO during the negotiation task. A univariate ANOVA, controlling for baseline CO, with two factors showed no main effects of emotion or strategy ( $F$ 's $<1$ ). There was an interaction between emotion and strategy, $F(1,76)=8.34, p=0.005$, $\eta_{p}{ }^{2}=.098$.

Using a Bonferroni adjustment, simple effects analyses revealed that participants in the soft strategy condition significantly differed from each other, $F(1,77)=5.34, p=$ $0.024, \eta_{p}{ }^{2}=.065$. Participants who interacted with the virtual confederate that displayed an angry facial expression while using a soft (more conceding) strategy had further reduced cardiac output compared to those participants in the soft-happy condition (see Figure 3).

## Eye Tracking

BeGaze eye tracking analysis (SMI) software was used to construct areas of interest (AOI) on different components of the task interface as well as the virtual confederate's facial regions.

Figure 3: Cardiac output reactivity scores in the two virtual human strategy and facial expression conditions.

A multivariate ANOVA was conducted with the eight AOI (see Figure 2). The MANOVA showed a significant difference among the different AOI, $F(7,504)=77.06, p<$ $0.001, \eta_{p}{ }^{2}=.517$. As Figure 4 shows, participants fixated on the offer section of the game interface the longest percentage of time throughout the task. However, the results suggest people also spend considerable time looking at the face. In fact, the percentage of time fixated on the total face-aggregate of eyes, mouth, and remainder of the face-did not differ from the time fixated on the offer, $t(72)$ $=.54, p=.6$.

## Mouth AOI

The main differentiating facial feature for the angry and happy expressions was the mouth area. Past work indicates

Figure 4: Percentage of time during the whole negotiation fixated on different areas of interest.
that individuals from samples similar to ours tend to fixate more on the mouth region (Blais, Jack, Scheepers, Fiset, \& Caldara, 2008; Jack, Blais, Scheepers, Schyns, \& Caldara, 2009). Thus, we conducted an ANOVA with the two factors

Figure 5: Percentage of time on the mouth as a function of the confederate's emotion and strategy.
of strategy and emotion on the percentage of time fixated on the mouth AOI.

There was no main effect of strategy or emotion, $F$ 's $<1$. There was a marginal interaction of strategy and emotion, $F(1,68)=3.281, p=.074, \eta_{p}{ }^{2}=.046$. As Figure 5 shows, participants in the soft-angry condition tended to fixate the mouth for a longer time compared to participants in the softhappy condition.

## Discussion

Virtual human confederates in a negotiation game caused a threat motivational response (reduced cardiac output) when their facial expressions were not congruent with their strategies. Specifically, participants had lower cardiac output when the virtual human negotiated using a soft strategy but displayed an angry facial expression. Additionally, despite not reaching significance, similar effects occurred when participants engaged with a tough agent that showed happy facial expressions. This incongruence could cause more uncertainty, which is related to increases in task demands (Tomaka et al., 1993).

Eye tracking results provide converging evidence. Participants in the incongruent strategy and emotion condition (e.g., soft-angry) tended to fixate on the most diagnostic facial region longer compared to participants in the congruent condition (e.g., soft-happy). This result suggests that participants tended to fixate longer at the mouth in order to try to gain potential cues to reconcile their uncertainty from the conflicting strategy and emotion coupling.

These results are compatible with the suggestion that people look at others' facial expressions in an attempt to reduce inherent uncertainty that occurs in social decision making situations with counterparts that might have different priorities and objectives (Van Kleef et al., 2010). Our results show specific psychophysiological evidence for this process, especially when there is an incongruence between the counterpart's strategy and the facial displays.

These results are also in line with other research which suggests that context matters when people decode others' emotions (Barrett et al., 2011; Lanzetta \& Englis, 1989; Singer et al., 2006; Szczurek, Monin, \& Gross, 2012). An
identical angry facial expression gave rise to different motivational states depending on the strategic context in which it was displayed during the negotiation task.

Finally, the results can have practical implications for the design of human-computer interaction systems. This work suggests that cardiovascular measures are sensitive at detecting incongruence and uncertainty in human users and suggests that affecting the context in which emotions are shown (for instance, in virtual humans) can lead to concomitant changes to the user's challenge/threat motivational state.

## Acknowledgments

Peter Khooshabeh performed this research while on appointment as a U.S. Army Research Lab Postdoctoral Fellow. We thank Kyle O’Donnell for help with analysis.

# A model of population dynamics applied to phonetic change 

James Kirby (j.kirby@ed.ac.uk)<br>School of Philosophy, Psychology, and Language Sciences, University of Edinburgh, Edinburgh EH8 9AD UK<br>Morgan Sonderegger (morgan.sonderegger@mcgill.ca)<br>Department of Linguistics, McGill University, Montreal, Quebec H3A 1A7 Canada

#### Abstract

We consider the problem of language evolution in a population setting, focusing on the case of continuous parameter learning. While theories of phonetic change tend to emphasize the types of transmission errors that could give rise to a shift in pronunciation norms, it is challenging to develop a model that allows for both stability as well as change. We model the acquisition of vowel-to-vowel coarticulation in both single- and multiple-teacher settings, considering progressively more restrictive prior learning biases. We demonstrate that both stability and change are possible at the population level, but only under fairly strong assumptions about the nature of learning and production biases.

Keywords: Language evolution; sound change; computational modeling; phonetics; coarticulation

## Introduction

The problem of language evolution and change has received increased attention from a computational perspective in recent years (e.g. Niyogi \& Berwick, 1995; Wedel, 2006; Kirby, Dowman, \& Griffiths, 2007). Most of this work has focused on modeling either lexical or syntactic change, where the task is usually cast as deciding between competing discrete representation, e.g. different grammars (Baker, 2008). A similar approach is often taken in models of the evolution of sound patterns, where the learning problem is cast as one of deciding between discrete pronunciation variants (e.g. Niyogi, 2006).

However, learning a sound pattern of a language also consists of learning continuous phonetic cue distributions that describe how the sounds of that language are realized. Understanding the dynamics of these distributions is important for understanding sound change, because the seeds of categorylevel change are often claimed to be based in continuous phonetic variation (Ohala, 1993). In this paper, we address the evolution of sound patterns by considering the acquisition of continuous parameter distributions in a population setting. While we consider the particular example of a phonetic parameter, the basic results are applicable to the learning of continuous parameters more generally.

## Stability and change in phonetic realization

In all languages, when a sound is produced in a connected stream of speech, its phonetic realization is influenced by the preceding and/or following context. This contextual variability, termed coarticulation, has often been argued to underlie a wide variety of sound changes in the world's languages. One example is a historical process known as primary umlaut, attested in Old High German beginning c. 750 AD, in which short low /a/ was fronted and raised to /e/ when a high front vowel or glide occurred in the following syllable,
e.g. *[gasti:] >/gesti/ 'guests' (modern German Gäste). It has been proposed that the roots of umlaut may be traced to vowel-to-vowel coarticulation (Iverson \& Salmons, 2003); however, vowel-to-vowel coarticulation did not invariably result in umlaut. For example, even while primary umlaut was spreading throughout West Germanic, it is clear that it did not affect Gothic (Campbell, 1998:75). The umlaut example illustrates a more general point: the mere presence of a potential trigger does not imply that phonetic change is inevitable. Thus, any empirically adequate model of how the sound pattern of a language evolves must account for instances of stability as well as change (Weinreich, Labov, \& Herzog, 1968).

## Learning bias in phonetic change

An important body of research on phonetic change has focused on establishing the preconditions for change to occur in a single speaker-hearer (Ohala, 1993). Similarly, computational models of phonetic change have mostly considered individuals, focusing on how biases in learning or in speech production/perception impact whether or not change occurs (Pierrehumbert, 2001). However, even if a change were to obtain at the level of a single speaker, its spread in the speech community is far from inevitable: social and cultural factors may conspire to inhibit or enhance a change in the population at large. In addition, the dynamics of linguistic populations are complex: how assumptions about individual speakers play out in population dynamics can be surprisingly nontrivial and dependent on assumptions about population structure (Niyogi, 2006). For both reasons, the general plausibility of accounts of contextually-driven phonetic change, and what role channel and learning biases play, cannot be properly assessed until their dynamics at the population level are better understood.

This paper explores the effects of different assumptions about bias and population structure on the evolution of phonetic categories in a population, as applied to a simplified version of primary umlaut in Germanic. In particular, we consider six models of learning how /a/ is pronounced before a high vowel. Our aim is a model which satifies three goals:

1. Stability of limited coarticulation in the population, as in pre-Old High German
2. Stability of full coarticulation in the population (e.g. umlaut), as in Old High German
3. Change from stable limited coarticulation to stable full coarticulation.

Figure 1: (a) Parallel diffusion chains (classic iterated learning). (b) Single-teacher scenario. (c) Multiple-teacher scenario.

## Properties of populations

Fig. 1 illustrates three types of population structure. Fig. 1a shows a classic iterated learning (IL) scenario, also known as a diffusion chain (Smith, Kirby, \& Brighton, 2003). In IL, each learner of generation $t+1$ receives input from a randomly chosen member of generation $t$. Thus, every member of a generation functions both as learner and as teacher. Fig. 1b illustrates single-teacher learning with replacement. This scenario differs crucially from classic IL in that while the input for a learner comes from exactly one teacher, some teachers may provide input to more than one learner, while others may not provide any. Finally, Fig. 1c illustrates multipleteacher learning with replacement. Here, input may come from more than one teacher, although some teachers may not provide data to any leaners in the following generation.

The IL scenario has frequently been assumed in work on language evolution and change (e.g. Smith et al., 2003; Kirby et al., 2007). ${ }^{1}$ While these models have well-understood dynamics and may be appropriate in some situations, in general different dynamics emerge in population learning scenarios (1b-c) (Dediu, 2009; Smith, 2009). In this work we focus on scenarios (1b-c), aiming to determine (1) what type of biases are necessary for stability and change to obtain in a population of learners, and (2) if and how such biases interact with differences in the number of teachers. We begin with a naive learning model (no prior) and then turn to consider progressively more restrictive priors.

## Framework

We assume that (1) speech sounds have been organized into discrete segments; (2) the phonetic realisation of segments is subject to coarticulation; and (3) the learner has access to the complete segmental inventory. We consider here a simple language with the lexicon $\Sigma=\left\{\mathrm{V}_{1}, \mathrm{~V}_{2}, \mathrm{~V}_{12}\right\}$, where $\mathrm{V}_{12}$ represents $\mathrm{V}_{1}$ in the potentially coarticulation-inducing context of $V_{2}$. For the primary umlaut example, $V_{1}$ and $V_{2}$ can be thought of as the vowels $/ \mathrm{a} /$ and $/ \mathrm{i} /$ in isolation, and $\mathrm{V}_{12}$ as the vowel /a/ in a context where it is coarticulated towards /i/.

For simplicity, vowel tokens are represented by their first formant (F1) value, an acoustic measure of vowel height. We assume that the F 1 distributions of $\mathrm{V}_{1}$ and $\mathrm{V}_{2}$ are known to all learners, are the same for all learners, and do not change over time. The distribution of $\mathrm{V}_{12}$ differs from that of $\mathrm{V}_{1}$ only by an offset to the mean $p$, indicating how much $\mathrm{V}_{1}$ is affected by coarticulation (i.e. raised) in the $\mathrm{V}_{2}$ context. In all

[^117]derivations below, we assume in particular that for a learner with parameter $p$, the three categories $\mathrm{V}_{1}, \mathrm{~V}_{2}$, and $\mathrm{V}_{12}$ follow normal distributions in a single dimension (F1):
\[

$$
\begin{equation*}
\mathrm{V}_{1} \sim N\left(\mu_{a}, \sigma_{a}^{2}\right), \mathrm{V}_{2} \sim N\left(\mu_{i}, \sigma_{i}^{2}\right), \mathrm{V}_{12} \sim N\left(\mu_{a}-p, \sigma_{a}^{2}\right) \tag{1}
\end{equation*}
$$

\]

We assume that learners are divided into discrete generations $\mathcal{G}_{t}$ of size $M$. Each learner in generation $\mathcal{G}_{t}$ receives $n_{\mathrm{V}_{12}}$ examples of $\mathrm{V}_{12}$ from the members of generation $\mathcal{G}_{t-1}$. The learner's task is then simply to infer $p$. The state of the population $\mathcal{G}_{t}$ can thus be characterized by the distribution $p \sim \pi_{t}(p)$. For simplicity, we assume that $M$ is infinite, so the evolution of the population is not a stochastic process.

In $\mathcal{G}_{t+1}$, each learner is presented with $n$ examples of $\mathrm{V}_{12}$ drawn from a sequence of teachers in $\mathcal{G}_{t}$ chosen by some sampling procedure $\mathcal{S} .{ }^{2}$ Given these examples, the learner applies some learning algorithm $\mathcal{A}$. Assuming $\mathcal{S}$ and $\mathcal{A}$ are the same for all agents in $\mathcal{G}_{t+1}$, this implies the following evolution equation for $\pi_{t}$ :

$$
\begin{equation*}
\left(\pi_{t+1}\right)=f_{S, \mathcal{A}}\left(\pi_{t} \mid \text { constants }\right) \tag{2}
\end{equation*}
$$

For a given $\mathcal{A}$ and $\mathcal{S}$, our goal is to determine $f$, and characterize its behavior, in particular which (if any) of our modeling goals it satisfies.

## Models

This section describes the evolutionary dynamics of a population of learners who estimate the degree of coarticulation from training data based on the assumption that these examples are independently and identically (i.i.d.) generated by a single source with a fixed $p$. We consider learners with three types of prior bias in estimating $p$, corresponding to three choices of $\mathcal{A}$ : no prior $\left(\mathcal{A}_{\text {naive }}\right)$, a simple prior $\left(\mathcal{A}_{\text {simple }}\right)$, and a more complex prior ( $\left.\mathcal{A}_{\text {complex }}\right)$. These learners are embedded in two of the types of populations shown in Fig. 1, corresponding to two choices of $\mathcal{S}$ : (1b), in which a learner's input is provided by a single teacher ( $\mathcal{S}_{\text {single }}$ ), and (1c), in which her input may be drawn from multiple teachers ( $\mathcal{S}_{\text {multiple }}$ ).

## $\mathcal{A}_{\text {naive }}$ : Naive learning models

We first consider maximum-likelihood (ML) learners who are "naive" in the sense of having no prior over estimates of $p .{ }^{3}$

[^118]Model 1.1: Naive learning, single teacher First we consider a situation in which a learner in generation $\mathcal{G}_{t+1}$ receives examples from a single member of generation $\mathcal{G}_{t}$. Each learner is associated with a value $p_{\text {parent }}$ (one draw from the $\pi_{t}$ distribution, representing the single teacher's degree of coarticulation), which is used to generate $n$ training examples $\vec{y}=\left(y_{1}, \ldots, y_{n}\right)$. Let $\bar{y}$ be the mean of this sample. Each example is normally distributed, following (1): $P\left(y_{i}\right)=N\left(\mu_{a}-p_{\text {parent }}, \sigma_{a}^{2}\right)$. The sample's mean is also normally distributed, with the same mean and reduced variance:

$$
\begin{equation*}
P\left(\left(y_{1}+\cdots+y_{n}\right) / n \mid p_{\text {parent }}\right)=N\left(\mu_{a}-p_{\text {parent }}, \sigma_{a}^{2} / n\right) \tag{3}
\end{equation*}
$$

Given $\bar{y}$, the learner's maximum-likelihood estimate of $p$ is $\hat{p}=\mu_{a}-\bar{y}$. Thus, using Eq. 3, the distribution over values of $\hat{p}$ the learner could acquire given $p_{\text {parent }}$ is:

$$
\begin{equation*}
P\left(\hat{p} \mid p_{\text {parent }}\right)=N\left(p_{\text {parent }}, \sigma_{a}^{2} / n\right) \tag{4}
\end{equation*}
$$

We are interested in the evolution of the distribution $\pi_{t}$ : that is, the marginal distribution of $\hat{p}$ as a function of the distribution of $p_{\text {parent }}$. Abbreviating $p_{\text {parent }}$ as $p$, this is:

$$
\begin{align*}
\pi_{t+1}(\hat{p}) & =\int \underbrace{P((\hat{p} \mid p)}_{\text {Eq } \cdot 4} \pi_{t}(p) d p \\
& =\int \pi_{t}(p) \cdot N_{\hat{p}}\left(p, \sigma_{a}^{2} / n\right) d p \tag{5}
\end{align*}
$$

To get a sense of the evolution of $\pi_{t}$, we can compute how its mean and variance change over time. Let $p$ be the random variable distributed according to $\pi_{t}$, and $\hat{p}$ the same for $\pi_{t+1}$. The expected value of $\hat{p}$ is then:

$$
\begin{align*}
E[\hat{p}]=\int \pi_{t+1}(\hat{p}) \hat{p} d \hat{p} & =\int\left[\int \pi_{t}(p) \cdot N_{\hat{p}}\left(p, \sigma_{a}^{2} / n\right) d p\right] \hat{p} d \hat{p} \\
& =\int \pi_{t}(p) \underbrace{\left[\int N_{\hat{p}}\left(p, \sigma_{a}^{2} / n\right) \hat{p} d \hat{p}\right]}_{=E[\hat{p} \mid p]=p} d p \\
& =\int \pi_{t}(p) p d p=E[p] \tag{6}
\end{align*}
$$

By a similar derivation for $E\left[\hat{p}^{2}\right]$, the variance of $\hat{p}$ can be shown to be:

$$
\begin{align*}
\operatorname{Var}(\hat{p}) & =E\left[(\hat{p}-E[\hat{p}])^{2}\right]=E\left[\hat{p}^{2}\right]-E[\hat{p}]^{2} \\
& =\sigma_{a}^{2} / n+\operatorname{Var}(p) \tag{7}
\end{align*}
$$

Thus, the distribution of $p$ in the $n+1^{\text {th }}$ generation has the same mean as in the $n^{\text {th }}$ generation, but larger variance; i.e., the distribution becomes more diffuse with each generation. ${ }^{4}$

[^119]Model 1.2: Naive learning, multiple teachers We now consider the case where a learner in generation $\mathcal{G}_{t+1}$ receives each training example from a randomly-chosen teacher in generation $\mathcal{G}_{t+1}$. This is equivalent to drawing $n$ values of $p$ from $\pi_{t}, \vec{p}=\left(p_{1}, \ldots, p_{n}\right)$, and for each $p_{i}$ generating one training example $y_{i}$ :

$$
\begin{equation*}
P\left(y_{i} \mid p_{i}\right)=N\left(\mu_{a}-p_{i}, \sigma_{a}\right) \quad i=1, \ldots, n \tag{8}
\end{equation*}
$$

As in the single-teacher case, we assume that the learner chooses the ML estimate for $p, \hat{p}=\mu_{a}-\bar{y}$. Using (8) and the fact that the $y_{i}$ are independent and normally distributed:

$$
\begin{align*}
P(\bar{y} \mid \vec{p}) & =N\left(\mu_{a}-\left(p_{1}+\cdots+p_{n}\right) / n, \sigma_{a}^{2} / n\right) \\
\Longrightarrow P(\hat{p} \mid \vec{p}) & =N\left(\bar{p}, \sigma_{a}^{2} / n\right) \tag{9}
\end{align*}
$$

where $\bar{p}=\left(p_{1}+\cdots+p_{n}\right) / n$. Thus, the learner's estimate $\hat{p}$ is the mean of the $p$ values which generated the training data, plus some noise.

To obtain $\pi_{t+1}(\hat{p})$, the marginal distribution of $\hat{p}$, we integrate out $p_{1}, \ldots, p_{n}$ from (9):

$$
\begin{equation*}
\pi_{t+1}(\hat{p})=\int N_{\hat{p}}\left(\bar{p}, \sigma_{a}^{2} / n\right) \prod_{i=1}^{n} \pi_{t}\left(p_{i}\right) d p_{i} \tag{10}
\end{equation*}
$$

As in the single-teacher case, we can get a sense of how the distribution of $p$ evolves by computing the mean and variance of $\pi_{t+1}$. Let $p_{t}$ be the random variable with distribution $\pi_{t}$. The expected value and variance of $\hat{p}$ can be shown to be:

$$
\begin{equation*}
E(\hat{p})=E\left(p_{t}\right), \quad \operatorname{Var}(\hat{p})=\sigma_{a}^{2} / n+\operatorname{Var}\left(p_{t}\right) / n \tag{11}
\end{equation*}
$$

Some algebra shows that

$$
\left(\operatorname{Var}(\hat{p})-\alpha_{*}\right)=\left(\operatorname{Var}(p)-\alpha_{*}\right) / n
$$

where $\alpha_{*}=\sigma_{a}^{2} /(n-1)$. The variance of the distribution of $p$ moves over time towards $\alpha_{*}$; if already at $\alpha_{*}$, it stays there forever. Thus, the mean of the distribution of $p$ stays the same over time, but its variance moves towards a single value.

Summary Whether the single-teacher (1.1) or multipleteacher (1.2) scenario is assumed, the naive learning models predict that the average degree of coarticulation in the population will not change over time. It follows that, under these assumptions, change from little coarticulation to full coarticulation (Goal 3) is not possible.

The single-teacher model has an additional problem. The variability of the degree of coarticulation in the population is predicted to increase with each generation., i.e. speakers come to coarticulate increasingly differently. Intuitively, because each production is noisy, the learner's estimate of the degree of coarticulation is inherently noisy (Eq. 4): it is impossible to exactly acquire the target value of the parent from a finite sample. Increasing population-level variation in the degree of coarticulation over time is clearly empirically inadequate, because the effects of umlaut are generally either present or absent in a given population. Thus, Model 1.1 does not allow for stability of a population with little coarticulation (Goal 1) or full coarticulation (Goal 2).

## $\mathcal{A}_{\text {simple }}$ : Simple prior models

Intuitively, the reason that the single-teacher naive learning model fails to allow for stability around a particular value of $p$ is that there is no force counteracting the noise in each learner's estimate (4), which causes the distribution of $p$ values to spread out over time. In this section, we consider the effect of a simple prior learning bias on the evolution of $p$.

As above, we assume the learner estimates $p$ based on the assumption that data is generated i.i.d. from a source with a fixed $p$. The distribution of the data under this assumption is

$$
\begin{align*}
P(\vec{y} \mid p) & =P\left(y_{1} \mid p\right) \cdots P\left(y_{n} \mid p\right)  \tag{12}\\
& =\frac{\exp \left[-\sum_{i=1}^{n}\left(y_{i}-\left(\mu_{a}+p\right)\right)^{2} /\left(2 \sigma_{a}^{2}\right)\right]}{\left(2 \pi \sigma_{a}^{2}\right)^{n / 2}} \tag{13}
\end{align*}
$$

However, we now assume that learners' knowledge about $p$ is probabilistic: they begin with a prior distribution $(P(p)=$ $\alpha(p)$ ) on how likely different values of $p$ are a priori, which is updated to a posterior distribution based on the data $(P(p \mid \vec{y}))$.

Recall that the population of naive learners from a single teacher did not show the simplest possible empirically adequate dynamics: stability of the distribution of $p$ over time near $p=0$; i.e., most people have a minimal (but fixed) degree of coarticulation. As a first pass to see if this behavior is possible with learners who reason probabilistically about $p$, we assume learners have a prior biasing them towards values of $p$ near 0 , with values away from 0 becoming increasingly less likely. Intuitively, this prior "should" sharpen the distribution of $p$ towards $p=0$ over time, counteracting the effect of transmission noise which tends to make the distribution of $p$ spread out more in each generation (as in Model 1.1).

For simplicity, we assume a Gaussian prior $\alpha \sim N\left(0, \tau^{2}\right)$. The posterior is then simply:

$$
\begin{equation*}
P(p \mid \vec{y})=P(\vec{y} \mid p) P(p) / P(\vec{y}) \tag{14}
\end{equation*}
$$

The learner must pick a point estimate of $p$, denoted $\hat{p}$, using $P(p \mid \vec{y})$. The two familiar strategies, choosing the maximum or expected value of the posterior (abbreviated MAP, EV), turn out to be equivalent:

$$
\begin{equation*}
\hat{p}_{\mathrm{MAP}}=\hat{p}_{\mathrm{EV}}=\frac{\left(\mu_{a}-\bar{y}\right)}{1+\sigma_{a}^{2} / n \tau^{2}} \tag{15}
\end{equation*}
$$

Abbreviating the denominator of (15) as $K=1+\sigma_{a}^{2} /\left(n \tau^{2}\right)$, these estimates of $p$ may then be equivalently written as $\hat{p}=$ $\left(\mu_{a}-\bar{y}\right) / K$.

As above, we can now consider the consequences of this learning strategy under different population scenarios. ${ }^{5}$

Model 2.1: Simple prior, single teacher We again first assume a scenario in which each learner in generation $\mathcal{G}_{t+1}$ receives $n$ training examples from a single member of generation $\mathcal{G}_{t}$, who has coarticulatory parameter $p_{\text {parent }}$, abbreviated as $p$. The distribution of $p$ is $P(p)=\pi_{t}(p)$.

[^120]We first determine the distribution of a learner's estimate $\hat{p}$, given fixed $p$ and data $\vec{y} . \bar{y}$ is normally distributed, as described by (3), as in the no-prior case. Because $\bar{y}$ is normally distributed and $\hat{p}=\left(\mu_{a}-\bar{y}\right) / K$, the distribution of $\hat{p}$ is

$$
\begin{equation*}
P\left(\hat{p} \mid p_{\text {parent }}\right)=N\left(p_{\text {parent }} / K, \sigma_{a}^{2} / n K^{2}\right) \tag{16}
\end{equation*}
$$

Thus, on average, the learner's estimate of $p$ is closer to 0 than the parent's value.

We can now compute the marginal distribution of $\hat{p}$ :

$$
\begin{align*}
\pi_{t+1}(\hat{p})=P(\hat{p}) & =\int \underbrace{P(\hat{p} \mid p)}_{(16)} P(p) d p  \tag{17}\\
& =\int N_{\hat{p}}\left(p / K, \sigma_{a}^{2} / n K^{2}\right) \pi_{t}(p) d p \tag{18}
\end{align*}
$$

As in the no-prior case, we can gain some understanding of the evolution equation (18) by examining how the expectation and variance of $p$ evolve. By a similar derivation to (6), it can be shown that the expectation of $\hat{p}$ is:

$$
\begin{equation*}
E(\hat{p})=E\left(p_{\text {parent }}\right) / K \tag{19}
\end{equation*}
$$

Because $K>1$ (for any values of $\sigma_{a}, n$, and $\tau$ ), the expected value of the coarticulation parameter decreases with each generation. By a similar derivation to the no-prior case, the variance of $\hat{p}$ can be shown to be

$$
\begin{equation*}
\operatorname{Var}(\hat{p})=\left[\sigma_{a}^{2} / n+\operatorname{Var}(p)\right] / K^{2} \tag{20}
\end{equation*}
$$

and some algebra shows that

$$
\left(\operatorname{Var}(\hat{p})-\alpha_{*}\right)=\left(\operatorname{Var}(p)-\alpha_{*}\right) / K^{2}
$$

where $\alpha_{*}=\frac{\sigma_{a}^{2}}{n\left(K^{2}-1\right)}$. Because $K>1$, the variance of $p$ moves over time towards the fixed point $\alpha_{*}$, as in Model 1.2. Thus (as noted by Smith, 2009 in other settings), the distribution of coarticulation in the population does not converge to the prior, unlike the well-known result of Griffiths and Kalish (2007).
Model 2.2: Simple prior, multiple teachers The situation is similar under $\mathcal{S}_{\text {multiple }}$. The mean of $p$ can be shown to evolve exactly as in the single-teacher case (19), towards 0 . Similarly, the variance looks very similar to the evolution in the single-teacher case (20), except for an extra factor of $n$ in the denominator. The variance again evolves towards a fixed point, now $\alpha_{*}=\sigma_{a}^{2} /\left(n K^{2}-1\right)$, but in this case more quickly than in Model 2.1. Intuitively, this means that because learners have a strong prior against coarticulation, evidence for coarticulation at the level of the individual is mitigated and is unlikely to spread throughout the population.
Summary For both single- and multiple-teacher scenarios, a simple Gaussian prior drives the value of $p$ to 0 , predicting phonologization of coarticulation to be impossible. Thus, both Model 2.1 and 2.2 meet modeling Goal 1 (stability of little coarticulation), but neither of Goals 2 or 3 .

## $\mathcal{A}_{\text {complex }}$ : Complex prior models

The preceding section has shown that the distribution of $p$ in populations of learners with a Gaussian prior always converges to 0 . This simple prior model is empirically inadequate, because it fails to predict the possibility of stable coarticulation in a population. We therefore considered several more complex priors. Here we discuss one such prior, a quadratic polynomial with a minimum at $\left(\mu_{a}-\mu_{i}\right) / 2$ which is concave up between 0 and $\mu_{a}-\mu_{i}$ :

$$
\begin{equation*}
P(p) \propto\left[a\left(\mu_{a}-\mu_{i}\right)^{2}+\left(p-\left(\mu_{a}-\mu_{i}\right) / 2\right)^{2}\right] \tag{21}
\end{equation*}
$$

Here, $a$ is a scale parameter controlling the "strength" of the prior: as $a \rightarrow 0$, values of $p$ near the endpoints are maximally weighted relative to values near $\left(\mu_{a}-\mu_{i}\right) / 2$; as $a$ is increased, the prior is progressively flatter.
We assume the learner takes the MAP estimate of $p$ for values of $p$ in $\left[0, \mu_{a}-\mu_{i}\right]$, which does not have a closed form solution, but can be found numerically. We thus proceeded by simulation to determine the evolution of the distribution of $p$ over time in this case. The results reported here assume $\mu_{a}-\mu_{i}=200$ and a strong prior $(a=0.01)$ in a multipleteacher setting. We used large generation sizes ( $M=10000$ ) to approximate the deterministic behavior of infinite populations. Due to space constraints we discuss only the results for multiple-teacher models; the results for analogous singleteacher models are similar, in terms of our modeling goals.
Model 3.1: Complex prior First, we considered cases where there is little coarticulation in the population ( $p_{0} \sim$ $N(10,10)$ ) and where primary umlaut is effectively complete ( $p_{0} \sim N(190,10)$ ). The evolution of density estimates for $p$ over 1000 generations can be seen in the first panel of Fig. 2. While there is a slight shift in the mean and variance, they reach relatively stable values by around 1000 generations. However, the strength of the prior, in terms of the value of $a$, is important: as seen in the second panel of Fig. 2, for a weak prior ( $a=0.99$ ), the variance of $p$ in the population increases quickly over time, with results similar to the no-prior case discussed above.

Figure 2: Evolution of density of $p$ over time (indicated by color) with (left) a strong polynomial prior ( $a=0.01$ ) or (right) a weak polynomial prior ( $a=0.99$ ).

The simulation results suggest that a strong polynomial prior can result in a stable distribution for $p$ in the population over time, with most learners having values near 0 (little coarticulation) or 200 (full coarticulation). Model 3.1 thus satisfies our Goals 1 and 2.
Model 3.2: Complex prior, production bias More extensive simulation with Model 3.1, however, suggests that it does not satisfy Goal 3: it is never possible for a population to transition from a stable state of little articulation to a stable state of full coarticulation. The reason is intuitively clear: the prior is strong enough to bias learners towards either $p=0$ or $p=\mu_{a}-\mu_{i}$, but there is no countervailing force which could bias learners towards full coarticulation.

One plausible type of bias is an external force that increases the likelihood of coarticulated variants. Here, we implement a systematic production bias by assuming that some percentage of the learner's data have been moved towards $\mu_{i}$ by a quantity $\ell \sim N(\lambda, \lambda / 2)$; that is, they are coarticulated more than expected from the teacher's value for the coarticulatory parameter. This kind of bias, corresponding to a general tendency in speech production to over- or undershoot articulatory targets, is commonly considered in computational models of phonetic change (e.g. Pierrehumbert, 2001).

Assuming a strong polynomial prior $a=0.01$, change from no to full coarticulation turns out to indeed be possible, but only for a sufficiently large bias. Fig. 3 illustrates this with bias factors $\lambda=2$ and $\lambda=10$, starting in a state with little coarticulation ( $p_{0}=10$ ), in which $10 \%$ of tokens in each generation were subject to a lenition bias. As in Model 3.1, for a strong enough prior (low $a$ ) with no bias, the littlecoarticulation state is stable. As the amount of bias $(\lambda)$ is increased past a critical value, there is a rapid shift of the population to a stable state where most learners have full coarticulation. That is, there is a bifurcation where the amount of bias has overcome the stabilizing affect of the prior, and the little-coarticulation state becomes unstable. These results also illustrate a more general tradeoff between the strength of the prior and the amount of bias observed in further simulations (not shown here): for a stronger prior, the critical value of $\lambda$ increases: more bias is needed to overcome the prior.

Thus, Model 3.2 meets all three of our modeling goals: (1) a stable population with little coarticulation, (2) a stable population with full coarticulation, and (3) a rapid transition from little to full coarticulation are all possible, for particular initial conditions and values of the system parameters $(a, \lambda)$.

## Discussion

Our main goal in this paper was to evaluate how assumptions about bias and population structure for a population of learners of a continuous parameter translated into population-level models capable of modeling three empirically-observed scenarios of stability and change.

One interesting result was that population structure did not necessarily have much effect on the dynamics. For the naive learning scenario, the single-teacher and multiple-

Figure 3: Evolution of density of $p$ over time (indicated by color) with a strong polynomial prior ( $a=0.01$ ), with $10 \%$ of tokens subject to bias factor $\lambda=2$ (left) or $\lambda=10$ (right).
teacher models had qualitatively different dynamics: the variance in the degree of coarticulation stabilized over time in the multiple-teacher model, but increased over time in the singleteacher model. But for the simple prior and complex prior models, whether a single-teacher or multiple-teacher scenario was assumed largely impacted the rate at which a stable state was reached, rather than changing the qualitative outcome. Given that social structure plays a key role in the actuation and spread of language change (Labov, 2001), future work should further explore the role of different population structures with more complex teacher-learner relations. ${ }^{6}$

On the other hand, assumptions about bias mattered a great deal. When no or weak learning bias $\left(\mathcal{A}_{\text {naive }}\right.$, or $\mathcal{A}_{\text {simple }}$ with high $a$ ) was assumed, stability of the distribution of the coarticulatory parameter $p$ in the population was impossible. When a strong bias towards non-coarticulation was assumed ( $\mathcal{A}_{\text {naive }}$ with low $a$ ), stability of minimal coarticulation was possible (Goal 1), but stability of full coarticulation and change between the two (Goals 2,3 ) were not. It was only after assuming learners have a strong prior biasing them towards either little or full coarticulation, along with introducing an explicit unidirectional pressure to coarticulate, that it was possible to have primary umlaut: change (Goal 3) from stability of little coarticulation (Goal 1) to stability of full coarticulation (Goal 2).

Model 3.2, which met all three goals, shows a bifurcation: change from one stable state (little coarticulation in the population) to another (full coarticulation in the population) occurred suddenly as a system parameter (the amount of production bias) was varied past a critical value. Bifurcations in linguistic populations have been suggested as a potential mechanism underlying the actuation of linguistic change, but to our knowledge have previously only been shown to occur in models of change in discrete parameters (e.g. Niyogi, 2006). Our demonstration that bifurcations are possible in a population of learners of a continuous parameter supports the

[^121]hypothesis that bifurcations play a key role in the actuation of language change more generally. Future work should explore whether such bifurcations emerge in models that more accurately reflect the social structure of speech communities, and where the outcome of learning is a distribution over multiple phonetic cues, rather than a single cue.

#### Abstract

We examined whether a bilingual advantage can be found in older bilinguals that share the same cultural background with monolinguals. Sixteen Gaelic-English bilinguals over the age of 60 years were compared with three monolingual control groups in performance on the Simon task, as well as in general intelligence and socio-economic status. Some of the monolinguals were bidialectal allowing us to also test whether switching between dialects can incur similar cognitive benefits as bilingualism. Results showed no group differences in overall reaction times as well as in the Simon effect suggesting that individuals that share a cultural background may not exhibit differences in inhibitory control even if they routinely use another dialect or another language. This opens up the possibility that other factors associated with bilingualism, like immigrant status, may be responsible for the bilingual advantage found in some but not in other studies. Keywords: Bilingualism; bildialectism; inhibitory control; Simon test.

## Introduction

A considerable number of studies have demonstrated a bilingual advantage in executive processing (for a review see Bialystok, Craik, Green \& Gollan, 2009), which seems to be most pronounced in young children and older adults (Bialystok, Martin \& Viswanathan, 2005). It has been suggested that knowing and using two or more languages on a regular basis requires individuals to inhibit one language while using the other, both at the level of selecting the appropriate linguistic setting as well as on the level of selecting individual words (Hilchey \& Klein, 2011). Thus, bilingualism has been causally linked to improved executive processing which transfers to non-linguistic domains. In older individuals, such improved executive processing may be beneficial for maintaining cognitive flexibility later in life (Bialystok et al., 2004) so much so as to even delay the onset of dementia (Bialystok, Craik \& Freedman, 2007).

However, because random assignment is not possible in quasi-experimental studies with bilingual participants, there is always the possibility that bilingualism is confounded with differences in a variety of hidden factors (Hilchey \& Klein, 2011), most notably socio-economic status (SES), but also educational and cultural background (Hakuta, Ferdman
\& Diaz, 1986), variables that can affect cognitive functioning (Mezzacappa, 2004). While recent studies reporting a bilingual advantage try to match bilinguals and monolinguals on SES, it is often difficult to match participants in cultural background, and immigrant status especially for older participants. For example, in Bialystok et al. (2004), the older monolinguals resided in North America while the majority of older bilinguals resided in India. Similarly, in Bialystok et al. (2008), 20 out of 24 older bilinguals were immigrants who had arrived in North America as children or adolescents suggesting that they belonged to an immigrant community likely to differ culturally from monolingual North American controls. Finally, while Schroeder and Marian (2012) do not explicitly report immigrant status or age of arrival in North America for their bilinguals, the range of languages spoken by their participants suggests that they were predominantly first or second generation immigrants from different cultural backgrounds than the monolinguals.

There is evidence that differences in cultural background are associated with differences in executive processing (Sabbagh, Xu, Carlson, Moses \& Lee, 2006). This can be attributed to culture-specific parenting attitudes or educational and leisure practices which influence exposure to activities that require and promote executive processing, such as musical training (Bialystok, 2011), playing of video games (Green \& Bavelier, 2003) and a host of other, as of yet, unknown factors.

There is also the possibility that genetic effects may be responsible for cultural differences in executive processing: For example, population-genetic studies have shown that the prevalence of the 7-repeat allele of the dopamine receptor gene (DRD4), is markedly lower in East and South East Asia compared to North America (Chang, Kidd, Kivak, Pakstis, \& Kidd, 1996). This allele has been associated with attention-deficit hyperactivity disorder (ADHD; Faraone, Doyle, Mick, \& Biederman, 2001), which, in turn, often manifests itself in poor executive processing (Schachar, Tannock, Marriott, \& Logan, 1995); although the relationship between DRD4 and ADHD itself seems to be subject to cross-cultural variation as culture may affect the
phenotypic realisation of this genotype (Nikolaidis \& Gray, 2010). Somewhat contradictory, Chen, Burton, Greenberger \& Dmitrieva (1999) have shown a link between the long alleles of DRD4 and population migration patterns, indicative of migration selecting for traits like noveltyseeking and openness. The personality trait of openness, in turn, has been associated with better performance in some aspects of executive functioning (Williams, Suchy, Rau, 2009). This may imply the possibility of a reverse causal relationship between bilingualism and executive processing: individuals with superior executive abilities might be more likely to be bilingual because of a potentially greater propensity to make life choices leading to migration or, when placed in a multi-lingual environment, greater success in maintaining use of multiple languages. Although reconciling these different findings is beyond the scope of this paper, they point to the intriguing possibility of a genetic origin of group differences in executive processing, which may co-vary with cultural background, immigrant status and bilingualism. Indeed, Morton and Harper (2007) failed to observe a superior inhibitory control when comparing non-immigrant bilingual with monolingual children matched for SES and cultural background. However, a similar study controlling for cultural background and immigrant status has not yet been conducted with older bilinguals. The present study therefore aims to test the bilingual advantage in executive processing in older bilinguals that share cultural background with the monolingual controls.

Studying Gaelic-English bilinguals allowed us to address this issue because Gaelic, a Celtic minority language, is spoken by a non-immigrant community of about 58,000 individuals residing mainly in the West of Scotland. Since Gaelic language schooling was abolished in 1872 and has been reintroduced only in 2006 there are no Gaelic monolinguals. Rather, older Gaelic-English bilinguals acquired Gaelic in early childhood before being introduced to English in school, and tend to use Gaelic in the home and in the local bilingual community. However, in terms of cultural attitudes and values, educational practices, leisure activities, media exposure and immigrant status, these bilinguals do not differ from English monolinguals.

In this study, we used the Simon test, closely modeled after Experiment 1 in Bialystok et al. (2004) to test whether Gaelic-English bilinguals exhibit benefits in inhibitory control compared to monolinguals recruited from the same cultural background. We restricted our exploration to the testing of inhibitory control, one component of executive processing, because this component had been examined in older bilinguals before (Bialystok et al., 2004; Bialystok et al., 2008; Schroeder \& Marian, 2012). In the Simon Task, participants have to inhibit a pre-potent spatially cued response when responding to the colour of a stimulus. This requires inhibitory control (Lu \& Proctor, 1995), which has been shown to be superior in bilinguals (Bialystok et al., 2004).

One issue that arises in a Scottish context is related to choosing appropriate monolingual controls: Britain is a country with extraordinary dialectal diversity and speakers of British English are often exposed to various local varieties of English. Specifically, in Scotland 85\% of the population report using one of the local varieties of the Scots dialect to varying degrees (Scottish Government Social Research, 2010), in addition to Standard Scottish English (SSE). Even though dialects of the same language are traditionally considered to be mutually intelligible there is considerable variability rendering the boundaries between languages and dialects fluid. Consequently, the linguistic classification of Scots, a Germanic language variety, is subject to much debate with some considering it a separate language, while others classifying it as a dialect of English or as a register used in specific social contexts (see Aitken, 1985). Indeed, local varieties of Scots differ considerably from SSE in their phonetic, lexical and even some syntactic features (Smith \& Durham, 2012). Thus, bidialectal speakers must monitor continuously who can or cannot be addressed in Scots, choose appropriate articulatory settings, and inhibit phonetic and lexical variants pertaining to the variety not currently used. It is therefore important to carefully control dialect use in the monolinguals. Moreover, the question as to whether use of multiple dialects can incur executive processing benefits similar to those observed in bilinguals is an interesting question in its own right, and will also be explored in this study. We tested three monolingual control groups: (1) bidialectal speakers who reported switching continuously between SSE and Dundonian, a local variety of Scots spoken in Eastern Scotland, (2) monodialectal speakers of SSE residing in the same locale as the bidialectals but who reported never or rarely using Dundonian, and (3) monolingual speakers of Anglo-English, a variety spoken in the South of England, for whom Scots was for the most part unintelligible. Note that the label monodialectal is used to refer to those monolingual participants who share a geographical and cultural background with the bidialectal participants. If inhibitory control advantages arise for different languages only then one would expect to find faster reaction times and a smaller Simon effect only in the Gaelic-English bilinguals. If regular switching to dialect also results in an inhibitory control advantage one would expect bidialectals to also exhibit shorter reaction times and a smaller Simon effect compared to monodialectals and monolinguals.

## Method

## Participants:

Sixty-four older adults ( $M=70.3$ years, SD $=7.6$ years, range $=60.2-88.7$ years) participated in the experiment. The 16 bilingual participants ( 6 men ) were speakers of Gaelic and SSE, the 16 bidialectal participants ( 7 men ) were speakers and regular users of both SSE and Dundonian Scots, the 16 monodialectal participants ( 5 men ) were monolinguals speakers of SSE who did not use Dundonian Scots, and the 16 monolingual participants ( 6 men ) were
speakers of Anglo-English. The monodialectal and bidialectal participants were recruited from the Dundee area, the Gaelic-SSE bilinguals were recruited from the Western Isles and the West coast of Scotland, and the English monolinguals were recruited from different parts of England and Scotland (all but one had not lived in Scotland for any considerable length of time and were either visitors or had recently retired to the area).

The Background Questionnaires (described below) revealed that the bilinguals' daily use of Gaelic and the bidialectals' use of Dundonian Scots ranged between 30\% and $70 \%$ of times. The monodialectals reported less than 25 $\%$ use of Dundonian Scots. Three other participants reported predominantly using Dundonian Scots. As it proved impossible to recruit further monodialectal speakers of this type, these monodialectals were excluded from the study. One bilingual participant was excluded due to $90 \%$ SSE and only $10 \%$ Gaelic usage, and one participant failed to perform the Simon Task correctly and was also excluded.

## Materials:

Background Questionnaire: A background questionnaire was used to gather relevant background information about the participants' educational background (including the age they left school, whether they continued to further or higher education and which qualifications they gained) as well as the occupations they had held throughout their working lives. It also inquired about their dialect usage and any second languages they had learned. The Gaelic-SSE bilinguals additionally received a modified version of the LEAP-Q (Marian. Blumenfeld \& Kauschanskaya, 2007), a questionnaire designed to determine bilingual language status that has been validated using behavioural measures of language proficiency.

Wechsler Abbreviated Scale of Intelligence (WASI): Two subscales of the WASI were used to determine participants' verbal and non-verbal IQ. The Vocabulary subscale tested the participants' verbal reasoning ability and required them to give definitions of words with increasing difficulty. The Matrix Reasoning subscale consisted of patterns designed to measure abstract non-verbal reasoning ability. Participants' raw scores were converted to $t$-scores which are normalised for each age range and combined to give an overall score from which a final IQ score was determined.

Simon Task: The Simon Task was modelled after Experiment 1 in Bialystok et al. (2004). Participants were presented with red and blue squares, half of which appeared on the left side of the screen, and the other half on the right. Participants were asked to press a key on the left (the ' 1 ' key) or the right (the ' 0 ' key) of the keyboard depending on the colour of the square. Assignment of colours to keys was counterbalanced across participants.

In congruent trials, the response associated with the colour of the square corresponded to the presentation location; in incongruent trials, the square was presented on the opposite side of the location of the response key. Thus,
in these trials participants had to inhibit the pre-potent response of selecting the spatially congruent key, and instead had to select the key associated with the colour of the square. The reaction time difference between incongruent and congruent trials is considered to be a measure of inhibitory control. Participants were given 4 congruent and 4 incongruent practice trials with feedback before moving on to the 28 critical trials (7 each of congruent red, congruent blue, incongruent red, incongruent blue) presented without feedback.

## Procedure:

Participants were first given the Background Questionnaire, which inquired about their knowledge and use of the various languages and varieties of English. The monolingual speakers were asked about their daily usage of different varieties of English and other foreign languages; for the Scottish participants these questions pertained to their use of Dundonian Scots. The responses indicated to what extent participants were fluent in one or two varieties and were using them on a daily basis. For the bilingual speakers, these questions pertained to their use of Gaelic and SSE. The bilinguals also received the LEAP-Q after the Background Questionnaire, to obtain information about their self-rated proficiency in each language, the age at which they starting learning each language, the age at which they became fluent and the proportion of time they currently use each language.

Participants were then given the Vocabulary and Matrix Reasoning subscale of the WASI. In the Vocabulary subscale, participants have to provide definitions of words. In the Matrix Reasoning subscale, participants were shown series of shapes instantiating a rule and were asked to identify which shape fits in the missing slot.

Finally, the Simon task was presented on a Toshiba laptop, with presentation controlled by Eprime. Participants first saw a fixation cross in the middle of the screen for 800 ms , followed by an interval of 250 ms . Half of the participants were randomly assigned to press the ' 1 ' key for 'red' and the ' 0 ' key for 'blue'; the assignment was reversed for the other half of participants. The keys were marked with white stickers on the keyboard. Then, a red or blue square appeared either to the left or the right of the screen, subtending five degrees of visual angle. The squares were visible for 1000 ms if there was no response. Timing began with the onset of stimulus, and was terminated with the response. The next item started after a 500 ms blank interval. The experiment began with 8 practice trials for which participants received feedback. Practice was followed by the 28 critical trials presented without feedback. Order of the 14 congruent and 14 incongruent trials was randomised.

## Results

We first compared the four groups on linguistic, demographic and cognitive measures which are presented in Table 1.

Table 1: Means and standard deviations (in parentheses) for linguistic, demographic and cognitive measures (voc: Vocabulary subscale of WASI, matrix: Matrix Reasoning subscale of WASI, skill: skill level as measure of SES,
\%use: \% daily use of Anglo-English or SSE). F denotes Fvalue in one-way ANOVAs with $\mathrm{df}=3,60$ for all conditions except the WASI subscales, where $\mathrm{df}=3,59$ ).

|  | monolinguals |  |  | biling | $\begin{aligned} & \hline F \\ & (3,60) \end{aligned}$ |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  | monoling (AngloE) | monodial (SSE) | bidial |  |  |
| age | $\begin{aligned} & 70.3 \\ & (7.6) \end{aligned}$ | $\begin{aligned} & 69.7 \\ & (7.6) \end{aligned}$ | $\begin{aligned} & \hline 72.4 \\ & (8.6) \end{aligned}$ | $\begin{aligned} & \hline 69.8 \\ & (5.5) \end{aligned}$ | 0.5 n.s. |
| voc | $\begin{aligned} & 60.3 \\ & (9.6) \end{aligned}$ | $\begin{aligned} & 57.1 \\ & (8.4) \end{aligned}$ | $\begin{aligned} & 55.5 \\ & (6.7) \end{aligned}$ | $\begin{aligned} & 57.9 \\ & (9.0) \end{aligned}$ | 0.5 n.s. |

| \%use | $\begin{aligned} & 100.0 \\ & (0.0) \end{aligned}$ | $\begin{aligned} & 94.6 \\ & (7.3) \end{aligned}$ | $\begin{array}{r} 52.6 \\ (9.7) \\ \hline \end{array}$ | $\begin{aligned} & 44.3 \\ & (15.3) \end{aligned}$ | $\begin{aligned} & 135.7 \\ & \mathrm{p}<.001 \end{aligned}$ |

Percent language use: Participants' self-reported percentages of daily use of either Anglo-English or SSE were submitted to a one-way ANOVA to compare the four groups. This analysis yielded a significant effect of Group (see Table 1). Post-hoc tests using Tamhane's T2 for unequal variances indicated that bilinguals and bidialectals reported significantly less use of English (i.e. only an average of $48 \%$ of time) than monolinguals and monodialectals, all p's $<.001$.

Socio-economic status (SES): To determine SES, we used the 2010 Standard Occupation Classification (UK Office of National Statistics) to categorise participants' occupations into one of four skill levels based in the amount of formal qualifications or work-based training estimated to be necessary to perform the occupational tasks. These skill levels ranged from 1 (occupations requiring general education) to 4 (professional/managerial occupations requiring degree-level education). We disregarded participant income as another measure of SES as $75 \%$ of participants were retired.
A one-way ANOVA for skill levels yielded a significant effect of Group (see Table 1). Post-hoc comparisons using Tamhane's T2 for unequal variances indicated that the bilingual group had a significantly higher skill level than the bi-dialectal group, $\mathrm{p}<.05$. No other significant differences were found.

WASI: WASI scores were missing for one monodialectal participant who was unable to complete the session. One-way ANOVAs comparing performance of the groups on each of the subscales separately yielded no significant effects (see Table 1).

Simon Task: Participants committed a total of $3.4 \%$ of errors. Error rates were submitted to a 4 (Group: bidialectal, monodialectal, bilingual, monolingual) x 2 (Trial Type:
congruent, incongruent) ANOVA, which yielded no significant effects.
For correct trials, reaction times greater than 2.5 standard deviations above the mean were excluded from the analysis (Ratcliffe, 1993), which affected an additional 56 (2.9\%) of trials. For the reaction times, a 4 (Group: bidialectal, monodialectal, bilingual, monolingual) x 2 (Trial Type: congruent, incongruent) ANOVA yielded a main effect of Trial Type, $F(1,60)=80.3, \mathrm{p}<.001$ (see Figure 1). There was no main effect of Group nor was there a significant interaction between Group and Trial Type. Thus, as expected, performance on incongruent items was slower indicating that inhibiting the incongruent spatial location of the stimulus required additional effort. However, overall reaction time and Simon effect did not differ between the groups.

Figure 1: Reaction times for congruent and incongruent trials in the Simon task in bidialectal, monodialectal, bilingual and monolingual speakers. Error bars show 1 S.E.

One possible explanation for the discrepant findings between this and the Bialystok et al. (2004) study may be related to differential treatment of reaction time outliers. Bialystok et al. (2004) do not report any exclusion of outliers. To achieve comparability with that study, we repeated the ANOVA with all reaction times from the correct responses included. This analysis yielded a main effect of Trial Type, $\mathrm{F}(1,60)=9.29, \mathrm{p}<.01$, but no effect of Group and no interaction between the two factors.

Because SES is associated with executive processing (Morton and Harper, 2007), we included skill level, our measure of SES, as a covariate in the ANOVA for the reaction times (outliers excluded), which did not change the outcome of the analysis. Moreover, an analysis ignoring language group and including only skill level as the between-subjects variable did not yield any significant effects either.

In sum, while all 4 language groups showed significantly slower reaction times for incongruent trials in the Simon Task, there were no significant differences between any of
the groups in global reaction time and levels of inhibitory control.

## Discussion

Our findings did not show a bilingual advantage in nonlinguistic inhibitory control for older Gaelic-English bilinguals, nor did we find such an advantage for bidialectal speakers who routinely switch between Dundonian Scots and SSE. Moreover, we also did not find a global reaction time advantage for bilinguals and bidialectals, which has been interpreted as an indicator of improved general executive processing. This is in contrast to a substantial body of evidence demonstrating a bilingual advantage in executive processing in general, and in inhibitory control specifically. We therefore carefully compared our findings to the three other studies that had tested older bilinguals and monolinguals to determine whether differences in administration of the Simon task may have resulted in these discrepant results.

Our experiment was closely modeled after Experiment 1 in Bialystok et al. (2004). For the monolinguals, that experiment showed mean reaction times of 1437 ms for the congruent trials, and 3150 ms for the incongruent trials. For the bilinguals, the reaction times were somewhat faster (congruent: 911 ms , incongruent: 1959 ms ). These are unusually slow reaction times, in stark contrast to the much faster reaction times in our study (see Figure 1), which contained the same timing, the same number of trials, and a comparable sample size. Moreover, in Experiment 2 of the Bialystok et al. (2004) study, participants received a centered control condition and a 4 -colour condition in addition to the standard 2-colour condition, as well as an increased number of trials. Still, reaction times in the comparable 2 -colour condition were of a similarly large magnitude (older monolinguals: 1012 ms vs. 1595 ms , older bilinguals: 889 ms vs. 1101 ms , for congruent and incongruent trials, respectively). Again, these overall reaction times and the Simon effect are far beyond what is considered to be the standard Simon effect in older adults (Hilchey \& Klien, 2011; Van der Lubbe \& Verleger, 2002). This leaves open the possibility that group differences between older bilinguals and monolinguals emerge only for unusually long reaction times which may be indicative of a substantial slowing of cognitive performance in some older populations, perhaps due to diminished experience with computerised testing or due to sub-clinical effects of dementia. However, the fact that Bialystok et al. (2008) and Schroeder and Marian (2012) found a bilingual advantage in the Simon effect for older bilinguals with overall reaction times similar to the ones reported here suggests that the bilingual advantage is not an artifact of long reaction times but emerges when bilinguals and monolinguals differ in cultural background and immigrant status.

Although an analysis of other age groups is beyond the scope if this paper, it is worth mentioning that a similarly inconsistent picture emerges for studies of inhibitory control
in children, and in younger and middle-aged adults. While a considerable number of studies report a smaller Simon effect for bilinguals (Bialystok et al., 2004, 2005; Bialystok, 2006), others failed to find such a difference (Humphrey \& Valian, 2012; Kosaie \& Phillips, 2012a,b; Paap \& Greenberg, 2013). Findings of a bilingual advantage also tend to be inconsistent for other tests of executive processing (e.g. Stroop task, Flanker task, anti-saccade task) and for different aspects of executive processing (e.g. response suppression, switching, monitoring, updating - for overviews see Hilchey \& Klein, 2011, and Paap \& Greenberg, 2013). We would like to suggest that differences in cultural background and immigrant status are likely candidates for explaining the differences between monolinguals and bilinguals.

It should be mentioned that our failure to find an executive processing advantage in older Gaelic-English bilinguals contrasts with the advantage of Gaelic-English bilingual children in various measures of verbal and nonverbal IQ such as the Block design, Vocabulary and Arithmetic sub-tests of the Wechsler Intelligence Scale for Children reported by Lachlan, Parisi and Fadda (2012). As the bilingual children were all schooled in Gaelic, the authors conclude that schooling in the minority language may have consolidated their bilingualism, in contrast to a group of Sardinian-Italian bilingual children who were not schooled in the minority language and did not differ from Italian monolinguals in performance on the same tests. We agree that Gaelic schooling may indeed have been a beneficial factor for children's intellectual development as considerable resources have been expended by the Scottish government on re-introduction of Gaelic-medium education, perhaps making it more compelling for more aspirational parents to enroll their children into the better funded Gaelic tracks. For these reasons, and because psychometric intelligence does not constitute a direct measure of executive processing, we are not convinced that this finding constitutes support for superior executive processing in Gaelic-English bilinguals.

In sum, our failure to replicate an inhibitory control advantage in older Gaelic-English bilinguals and Scots-SSE bidialectals points to the importance of controlling factors like cultural background and immigrant status when studying the link between bilingualism and executive processing.

# Bayesian Speech Production: Evidence from Latency and Hyperarticulation 

Christo Kirov(kirov@cogsci.jhu.edu)<br>Department of Cognitive Science, 3400 N. Charles Street Baltimore, MD 21218 USA<br>Colin Wilson (colin@cogsci.jhu.edu)<br>Department of Cognitive Science, 3400 N. Charles Street<br>Baltimore, MD 21218 USA

#### Abstract

Both response latency and phonetic variation reflect competition among alternatives during the speech production process. A review of the literature finds an apparent contradiction in the latency results. In some tasks where latency is measured, similarity between targets and competitors results in slower reaction times. In other tasks, similar competitors appear to facilitate production times relative to non-similar competitors (though a lack of any competition at all results in the shortest response latencies). With respect to phonetic realization, experiments suggest that high levels of competition induced by sufficiently similar competitors result in hyperarticulation of target utterances. We present a Bayesian model of speech production that formalizes the selection and planning of spoken forms as noisy-channel communication among different levels of processing. The model resolves the apparent contradiction found in the latency results, and establishes a novel connection between those results and observed patterns of hyperarticulation.

Keywords: Speech production; competition; Bayesian modeling

## Introduction

Competition among alternatives, and the need to resolve competition efficiently and correctly, are pervasive in speech perception and speech production (e.g., Luce \& Pisoni, 1998; Marslen-Wilson \& Zwitserlood, 1989; Dell \& Gordon, 2003). A number of studies have examined how such competitive processes are reflected in the time it takes to plan speech, and in the fine-grained phonetic realization of speech sounds. The goal of this paper is to develop a unified explanation of these potentially conflicting results, which have typically been treated independently.

In various speech production tasks, response latency is affected by the relationship between the target response and any primes, distractors, or competitors in the experimental speech environment (e.g., masked priming (Ferrand et al., 1996), plan switching (Meyer \& Gordon, 1985; Yaniv et al., 1990), cue distractor tasks (Gordon \& Meyer, 1984; Galantucci et al., 2009; Roon, 2012). A review of these results reveals an apparent contradiction with respect to how similarity between targets and competitors affects response latency.

In some production tasks, similarity between target utterances and competitors results in delayed (longer) response latencies (Meyer \& Gordon, 1985; Yaniv, Meyer, Gordon, Huff, \& Sevald, 1990; Roelofs, 1999). One example is the plan-switching task (Meyer \& Gordon, 1985), in which participants are prompted to plan to say one form (e.g., the syllable UP), but are sometimes cued to say an alternative (e.g.,
the syllable UB). The findings from this task are summarized in Table 1. When the alternative response is highly similar to the originally planned target response, the time to initiate the alternative is lengthened. This effect drops off rapidly with increased phonological/phonetic distance. Only alternative responses that are about one feature away from the target seem to induce a significant delay.

Table 1: Plan Switching Task: Similarity = Higher Latency

| Planned | Alternative | Difference | Latency |
| :---: | :---: | :---: | :---: |
| UP | UB | voicing | high |
| UP | UT | place | high |
| UP | UD | voicing + place | low |

In cue-distractor tasks, on the other hand, similarity seems to play the opposite role (Gordon \& Meyer, 1984; Galantucci et al., 2009; Roon, 2012). In a cue-distractor task, participants are taught to associate a visual cue with a particular verbal response (e.g., the syllable KA or GA). Upon receiving the cue, the participant attempts to produce the associated response as quickly as possible. However, before the subject is able to initiate speech (e.g., at 200 ms after the cue), an auditory or visual distractor is presented (e.g., the syllable PA).

In spite of the fact that the subject has been given instructions to ignore the distractor, it has an effect on response latency as summarized in Table 2. It seems that when the distractor is sufficiently similar to the target response, production is facilitated relative to the case when the distractor is at a greater distance. However, it is always the case that the presentation of a distractor, no matter how it is related to the target, results in some production delay relative to the nodistractor case.

Table 2: Cue-Distractor Task: Similarity = Lower Latency

| Response | Distractor | Difference | Latency |
| :---: | :---: | :---: | :---: |
| KA | none | NA | minimal |
| KA | GA | voicing | low |
| KA | TA | place | low |
| KA | DA | voicing+place | high |

Finally, high levels of competition have been shown to influence phonetic realization: salient competitors in the speech environment give rise to hyperarticulation of spoken forms.

Figure 1: Experimental paradigm.

For example, Buz \& Jaeger (2012) found that word duration in a corpus of running speech is negatively correlated with distance to the nearest previously mentioned neighbor: neighbors mentioned in the recent past, against which the current word must plausibly compete, condition longer phonetic realizations. Baese-Berke \& Goldrick (2009), using the same paradigm as our own experiments reviewed below, found VOT lengthening for voiceless-initial target words in the context of voiced-initial neighbors (e.g., the word CAP in the context of the word GAP). ${ }^{1}$

The Baese-Berke \& Goldrick (2009) paradigm is designed to simulate a situation in which a speaker must accurately communicate a target word to a listener in the presence of contextually-salient competitor words that could delay recognition or cause miscommunication. The paradigm involves two participants, one playing the role of speaker and the other the role of listener. Each participant sits at a separate computer terminal (which is not visible to the other participant). In each trial of the experiment, two or more words appear on both screens: a target word along with competitor words that are sometimes phonological neighbors of the target. After approximately 1 s , the target word is highlighted on the speaker's screen, who then produces it aloud. At this point, the listener clicks the word that was heard - the same word produced by the speaker, if communication is successful. The speaker's pronunciation of the target is recorded and analyzed acoustically after the experiment. The experimental setup is illustrated in Figure 1. This paradigm has the advantage of being able to precisely control a target word's "context" (the neighbors that appear on-screen with it) and including motivation for the speakers to communicate clearly, as they receive feedback indicating whether the listener has selected the intended word.

Using the same paradigm, we performed a battery of experiments (see Kirov \& Wilson (2012) for details) to determine in what ways competitors could differ from the target utterance and still induce VOT hyperarticulation. The results, summarized in Table 3, point to the following generalization. Competition induces hyperarticulation only when competitors are sufficiently similar to the target word (a difference

[^122]of roughly one phonological feature). The effect drops off quickly as phonological and/or phonetic distance increases.

This nonlinear relationship between feature distance and effect size mirrors the pattern found in the plan-switching task described earlier, suggesting that both effects might be linked through a common mechanism. Although, to our knowledge, no published experiment has directly attempted to correlate response latency with VOT hyperarticulation, there is some additional evidence that latency and hyperarticulation are linked. Bell et al. (2009) suggest that lexical access latency and utterance duration are correlated. Munson (personal communication) has also found that latency in a picture naming task is a good predictor of overall vowel-space expansion: longer latencies are associated with greater vowel expansion, which is a well-known type of hyperarticulation that can be conditioned by lexical competition (e.g., Wright, 2003; Munson \& Solomon, 2004).

Table 3: Summary of Hyperarticulation Results

| Target | Competitor | Difference | Effect |
| :---: | :---: | :---: | :---: |
| CAP | DOLL | unrelated | X |
| CAP | CAD | coda | X |
| CAP | CUP | vowel | X |
| TAP | NAP | onset voicing + nasality | X |
| CAP | TAP | onset place | $\checkmark$ |
| CAP | GAP | onset voicing | $\checkmark$ |

In this paper, we present a Bayesian model of speech production that resolves the apparent contradiction present in the latency data, and links the latency results to the hyperarticulation results, explaining why these effects share the same rapid drop-off as feature distance increases between competitors in speech production. We are not aware of previous work that has attempted to unify this body of results. Indeed, Roon (2012) has recently suggested that since the planswitching task and cue-distractor tasks show different effects of similarity they must engage different levels of representation/processing. However, ascribing the effects to different processing levels would not make it clear why both tasks are sensitive to distance in the same phonetic/phonological space, and most importantly would not explain why some effects of similarity are inhibitory and others facilitative.

The proposed model posits that selection and planning of spoken forms involves optimal communication over noisy channels that link levels of mental processing/representation. Like well-known models of perception and recognition, our model takes Bayesian belief updating to be a fundamental component of psychological algorithms. This is in the spirit of other recent attempts to explore the mechanistic, as opposed to computational, utility of the Bayesian formalism (e.g., Sanborn et al., 2010).

## Bayesian Word Production Introduction

Bayesian models have been productively applied to many aspects of perception (e.g., Knill \& Richards, 1996; Girshick et al., 2011), including speech perception (Feldman, Morgan, \& Griffiths, 2009; Norris \& McQueen, 2008) and written word recognition (Norris \& McQueen, 2008). In perceptionoriented modeling, the mental system interprets noisy signals gained by the senses, updating internal beliefs about the external state as more and more evidence accumulates.

In the Bayesian word production model developed here, shown schematically in Figure 2, the signals of interest originate and are processed wholly within the mental system. Instead of interpreting noisy signals from the external world, the levels of processing/representation studied here interpret noisy messages from other levels. Each level maintains a probability distribution over representational states, receives noisy messages from one or more other levels indicating which state it should take adopt, and in turn sends noisy messages to other levels.

As is standard in Bayesian models of perception, we take noise to be an ineluctable feature of any communication system: noise is present in a signal regardless of whether that signal originates externally (from the environment, or the senses) or internally (from another mental level). One of the simplest approaches to successful transmission over a noisy channel is to use a repetition code. Repeated sampling in perception can result in a more accurate representation of the external world. For the same reason, repeated transmission of the same message to a level of processing can lead it to adopt a more functionally-appropriate representational state.

Figure 2: Bayesian Word Production Schematic

To further clarify the model, we will explain how the message passing process works, using the link between the lemma and phonology levels as an example. The construction of a message is shown schematically in Figure 3. Each
possible lemma can send a characteristic message consisting of a phonological feature vector. The simulations reported here used phonologically realistic feature representations, but for reasons of space we show only part of each vector in the figure. In the construction of a message, first one lemma is sampled from the lemma distribution. The characteristic message of that lemma is then corrupted by noise and passed to the phonology level.

Figure 3: Message Construction

The receipt of the message by the phonology level, and the way in which the message is used to update the distribution over word forms at that level, is shown in Figure 4. Each phonological form represented by this level expects a particular message. The difference between this expected message and the message received is passed through a likelihood function to determine the probability that the message received corresponds to that particular form ( $p$ (message|form)). The form of the likelihood function is determined by the type of noise that corrupts the message; in the simulations reported here we assume that noise in the word production system has a Gaussian distribution, but we have found that other types of noise are equally compatible with the experimental results (e.g., random flipping of binary feature values). Using the likelihood value, and the prior probability of each form, the level's probability distribution is updated according to Bayes' Rule:

$$
p(\text { form } \mid \text { message }) \propto p(\text { message } \mid \text { form }) p(\text { form })
$$

When simulating word production using the model, a phonological form is chosen for production when it passes a high threshold probability. In the simulations reported here, the threshold is set to 0.95 , which means that a form can be chosen only when it has $95 \%$ (or more) of the total probability after an instance of the Bayesian belief update. In most situations, a single message will not provide sufficient evidence for any form to reach this threshold after a single update. The necessary level of evidence is accumulated through multiple messages over time. This temporal repetition code for communication among mental levels will lead to accurate word

Figure 4: Bayesian Belief Updating
form selection with high probability, and lends itself well to accounting for latency and other effects observed in production.

## Resolving Latency Contradictions

We will demonstrate how the model can resolve the apparent contradiction in the latency data with the help of characteristic examples. We begin with the plan switching task, where similarity between target and competitor appears to have an inhibitory effect. There are two relevant conditions. In the first case, shown in Table 4, the participant must plan to say a target utterance (the syllable UP), but is given a cue to say a different but similar alternative (the syllable UB) instead. Initially, the distribution of forms at the phonology level favors the target utterance. After the cue, this level begins to receive messages favoring the alternative. Since the target and the alternative are very similar, the likelihood function favors both of them, and the posterior distribution after each message is received is only slightly different from the prior distribution. Thus, it takes many messages (i.e., higher latency) for the alternative to reach the threshold probability required for production.

Table 4: Similar Alternative - Plan UP with potential alternative UB: Each message causes small posterior change.

|  | UP | UB |
| :--- | :---: | :---: |
| 1) Initial state | 0.75 | 0.25 |
| 2) UB message likelihoods | 0.85 | 0.95 |
| 3) Updated state | 0.73 | .27 |

Table 5 shows the case when alternative response (UD) is
substantially different from the target (UP). Once again, the initial distribution at the phonology level favors the target. This time, however, the likelihood function responds differently to the messages received after the response cue. Since the target and alternative are substantially different, the likelihood favors the alternative but not the target. As a result, the posterior distribution after each message is received is more significantly shifted. Since the posterior distribution experiences a larger change with each incoming message, it takes many fewer messages - hence less time - for the alternative response to reach threshold probability.

Table 5: Non-similar Alternative - Plan UP with potential alternative UD: Each message causes large posterior change.

|  | UP | UD |
| :--- | :---: | :---: |
| 1) Initial state | 0.75 | 0.25 |
| 2) UD message likelihoods | 0.25 | 0.95 |
| 3) Updated state | 0.44 | .56 |

Overall then, latency is higher when the alternative response is more similar to the target, since both the alternative and the target are favored by the likelihood (i.e., there is evidence to produce both forms).

Next, we consider the cue-distractor task, where it seems a similar distractor has a facilitatory effect, relative to a different distractor. Again, there are two relevant conditions. In both cases, we will follow the setup in Roon (2012): depending on a response cue, the participant must say either KA or GA. We will assume that the KA cue is given, and some time has passed so that the distribution at the phonology level has shifted in favor of KA. In the first case, shown in Table 6, some time after the response cue the participant is presented with a distractor $(\mathbf{P A})$ similar to the target, and a few messages corresponding to the distractor are sent to the phonology level. Since the distractor is similar to the target and different from its competitors, the likelihood function provides high evidence for the target and low evidence for any competitors, resulting in a favorable shift in posterior distribution. ${ }^{2}$ Note that if the message received corresponded to the target exactly and not just a similar distractor, the target likelihood would be even higher, and the distribution would shift more favorably. Hence, latency is lowest when there is no distractor.

In the second case, shown in Table 7, the distractor presented after the cue (BA) is substantially different from the target, but similar to the alternative response. The distractor messages now provide low evidence for the target and high evidence for its competitors, causing the posterior distribution to shift in the wrong direction. Correcting this shift requires collecting more evidence for the target, resulting in greater latency.

[^123]Table 6: Similar distractor - PA: Distractor message provides more evidence for target than competitors.

|  | KA | GA |
| :--- | :---: | :---: |
| 1) Initial state | 0.75 | 0.25 |
| 2) PA message likelihoods | 0.85 | 0.25 |
| 3) Updated state | 0.91 | 0.09 |

Table 7: Non-similar distractor - BA: Distractor message provides more evidence for competitors than target.

|  | KA | GA |
| :--- | :---: | :---: |
| 1) Initial state | 0.75 | 0.25 |
| 2) BA message likelihoods | 0.25 | 0.85 |
| 3) Updated state | 0.47 | 0.53 |

In sum, a non-similar distractor causes a larger delay than a similar distractor because it provides strong evidence for the target's competitors and creates a shift in posterior probability towards them which must be overcome. There are certain situations where this generalization will not hold. In particular, if the non-similar distractor is also very different from all competitors (e.g., if the target is very similar to all possible alternatives), then it may create a smaller posterior shift towards the competitors than a similar distractor. Such situations have not arisen in the cue-distractor experiments to date, and so remain a novel prediction of the model.

Overall, we see that if speech production is a Bayesian process as proposed in this paper, the apparent contradiction found in the latency literature is resolved. In the planswitching task, similarity is inhibitory because messages for the correct form also support the originally planned competitor form. In the cue-distractor task, similarity facilitates responses because messages from the distractor are transient and favor the correct form more than any competitors.

## Linking Latency and Hyperarticulation

As shown in Figure 2, the phonology level in the model can be linked to a phonetics level that maintains a distribution over prototypical phonetic realizations. Formally, the channel between phonology and phonetics works identically to the channel between lemmas and phonology, or any other pair of connected levels. The phonology level sends messages to the phonetics level indicating which phonetic realization is preferred, and the phonetic level updates its distribution according to Bayes' rule.

The message passing between phonology and phonetics stops when a decision about which form to produce is made at the phonology level (i.e., some form achieves threshold probability). At this point, the phonetic realization of that form can be extracted as a deterministic function of the posterior distribution in the phonetic level.

Figure 5 shows the results of a series of simulations that
varied the distance between the target utterance and its closest competitor in the salient-competitor paradigm of BaeseBerke \& Goldrick (2009). As feature distance increases, there is a rapid drop-off in both the time it takes for the phonology level to settle on the target form and the value of the phonetic parameter associated with the form. This pattern arises with a variety of model parameterizations with respect to noise and likelihood functions.

Figure 5: Simulation Results: Selection time and VOT hyperarticulation as distance between target and competitor varied from 1 to 5 features.

As previously shown for the plan-switching experiment, decisions at the phonology level take longer when competitors are very similar to the target. These longer planning times allow more messages to be sent from the phonology level to the phonetics level, so the latter will ultimately be presented with a greater amount of evidence for the max VOT prototype. This results in a more skewed posterior distribution and ultimately a longer VOT value.

The crucial result is that the modeling approach presented here predicts that hyperarticulation is a mechanical consequence of planning latency, and the two are closely correlated. This would explain why both types of effects show a similarly rapid drop as feature distance between competitors increases.

## General Discussion and Future Research

We have presented a Bayesian model of word production that resolves an apparent contradiction found in latency-centered word production studies, and links latency results with results describing hyperarticulation. The fundamental claim of the model is that the selection and preparation of spoken forms should be formalized as Bayesian communication among levels of the speech production system. The model occupies a unique place in the overall space of production models, having distinct advantages and avenues for further development.

Most modeling based on interactive activation (e.g., Dell \& Gordon, 2003) has not attempted to explain latency data, focusing instead on what errors the model makes after running for a predetermined amount of time. While the Bayesian model presented in this paper can be pushed to make errors by increasing the level of noise, it is left to future research to determine if the error distribution predicted conflicts with the available empirical data.

Some models, including Roon's dynamic field theory (DFT)-based production model (2012) and Roelofs'

WEAVER++ (1997), have addressed latency results, but have not been simultaneously used to explain hyperarticulation results. In addition, the extant models do not appear to address the full range of latency effects, focusing only on those cases, such as the cue-distractor task, in which similarity between targets and competitors appears to facilitate production. It remains to be seen whether cases in which similarity has an inhibitory effect, including the results from plan-switching tasks, can be accounted for by the models in their present form.

Up to this point, we have focused on modeling empirical data where the speaker's potential utterances were limited to a small closed set. Many studies deal with situations where any word in the lexicon is a potential output utterance. These studies typically examine the effects of global lexical factors such as frequency and neighborhood density on word production. Words with low lexical frequency and high neighborhood density tend to be produced with an expanded vowel space and longer VOT (Munson \& Solomon, 2004; Wright, 2003; Goldinger \& Summers, 1989).

An important question to pursue with respect to our model (or any model) is whether or not it can scale up to explain these results. One convenient feature of the Bayesian model is that the likelihood calculation performed when updating the distribution in a level quickly rules out competitors that differ significantly from the target utterance (i.e., their likelihood is close to 0 ). This means that selection among a large open set of potential outputs quickly begins to resemble selection between a small closed set of the type used in our experiments and simulations.

# Transitive and periphrastic sentences affect memory for simple causal scenes

#### Abstract

Can linguistic structures influence how people perceive and remember causal events? Using a change-detection method, we presented participants with direct causal scenes paired with either transitive (He stretched the toy) or periphrastic sentences (He made the toy stretch.) Participants then viewed movies with changes to the manner of action (stretching the toy with palms up vs. down), the result (stretching it a shorter vs. longer distance), or no change. Participants judged whether the two movies were identical. Reading periphrastic sentences made people more likely to notice a change in manner than a change in result. Reading transitive sentences had the reverse effect - participants were more likely to notice changes in result. This work provides an important advance in our understanding of how rich conceptual representations map into the grammatical structures of language. We discuss how this novel method can provide insight into the nonlinguistic representations recruited by particular sentence structures.

Keywords: Causal language; event structure, change blindness, memory and language

## Introduction

How do speakers map between richly structured event representations and structured linguistic descriptions? For many kinds of events, speakers have a wide range of options. A speaker who sees a boy breaking a window with a baseball can choose to say: "The window broke"; "The boy broke the window"; "The boy broke the window with a baseball"; "The boy broke the window with a baseball during a Little League game" or, if the event was unintentional, "The boy accidentally broke the window." Each of these choices selectively highlights some aspects of the event (the result, the cause, the manner, the context, the intent, etc.) perhaps at the cost of neglecting others ("The boy broke the South Rose window of Notre-Dame"). Many theories of verb argument structure and event representation have been proposed to explain the conceptual primitives that might underlie these descriptions (Gleitman 1990; Jackendoff 1990; Levin \& Rappaport-Hovav 2005; Pinker 1989; Talmy 1985).

Although all of these sentences describe the same actual occurrence, how the speaker represents the event will
influence the type of description chosen. Conversely of course, the way an event is described influences how people represent it. Fausey and Boroditsky (2010) showed for instance that listeners were more likely to attribute blame and financial responsibility to the perpetrator of a causal event following agentive descriptions ("He broke the vase") than non-agentive descriptions ("The vase broke"). Other studies of event representations involved in language have focused on generalizations above the level of individual event-description pairings (Fausey and Boroditsky 2011; Lakusta \& Landau 2012). For instance, Fausey and Boroditsky show that English speakers are more likely than Spanish speakers to remember the perpetrator of an accidental causal event, even when the events are presented non-linguistically. They suggest that this may be because typical descriptions of accidental causal events in English ("He broke the vase") focus on the agent whereas typical descriptions of accidental causal events in Spanish do not ("Se rompió el florero", roughly "the vase broke itself"). However, because this was a purely nonlinguistic task, we cannot conclude whether the memory differences in this study were primarily an effect of these particular sentences, as opposed to other effects of language or culture.

Nonetheless, when different sentences include different components of the event (i.e., by including or omitting reference to the causal agent) it seems evident that linguistic descriptions might influence event representation (and vice versa). However, in some cases, more than one sentence is available even to describe the same components of the event (e.g., "The boy broke the window"/"The boy made the window break").

What nonlinguistic event representations might underlie linguistic distinctions like these? One factor known to influence event descriptions is the directness of the causal event. In direct causal events, the causal agent immediately impacts the causal patient. By contrast, in mediated causal events, the causal agent's action on the causal patient is less direct; for example, acting through an intermediary (e.g., a tool used to bring about the effect).

Work comparing direct and mediated causal events has predominantly examined two types of linguistic structures: lexical causatives and periphrastic causatives. While lexical causatives encode the result in the main verb of a transitive sentence ("The boy broke the window"), periphrastic

[^124]causatives ("The boy made the window break") are multiclausal and encode the result in the embedded verb. The exact syntactic differences between these sentence types are subject to the particular linguistic framework used, but the situations under which speakers tend to use each type have been studied extensively. Research has shown that adults both prefer and produce transitive sentences more often to describe direct causal events than mediated events (Wolff, 2003; Song \& Wolff 2005).

Here, we look at the impact of specific syntactic structures on adults' memory for events. We examine transitive and periphrastic descriptions because unlike agentive and non-agentive sentences, these two sentence types both encode the causal agent and the result. When both transitive and periphrastic sentences are acceptable, does sentence choice affect participants' visual memory for causal scenes?

We used a change blindness paradigm (Pashler 1988; Simons \& Levin 1998; Simons \& Chabris 1999) in which we asked participants to report whether a movie changed between the first and second viewing. Our hypotheses concerned the effect that reading different sentences would have on change detection. Wolff (2003) suggests that causal transitive sentences should lead listeners to expect direct
causal scenes. Motivated by this hypothesis, we predicted that when viewing intentional, direct causal scenes, participants who read transitive sentences (e.g., "The boy stretched the accordion") would be relatively better at detecting result changes (e.g. stretching an accordion toy a little vs. a lot) and relatively worse at noticing changes in manner (e.g. stretching an accordion toy with hands facing up vs. down). In contrast, since periphrastic (but not transitive) causal sentences can be used to describe mediated causal events, we expected that participants who read these sentences would be better at detecting manner changes.

## Experiment

## Method

Participants 329 adult participants took part in the experiment, which was conducted on Amazon's Mechanical Turk platform. Participants were screened to be located in the United States and self-reporting as native English speakers. Testing was conducted over several days, and care was taken (by monitoring user ID numbers assigned by

Figure 1. Sample stimuli images from 2 events. Each of 12 events had a base movie and 2 change movies (manner change, result change). In the "Roll" event, the manner change involved the woman switching from using one hand to using two hands. In the result change, the toy truck rolled across the table with its wheels up, rather than its wheels down. In the "Rattle" event, the manner change involved the woman changing the direction she shook the toy ring. The result change involved changing the sound the rattle made. The 10 additional event type triads were Bend, Bounce, Close, Drop, Tip Over, Ring, Rotate, Spill, Spin and Stretch. In addition to the critical movies, all participants received 6 control 'base-movie/no-change' trials (not depicted).

Figure 2. A visual depiction of the procedure for a stimulus (ROLL) in the Periphrastic x Manner-Change condition. Notice how the woman's hands are positioned in each movie. For each experimental trial $(\mathrm{n}=12)$, participants viewed the target sentence followed by a base movie. After a 5-s delay they saw the altered movie followed by the detection question.

Amazon) that participants did not take the survey more than once.

Materials We constructed 12 stimulus movie sets, each based around a simple, intentional causal action that could be described in a simple transitive sentence. Two example stimulus sets are shown in Figure 1, and videos of all stimuli used the experiment are available online at http://mit.edu/~mekline/www/KMS_cogsci13.html. In addition to the base movie, each set included a mannerchange version and a result-change version. In addition to the twelve target stimuli, six movies used in a previous study of direct, intentional causal actions (Muentener \& Lakusta, 2011) were included as control 'no-change' stimuli.

Stimuli were presented online using the Python package EconWillow (http://econwillow.sourceforge.net).

Procedure Each participant was randomly assigned to one of six conditions, crossing sentence type (Transitive, Periphrastic, Baseline/no sentence) and change type (Manner, Result) in a between-subjects design. To ensure that participants were able to view and hear the movies presented over the Internet, and to check language skills, all participants first watched a movie similar to the experimental stimuli and provided a short description. Participants were informed that they would view pairs of movies and be asked to report whether they were the same or different.

A schematic of a sample trial is shown in Figure 2. On each trial, participants were first instructed to get ready for the next movie, with the target sentence (or no sentence, in the Baseline condition) printed below. Then they saw the base movie for that stimulus - playback controls were disabled so that participants could not watch movies more
than once. After reading the target sentence again, participants performed math problems during a 5 second delay. Finally, they viewed a second movie. In the nochange trials, they simply saw the initial movie a second time. In the change trials, they saw the altered version of the movie that was appropriate for their condition (Manner or Result.) Participants were asked whether they thought the second movie was the same or different from the first, and feedback was given after every trial. In total, participants saw 12 change trials and 6 no-change trials.

## Results

To ensure that participants were not simply reporting that all movies contained changes, performance on the nochange trials was used as criteria for inclusion in the analysis. 206 participants (mean 34.3 per condition) answered at least 5 of 6 no-change trials correctly and were included in all analyses below.

Figure 3 plots participants' accuracy on change trials. There was a significant Change x Sentence interaction ( $\mathrm{F}(2$, $200)=4.54, \mathrm{p}<0.02$ ) as well as a significant main effect of Change type $(\mathrm{F}(1,200)=8.22, \mathrm{p}<0.01$.) In the Transitive condition, participants were significantly better at noticing Result changes than Manner changes $(\mathrm{t}(75)=3.53$, $\mathrm{p}<$ 0.01 ); this difference was marginal in the Baseline condition $t(63)=1.74, p=0.086$.) For Periphrastic sentences, there was no difference in accuracy between Manner and Result conditions $(\mathrm{t}(62)=0.61, \mathrm{p}=0.55)$. As predicted, a planned comparison showed that result changes were detected more often following transitive sentences and manner changes were detected more often following periphrastic sentences $(\mathrm{t}(200)=3.22, \mathrm{p}<0.01)$.

Figure 3. Participants' accuracy on the 12 change trials

Because there was an unanticipated difference in detection rates for the Baseline (no sentence) conditions, we examined detection rates on each of the 12 individual 'change' items. This difference was almost entirely due to just three items where the salience of the manner and result changes were not well matched. For these three items, the result change was easier to detect at baseline than the manner change. (Close $-\mathrm{X}^{2}=7.79, \mathrm{p}<0.01$; Drop $-\mathrm{X}^{2}=$ 7.61, $\mathrm{p}<0.01$; Tip-Over $-\mathrm{X}^{2}=8.90, \mathrm{p}<0.01$ ). To clarify the nature of the differences observed for Transitive and Periphrastic sentence conditions, we removed these three items from subsequent analyses.

Following this removal of salience-mismatched items, the only significant omnibus result was a significant Change x Sentence interaction $(F(1,200)=4.14 \mathrm{p}<0.02)$. Again, the planned comparison was significant: result changes were detected with greater success after reading transitive sentences, while manner changes were detected more often following periphrastic sentences $(\mathrm{t}(200)=2.99, \mathrm{p}<0.01)$. These results are depicted in Figure 4.

## Discussion

As predicted, the choice of transitive or periphrastic descriptions had a marked impact on participants' memory

Figure 4. Accuracy on the 9 trials which did not show a significant baseline difference in detection rate between Manner and Result changes.
for scenes. Participants who heard transitive sentences were more likely to detect changes in the result of a direct causal event than changes in the manner. Participants who heard periphrastic causal sentences showed the reverse pattern, showing better performance when detecting manner changes. This pattern persisted when three items which were not matched on baseline manner/result salience were removed.

One concern with these results is that the periphrastic is a less frequent and more complex linguistic description than the transitive. As a result, participants may have simply been more attentive to the events after they were described with periphrastic sentences. Arguing against this interpretation however, participants in the periphrastic conditions were not more attentive to event changes across the board: indeed, they were more likely to neglect result changes. However, to further address this alternative explanation, we are currently investigating participants' memory for manner and result changes when they read other complex or infrequent sentences.

Note that the effect of sentence structure on scene representation in this experiment consists of relative inattention to particular change categories. While the manner and result detection rates are different for transitive and periphrastic sentences, the more frequently detected change in each case is statistically identical to the baseline detection rate $(\mathrm{t}(63)=0.96, \mathrm{p}=0.34 ; \mathrm{t}(79)=0.23, \mathrm{p}=0.82$.) This finding is consistent with the within/between category effect found for color words (Winawer et al 2007.) Russian speakers, who have separate basic color words for light and dark blue (goluboy and siniy), showed a between-category advantage for color perception. When they were asked to distinguish between color chips that were both siniy or both goluboy, they showed decreased performance compared to color chips which were equally similar but crossed the naming boundary. English speakers showed no such advantage for dark blue vs. light blue colors.

Together with Winawer et al's study, the current results suggest that event perception helps us identify the conceptual categories that are mapped to particular linguistic structures. When no sentence is presented, both manner and result changes are considered potentially relevant. However, when people read a sentence description, a particular perspective is imposed on their event representation which seems to make some categories important and some less important. For transitive sentences, manner changes which preserve the result (e.g. bending a toy with right vs. left hand, but reaching the same final position) seem to constitute a relatively unimportant difference, and changes are neglected. In contrast, the result of the action is central to the event representation, and participants continue to notice these changes. For periphrastic causal descriptions, the reverse is true: minor changes in the result are seen as relatively unimportant whereas minor changes in the manner are seen as central to the event.

Note that Wolff's theory of causal descriptions suggests that lexical (transitive) causatives are used only for direct causal events, while periphrastics are also used to describe mediated events. Wolff focuses on how people choose between the two sentence types for different scenes but does not make specific reference to how these descriptions affect attention to the manner in which a causal event is brought about. In this study, we are able to extend this work by showing that these descriptions have a specific effect on event perception. Even when considering events that can be described with either type of sentence, participants pay more attention to how an event took place after reading periphrastic causal descriptions than after reading transitive descriptions. With this change-detection method, it will also be possible to test other event aspects that have to do with the types of events Wolff has studied, such as changes in instrument or type of agent-patient contact.

Moving beyond causal descriptions, this method can also be used to test other hypothesized correspondences between syntactic structures and particular event features or semantic concepts. After viewing sentence-event pairings, the prediction is that participants will be more sensitive to changes that have to do with the event feature representations that map to the sentence. In contrast, when changes of the same salience are made to event aspects that are not central to the sentence-event mapping, participants will fail to notice these changes. Thus, patterns of memory and attention can allow us to discover the specific semantic content of particular sentence types.

This work provides an important advance in our understanding of how rich conceptual representations map onto the grammatical structures of language, a key problem in the study of language and thought. The mapping between language and thought goes in both directions - language provides the tools to describe a wide range of event construals, and in turn, the specific descriptions we use can influence event perception, altering which components of event representations are seen as most important. By testing how memory for events changes when people encounter different types of sentences, we can experimentally discover the underlying event features which structure our cognitive and linguistic representations, and begin to understand how these representations are used in the moment to understand and describe events in the world.

## Acknowledgments

This project was supported by funding from National Science Foundation and the John Merck Scholars Fund. Thanks also to Daniel Friel and Tara Venkatesan for their assistance with stimuli creation, and to the entire Early Childhood Cognition Lab at MIT for helpful discussion and feedback.

# Semantic Distance Modulates the N400 Event-Related Potential in Verbal Analogical Reasoning

#### Abstract

Computational accounts have traditionally focused on mapping between structured representations as fundamental to analogical processing. However, a recent connectionist model has been used to argue that structured representations may not be necessary to solve verbal analogies. Green and colleagues (2010) have shown that brain areas associated with analogical mapping become more engaged as semantic distance increases between verbal analogy source and targets. Herein, we had participants verify verbal analogies characterized for semantic distance while we monitored their brain waves using EEG. Our results suggest that the semantic distance between the source and target of a verbal analogy does influence early semantic processing as reflected in the N400 Event-Related Potential. However, successfully differentiating valid and invalid verbal analogies engages areas of prefrontal cortex widely associated with inhibitory processing and the integration of abstract relations in working memory. Thus, it appears that traditional semantic priming alone is likely insufficient to explain the full extent of analogical processing.

Keywords: analogy, semantic distance, EEG, N400

## Introduction

Analogical reasoning is fundamental to the way that humans learn and reason in day-to-day life.. Likewise, analogies have long been considered to be a core component of analytic intelligence (Spearman, 1927) and of great importance in learning and discovery (Holyoak \& Thagard, 1995). For nearly a century, researchers in cognitive science have developed theories and computational models to offer potential mechanisms for analogical processing (French, 2002). More recently patient-based (Morrison et al., 2004; Krawczyk et al., 2008) and functional neuroimaging studies (e.g., Bunge et al. 2005; Bunge et al. 2009; Green et al. 2010; Krawczyk et al., 2010; Volle et al., 2010; Watson \& Chatterjee, 2012) have begun to identify a network of brain areas, particularly the prefrontal cortex (PFC), essential for analogical reasoning.

Four-term verbal analogies have long been used as both a standard measure of intelligence and vocabulary knowledge. According to traditional accounts of analogical processing, to solve this type of problem the reasoner needs to (1) retrieve word meanings from semantic memory, (2) bind words into explicit abstract relations in working memory, and (3) perform a mapping in working memory between corresponding sets of words in the source and target. For instance, to verify the analogy:

> animal : zoo :: person : house
participants may (1) retrieve the meanings of the words animal, zoo, person, and house, (2) bind housed (animal), lived-in (zoo), housed (person), and lived-in (house) (3) and then map lives-in (animal, zoo) to lives-in (person, house) specifically discovering that animal analogically maps to person and zoo maps to house. Several researchers have used this type of approach as embodied in the LISA model (Hummel \& Holyoak, 1997; 2003) to account for patterns of verbal analogy performance (Morrison et al., 2004; Michael Vendetti \& Knowlton \& Holyoak, 2012).

In contrast, recent connectionist models of analogy (Leech, Mareschal \& Cooper, 2008) have proposed that four-term verbal analogies may be solved without the use of structured relations via a mechanism utilizing guided pattern completion in semantic memory. Contrary to previous accounts of analogical priming (Spellman, Holyoak, \& Morrison, 2001), Leech and colleagues argue that this mechanism of analogy could occur automatically without the use of explicitly represented relations and analogical mapping.

In addition to many experimental studies (see Holyoak \& Hummel, 2008) the former traditional relationally explicit approach is supported by findings showing that solving verbal analogies engages anterior regions of the PFC (Bunge et al., 2005; Green et al., 2010) frequently associated with processing abstract information (e.g., Christoff et al., 2009; Nikitin \& Morrison, 2011; Volle et

Figure 1: (a) Trial timeline. Participants were instructed to think of how the A:B were related and then decide whether the C:D pair was related in the same way. Calculated ERPs were time-locked to presentation of the C:D pair. (b) C:D pairs were used for all four conditions across four blocks of trials. Valid and invalid problems were matched for semantic distance using LSA for both near and far conditions.
al., 2010) and explicit relational integration (e.g., Bunge et al., 2009; Nikitin \& Morrison, 2011; Volle et al., 2010; Watson \& Chatterjee, 2012). However, a recent set of functional magnetic resonance imaging (fMRI) studies suggest that verbal analogical reasoning may exist on a continuum between the two approaches depending on the nature of the analogies. Green et al. (2010) developed a problem set of four-term verbal analogies that varied in the semantic distance between the source and target as measured using Latent Semantic Analysis (LSA, Landauer, Foltz, \& Laham, 1998). Green and colleagues found that the anterior regions of PFC frequently associated with relational integration and/or abstract information processing were engaged to a greater extent when the source and target domains of the analogy were more distant ("far" analogies). This result suggests that "near" analogies may employ processing less dependent on structured representations.

To further explore this distinction we employed Green and colleagues' method of differentiating near and far analogies to develop a large set of verbal analogy problems for use with scalp electroencephalography (EEG). Researchers interested in the use of semantic memory during language processing have frequently used EEG analyzed with event-related potentials (ERPs) to investigate the time-course of semantic processing. Specifically, the

N400 is a negative ERP component that typically peaks around 400 ms after presentation of the stimulus. The N400 increases in negativity as a stimulus (usually a single word) becomes more incongruous from its context (Kutas \& Federmeier, 2011). The N400 effect was first documented in sentence processing. For example, the italicized word in the sentence, "The cat will bake the food" will elicit a more negative N400 relative to, "The cat will eat the food" (Kutas \& Hillyard, 1980). Many studies of language processing and semantic processing have shown the N400 to be sensitive to contextual semantic meaning (Kutas \& Federmeier, 2011). Subsequent work has shown that the N400 effect is elicited in response to conceptual incongruities in other domains. For example, incorrect answers to simple symbolic (e.g., " 4 x $4=2 l "$ ) and verbal (e.g., "Twelve plus three equals sixteen.") arithmetic problems elicit an N400 effect (e.g., Niedeggen \& Rosler, 1999).

Importantly, this type of automatic semantic congruity processing as measured by ERP methodology occurs earlier in the time course of processing than structured comparisons such as syntactic processing or analogical mapping. For instance, a positive ERP component typically peaking around 600 ms after stimulus presentation (the P600) is sensitive to violations of syntax within a sentence (e.g., "The student will studying the lecture the professor gave on tuesday."; Osterhout \& Mobley, 1995). Likewise the P600 is also sensitive to violations in structure of music (Patel et al., 1998). Likewise, Nikitin and Morrison (2011) found that an ERP component linked to the comparison of relational structures during visual analogical reasoning began approximately 500 to 600 ms post stimulus presentation, once again after the N400.

To further explore the influence of semantic distance on analogical reasoning, we recorded EEG while participants solved sequentially presented four-term verbal analogy problems (e.g. $A: B:: C D$; see Figure 1) varying in the semantic distance between the source ( $\mathrm{A}: \mathrm{B}$ ) and target (C:D) word pairs. Semantic distances between the first and second word pairs were split into near (semantically similar) and far (semantically less similar) analogies. We hypothesized that near analogies would be more likely than far analogies to be solved via automatic semantic priming and thus the N400 ERP would be less negative for near than far analogies.

## Method

## Participants

Seventeen Loyola University Chicago undergraduate students ( $\mathrm{M}=21.4$ years old) participated in the experiment. Participants gave informed consent to take part in the study and were paid according to procedures approved by the Loyola University Chicago Institutional Review Board. One participant was excluded from the analysis due to poor EEG recording quality.

## Materials

Four-term verbal analogy problems were constructed from pairs of words representing one of five possible relations: kept in (e.g. animal:zoo), kind of (e.g. aluminum:metal), made of (e.g. candle:wax), used to (e.g. train:travel), and works for (e.g. curator:museum). To ensure that word pairs were representative of the claimed relation we had an earlier group of 10 participants perform a relation naming task with a candidate list of word pairs. In the present study we only included word pairs in which participants could quickly name the stated relation from the five possibilities. Word pairs with identical relations were paired to form valid analogies and pairs representing different relations were paired to form invalid analogies.

Following the methods of Green and colleagues (2010) we further divided valid and invalid analogies based on 4term semantic distance using Latent Semantic Analysis (LSA) into either near or far analogies. LSA performs complex algorithms on large corpora of text (semantic spaces) to produce semantic similarity ratings for pairs of words (Landauer, Foltz \& Laham, 1998). The Matrix Comparison feature in LSA allows users to enter a list of $n$ terms or word pairs and produce similarity ratings between all terms or pairs of words ( $n \times n$ ) entered in the list. Similarity ratings within the source ( $\mathrm{A}: \mathrm{B}$ ) and target ( $\mathrm{C}: \mathrm{D}$ ) of each analogy problem, as well as similarity ratings between the source and target, were acquired. The source word pairs and overall analogies were characterized for both near and far semantic distance using the obtained similarity ratings from LSA.

Two counterbalanced versions of 360 unique problems were created with 90 of each type of trial. For each version every C:D word pair was used in all four conditions. To minimize the chance of confounding the N400 due to repetition effects we divided each version into quarters so that CD word pairs could be separated in time, one in each quarter. Both valid and invalid problems differed with respect to semantic distance in the same way, and this was consistent across the quarters of the experiment. Importantly, problems did not differ with respect to mean word length or word frequency as measured using HAL (Burgess \& Lund, 1997; Balota et al., 2007) across problem types.

## EEG Recording Procedure

EEG was recorded from each participant using a 72-channel Biosemi Active2 EEG system. 64 electrodes were located at equidistant locations in a nylon cap. To expand the coverage of EEG monitoring we placed two electrodes on the inferior edge of the orbit of each eye. Raw EEG was re-referenced to an average of the two mastoid electrodes and then highpass filtered at 0.01 Hz . The signal was then band-stop filtered from 59 to 61 Hz to remove any AC electrical contamination. EEG signal was corrected for ocular artifacts using a spatial PCA filter, a method available in EMSE (Source Signal Imaging, San Diego CA). Signal was further cleaned via a $\pm 100 \mu \mathrm{~V}$ rejection criterion. Included
participants had fewer than $15 \%$ of trials rejected due to EEG artifacts. A 20 Hz low-pass filter was applied to ERPs for visualization only.

## Procedure

After being prepared for the EEG recording, participants sat in a quiet room equipped with a 21 -inch CRT monitor and an electronic response box. Participants sat 100 cm from the monitor. Stimulus width was adjusted to 4 degrees of visual angle. The task was run and data were collected using e-Prime 2.0 (Psychology Software Tools, Sharpsburg, PA).

After task instructions the participant performed 20 practice trials with feedback. Each trial began with a randomly jittered fixation screen that lasted 500 to 1000 ms (See Figure 1a). The first word pair was presented at the center of the screen for 3.3 s . Participants were instructed to think of how the pair of words was related. Following an equal sign presented for 750 ms , a second pair of words was presented for 3.5 s during which participants were decide whether the two pairs of words were related in the same way (i.e., formed a valid analogy). Participants indicated their choice by pressing one of two buttons with two fingers from their right hand. The entire experiment consisted of 360 trials divided into twelve blocks separated by 20 s rests.

## Results

## Behavioral Results

Participants were more accurate in judging near than far analogies (see Figure 2a; $F(1,15)=28.6, p<.001, \eta_{\mathrm{p}}{ }^{2}=$ .66). There was no difference in accuracy with respect to validity $\left(F(1,15)=.2, n s, \eta_{\mathrm{p}}^{2}=.01\right)$; however, there was a significant interaction between semantic distance and validity $\left(F(1,15)=8.5, p=.01, \eta_{\mathrm{p}}^{2}=.36\right)$. Further contrasts suggested that this interaction was driven by participants being more accurate for valid near than valid far problems $\left(F(1,15)=24.9, p<.001, \eta_{\mathrm{p}}^{2}=.62\right)$.

Participants were also faster in judging near than far analogies (see Figure 2b; $F(1,15)=12.1, p=.003, \eta_{\mathrm{p}}{ }^{2}=$ .45), faster in judging valid compared to invalid problems $\left(F(1,15)=9.7, p=.007, \eta_{\mathrm{p}}^{2}=.39\right)$, and the two factors also interacted $\left(F(1,15)=15.9, p=.001, \eta_{\mathrm{p}}^{2}=.51\right)$. The interaction was driven by participants being faster for valid near than valid far problems $\left(F(1,15)=22.6, p<.001, \eta_{\mathrm{p}}{ }^{2}=\right.$ .60) and faster for valid than invalid near problems $(F(1,15)$ $\left.=18.5, p=.001, \eta_{\mathrm{p}}^{2}=.55\right)$.

Figure 2: Verbal analogy (a) accuracy and (b) RT.

## EEG Results

We calculated grandaverage ERPs for correct trials for each of the four conditions (see Figure 3a). Initially we divided the first 1400 ms of processing into seven 200 ms epochs and performed a 2 (near vs. far) x 2 (valid vs. invalid) x 7 (Time) repeated measures ANOVA on mean amplitudes from a central electrode (i.e., Cz ) frequently used in N400 analyses. There were reliable main effects of semantic distance $\left(F(1,15)=20 ., p<.001, \eta_{\mathrm{p}}^{2}=.57\right)$, and time $\left(F(6,90)=11.8 ., p<.001, \eta_{\mathrm{p}}^{2}=.44\right)$, and a trend towards a difference based on the validity of the analogy $(F(1,15)=$ 3.5., $p=.08, \eta_{\mathrm{p}}^{2}=.19$ ). Importantly there was a three way interaction of type, validity and time $(F(6,90)=5.1 ., p<$ $.001, \eta_{\mathrm{p}}{ }^{2}=.26$ ). As can be seen in Figure 3a far problems have more negative ERPs beginning around the N400; however, near invalid problems later join far valid and invalid problems as being more negative than near valid problems. While topographies based on valid/invalid subtractions (see Figure 3b) are broad they tend to suggest that differences in the near valid vs. invalid conditions move from more central to more right frontal distributions.

Second, we focused on the N400 and calculated mean amplitude for an early $300-500 \mathrm{~ms}$ time window typically used for analyzing the N400 in studies of semantic priming. We ran a 2 (near vs. far) x 2 (valid vs. invalid) repeated measures ANOVA. The N400 as measured in this time window was more negative for far than near problems regardless of problem validity $\left(F(1,15)=19.5 ., p<.001, \eta_{\mathrm{p}}{ }^{2}\right.$ $=.57)$, with no interaction $\left(F(1,15)=1.5, p=.24, \eta_{\mathrm{p}}{ }^{2}=.09\right)$.

To compare our results to those of Green and colleagues (2010) and to attempt to understand the time course of neural activity with respect to semantic distance and topography, we conducted an additional analysis on just correct near and far valid problems (see Figure 4). In this analysis we focused on the early $300-500 \mathrm{~ms}$ time window previously mentioned and a later $900-1100 \mathrm{~ms}$ time window closer to the response. Nikitin and Morrison (2011) have previously shown this later time window to be associated with analogical mapping in a visual analogy task. Adapting
the methods of McCarthy and Woods (1985) we normalized the subtraction of near and far mean amplitudes for each time window. A 2 (near vs. far) x 2 (early vs. late) repeated measures ANOVA demonstrated that the normalized near/far subtraction reversed from initially being greater in central areas to later being greater in frontal areas yielding a reliable interaction (see Figure $4 \mathrm{~b} ; F(1,15)=9.6, p=.007$, $\eta_{\mathrm{p}}{ }^{2}=.39$ ). Normalized subtractions showed an increase in frontal channels over time $\left(F(1,15)=5.9, p=.02, \eta_{\mathrm{p}}^{2}=.28\right)$, while central channels showed a trend towards a decrease $\left(F(1,15)=3.6, p=.08, \eta_{\mathrm{p}}^{2}=.19\right)$. Thus, we believe that Green and colleagues (2010) result that frontopolar areas were more active for far than near analogies may be driven by later processing likely reflective of the greater reliance on analogical mapping while solving far analogies.

## Discussion

As hypothesized, we found that the semantic distance between source and target word pairs in verbal analogy problems modulated the mean amplitude of the N400 ERP with near analogies eliciting less negative N400s compared to far analogies. The N400 ERP is sensitive to word repetition, semantic integration, and semantic expectancy effects (Kutas \& Federmeier, 2011). Controlling word repetition effects by utilizing identical second word pairs across all four conditions ensured semantic integration processes were isolated when analyzing N400 modulation. A more negative N 400 for far analogies can be explained by the 'knowledge integration effort' view, which suggests negativity in N400 amplitude is directly proportional to the integration effort required to extract lexical representations for each target (Holcomb, 1993). Increases in semantic integration effort in far analogies were reflected in more negative N400 mean amplitude as semantic distance between source and target analogs increased.

The knowledge integration effort view also explains the less negative N400 mean amplitude observed in near analogies. As semantic distance between source and target analogs decreased, less semantic integration effort was

Figure 3: a) Grandaverage stimulus-locked ERPs (electrode Cz ) for correct Valid and Invalid, near and far analogies. b) Topographic maps of valid/invalid subtractions for near and far analogies across the time course.

b) Early ( $\mathbf{3 0 0}-500 \mathrm{~ms}$ )

Late ( $900-1100 \mathrm{~ms}$ )

required to derive lexical representations. In other words, deriving the semantic information of the first word pair and determining the source analog relation facilitated access to the second word pair, resulting in a less negative N400 in near analogies. A previous study demonstrated that analogous source pairs facilitated lexical access to target words when participants were instructed to attend to and use relational information (Spellman, Holyoak \& Morrison, 2001). Since participants were solving analogies and attending to the relations between words, analogical priming
may have facilitated semantic integration particularly in the near analogy condition.
However, while semantic priming may be sufficient to explain near valid analogies it may not be sufficient to reject false analogies or perform far analogies. Beginning at the N400, valid and invalid ERPs for near analogies diverge. Closer inspection of the topographies (see Figure 4) suggests engagement of areas of the brain traditionally associated with inhibitory processing during analogy (Cho et al. 2010; Watson \& Chatterjee, 2012). In fact, Morrison and colleagues (2004) have previously demonstrated that frontal patients have great difficulty rejecting lures in twochoice verbal analogy problems where semantic congruity for the false item is greater than for the true item.
Likewise, while far analogies do show a more negative N400 than near analogies, suggesting that automatic semantic processing is indexing semantic distance in analogy, there is no difference in the N400 between far valid and invalid analogies demonstrating that semantics alone are insufficient for complete analogical processing. In fact, like invalid near condition analogies, far analogies engage prefrontal cortex to a greater extent, consistent with findings by Green and colleagues (2008).
Thus, our findings suggest approaches relying solely on tranditional semantic priming, such as recent connectionist approaches (e.g., Leech, Mareschal \& Cooper, 2008),have limited applicability when the distance between the source and targets of analogies increases, or when the reasoner must choose between alternative analogues where semantics alone do not indicate the more relationally similar match.

## Acknowledgements

#### Abstract

The temporal co-occurrence of a novel word and a visual referent undoubtedly facilitates establishing the meaning of a word. It is less understood, however, how precisely learners can keep track of the frequencies of these co-occurrences across situations. Observational learning may rely on one or few highly informative exposures (propose-but-verify) or it may be driven by the collection of evidence in a more gradual and parallel manner (multiple-hypotheses tracking). We evaluated both hypotheses within two experiments and found that learners were able to keep track of more than one hypothesis for a novel word. However, this memory was strongly dependent on each learner's individual learning path (i.e., which meanings they had considered before) and influenced by the order of presentation of potential referents. We argue for an account of a multiple-proposal memory rather than a multiple co-occurrence memory.

Keywords: observational word learning; memory; crosssituational analysis; multiple hypotheses tracking; propose-but-verify; individual learning paths

## Observational Word Learning

While observing the world can be a very direct path to the meaning of a novel word (fast mapping, Carey, 1978), the relationship between both sources of input is often too ambiguous to make a promising immediate guess. The learner could solve this problem in various ways: On each learning instance, she could store multiple possible solutions and then identify the best solution across several learning instances through an intersective process, an assumption that is commonly understood to underlie the idea of crosssituational word learning (Quine, 1960; Yu \& Smith, 2007). Alternatively, she could make an immediate guess about the word's meaning and wait for confirmation or rejection. In this case, the learner would have no memory for the alternatives that were not guessed, but maximally a memory for the different guesses tried along the way until the correct one is identified.

While experiments reported in Medina, Snedeker, Trueswell, \& Gleitman (2011) and Trueswell, Medina, Hafri, \& Gleitman (2013) support this latter idea (propose-butverify account), other studies indicate that learners are able to extract multiple hypotheses on each learning instance (Vouloumanos, 2008; Vouloumanos \& Werker, 2009; Koe-
hne \& Crocker, 2011). An important aspect that is ignored in these studies, however, is the role that each learner's individual learning path plays. It is therefore unclear whether one and the same person in fact stores multiple possibilities for a word and if this is the case, under which circumstances. One factor that has been shown to be relevant to this question is the order in which the language novice has encountered and re-encountered potential referents (Medina et al., 2011).

We evaluate the way learners exploit observational word learning situations within two experiments, employing the standard paradigm of psychologically investigating crosssituational word learning. Importantly, we consider both the learner's individual learning path and the order of exposures and re-exposures of potential referents. We moreover address the possibility that the different outcomes in different studies may be due to the implemented experimental procedure. In particular, we compare a procedure, in which participants make a choice on each learning trial (Exp. 1) to a passive look-and-listen learning phase (Exp. 2).

## Learning based on Co-occurrence Frequencies

Trueswell et al. (2013) examined learners' memory in observational learning situations in a series of experiments. During the learning phase, participants were presented two or five visual referents and a spoken sentence containing one novel noun per trial. The task was to choose that referent (by mouse click) in each trial that the learner believed to match with the novel noun. Trueswell et al. found that even if the learning situations were greatly simplified but still ambiguous (just two possible referents), participants later showed no sign of memory for any referent other than the one they had selected. Specifically, when a learner reencountered a noun (e.g., mipen), he was at chance at selecting the correct referent (e.g., bear) if he had made the wrong choice the previous time he had encountered mipen (e.g., if he had chosen door rather than the correct bear). Had he remembered that the unselected (but correct) referent (bear) had co-occurred with mipen, he could have unambiguously identified it as correct in the current situation.

Interestingly, other studies indicate that learners are able to precisely differentiate the co-occurrence frequencies of different alternatives for one noun. Vouloumanos (2008)
employed a passive look-and-listen learning phase with one referent and one noun per trial. Over the course of the experiment, each noun co-occurred with several referents with varying frequencies. In a final forced-choice vocabulary test, learners could differentiate between these alternatives based on small differences in their co-occurrence statistics. However, since there was only one referent per learning trial, this study does not answer the question whether multiple possibilities are memorized from one situation. Addressing this issue, Koehne \& Crocker (2011) integrated a learning procedure with four objects depicted for each novel noun. As in Vouloumanos (2008), nouns co-occurred with objects with different frequencies ( $83 \%, 50 \%$, and $17 \%$ ). Interestingly, when the $83 \%$ referent was not available in a final forced-choice test, learners preferred the $50 \%$ referent over $17 \%$ alternatives. This result suggests sensitivity to differences in co-occurrence statistics even when learning trials are ambiguous.

Differences between Trueswell et al. and Koehne \& Crocker could be due to the experimental procedure (forced choice vs. look-and-listen during learning). However, individual learning paths were not considered in Koehne \& Crocker: It is unclear whether selecting the $50 \%$ referent depended on the choices, or proposals, the learner had made before and whether one and the same learner had stored multiple alternatives for one noun.

Indeed, as noted by Trueswell et al. (2013), the strictest version of a propose-but-verify procedure, in which only a single meaning is ever maintained, is inadequate because it fails to explain the learning of ambiguous words. They therefore propose that "when a confirmed (and even reconfirmed) hypothesis for a word is then not supported by a later context, the learner would actively search memory for past rejected hypotheses, and may ... establish a second meaning for the word." Here we call this multiple-proposal memory, in which only previously proposed meanings are available in memory rather than entire referential sets from past learning instances (i.e., the context) as stipulated by the most common cross-situational accounts.

The method used in the two experiments presented here allows us to differentiate between the predictions from the propose-but-verify versus the multiple-hypothesis-tracking account. In particular, it addresses the question whether one and the same learner keeps track of more than one hypothesis for a novel word.

## Experiment 1

Experiment 1 addresses the questions of whether and how learners track multiple meanings for a novel word and what role both the learning path and the order of (re-) exposures of potential referents play in this process.

## Methods

Participants 36 participants were tested, four of which had to be excluded due to technical and eye-tracking problems.

Data of 32 participants (11 Male, average age 22) was analyzed.

Design, Materials, \& Procedure The overall task of Experiment 1 was to learn the meanings of 16 novel nouns. Learning trials consisted of one spoken English sentence containing one of the novel words (e.g., I see a moke!) and four objects that were depicted on the screen. During training, each noun had six learning trials, intermixed with the other learning trials. Crucially each of the 16 nouns was assigned two meanings with different co-occurrence frequencies: One referent was present whenever the noun was present (six times, $100 \%$ referent, e.g., television), the other referent was present in only half of the cases the noun was (three times, $50 \%$ referent, e.g., dog). All other objects cooccurred only once with a noun (17\%). We manipulated the order in which trials including and excluding the $50 \%$ referent were presented within four levels (within participants): Firstly, the $50 \%$-present (P) and $50 \%$-absent (A) trials could be either blocked (AAAPPP and PPPAAA) or not blocked (APAPAP and PAPAPA); secondly, the first encounter of a noun could be either an A trial (AAAPPP and APAPAP) or a P trial (PPPAAA and PAPAPA).

On each learning trial, participants selected by mouse click the referent they thought belonged to the novel noun. After each response, they gave a confidence rating for their selection (on a scale from 1 to 9 ). No feedback was given and participants were not informed that nouns may have multiple meanings.

After all six learning trials had been encountered for a word, a final test was given for each word, in which eight objects and one spoken word were presented and learners were asked to again select the matching referent and indicate their confidence. The $100 \%$ referent, however, was not available which means that the $50 \%$ object was the one with the highest co-occurrence rate - all other objects were $0 \%$ and $17 \%$ referents.

The experiment consisted of two parts: Eight novel nouns were taught and tested (Block 1) before the other eight noun were taught and tested (Block 2). Order of presentation of learning and test trials was pseudo-randomized: Between two exposures of the same noun, there was always at least one but not more than 8 trials with other nouns. Participants were run individually and the experiment lasted approximately 30 minutes.

Predictions Standard cross-situational accounts (such as Yu \& Smith, 2007, Vouloumanos, 2008, and Koehne \& Crocker, 2001) predict that learners precisely keep track of the co-occurrence frequencies between nouns and referents. The $50 \%$ referent should therefore be chosen at final test above chance in all conditions, independent of both the learning path and the order of (re-)exposures of $50 \%$-present trials.

According to a strict propose-but-verify account selection of the $50 \%$ alternative at final test would occur if and only if it is the current working hypothesized meaning - that is, if
the $50 \%$ referent had been selected on the preceding learning instance. This is impossible when the $50 \%$ referent is Absent on the last learning trial, predicting chance performance in conditions PPPAAA and PAPAPA. During the final test in the other two conditions, the $50 \%$ alternative would be selected above chance on those rare occasions when the learner had selected the $50 \%$ referent on the last learning instance (i.e., when they failed to learn the $100 \%$ target by Instance 6).

According to the weaker propose-but-verify account, a final test with the $100 \%$ referent absent will trigger consideration of all past proposed meanings. This means that abovechance performance on the $50 \%$ referent is expected if and only if the learner had previously selected (clicked on) a $50 \%$ referent during the learning phase. One might expect such a memory to have a recency component: More recently proposed meanings will be easier to remember. Moreover, early encounters of a string of $50 \%$ referents (i.e., PPPAAA) will increase the probability that this referent will be selected during the learning phase and thus more likely to be recalled at test. Conversely, it is very unlikely during learning that the $50 \%$ referent will be selected on any trial when these occurrences are grouped late in the sequence (AAAPPP): Most learners will have already locked onto the $100 \%$ item as the referent by Instance 4, and thus rarely select the $50 \%$ referent during learning. Therefore, they will not select it at test either.

## Data Analysis, Results, \& Discussion

The results are most consistent with the weaker propose-but-verify account. Across conditions, participants selected the $50 \%$ referent in the final test significantly more often than chance $(25.4 \%$ vs. $12.5 \%$ chance; $t(31)=7.77, p<$ $.001)^{1}$. Both confidence ratings and reaction times support that this difference is meaningful: Ratings were significantly higher $(\chi 2(1)=17.87, p<.001)$ and reaction times were significantly lower $(\chi 2(1)=9.36, p<.01)$ when the $50 \%$ referent was chosen than when it was not. Moreover, it was chosen significantly more often than any other of the seven ( $0 \%$ and $17 \%$ ) objects.

While this trend holds for all four conditions, differences to chance were significant only in Conditions PPPAAA $(34.4 \% ; t(31)=4.91, p<.001)$, PAPAPA $(27.3 \% ; t(31)=$ $4.32, p<.001)$, and APAPAP ( $23.4 \% ; t(31)=2.80, p<.05)$ but not in AAAPPP $(16.4 \% ; t(31)=1.02, p=.32$; Figure 1). This finding is inconsistent with a standard cross-situational account because all conditions should have been above chance independent of presentation order. It is also inconsistent with the strict propose-but-verify account because PPPAAA and PAPAPA ought not be above chance, but they are. Consistent with the weaker propose-but-verify, PPPAAA offers the best performance overall whereas AAPPP offers the worst.

To get insight into the roles of ordering and learning paths on the final test, we analyzed the effects of Condition and

[^125]Previous Selection of the 50\% Referent, that is, whether the $50 \%$ referent had been chosen in the previous encounter when it had been present. Note that this trial was in different positions depending on condition: It was the last trial in Conditions AAAPPP and APAPAP in Condition PAPAPA, and the fourth to last trial in Condition PPPAAA.

Figure 1: Selections in test, Exp. 1
Consistent with the weaker version of propose-but-verify, we found that participants were only above chance at selection of the $50 \%$ referent at test if they had selected the referent on its last encounter during learning (Figure 2). Note that the number of observations contributing to each proportion differs in the way expected if learners were using the weaker propose-but-verify procedure during the learning phase; the $50 \%$ referent was selected on the previous encounter during learning only 24 times (out of 128) in AAAPPP, but 56 times in PPPAAA. In APAPAP it was chosen 27 times and in PAPAPA 32 times. If selected during learning however, it was recalled at final test at similar rates regardless of condition (i.e., Figure 2).

To confirm the reliability of the effects in Figure 2, we conducted a multi-level logistic regression using Condition and Previous 50\% Referent Accuracy as predictors of selecting the $50 \%$ referent at test, entering both as fixed effects (using the lme4 package in R, Bates, 2005). Random intercepts and slopes of Subjects and Items were integrated. If a model did not converge, random effects were reduced until convergence was reached (always discarding the random effect with the smallest effect). Main effects were tested using model comparison (Chi-Square values are reported; Baayen, Davidson, \& Bates, 2008). We found a significant effect of Previous 50\% Referent Accuracy only $(\chi 2(1)=$ 80.21, $p<.001$ ) but no effect of Condition $(\chi 2(3)=3.67, p$ $=.30)$ and no interaction $(\chi 2(3)=4.52, p=.21)$. T-tests confirm that for that subset of trials for which it was not the case that the $50 \%$ referent had been chosen in the previous learning trial in which it had been present, selecting the $50 \%$ referent was not above chance $(t(31)=-.68, p=.50)$. This reveals that, independent of condition, the $50 \%$ referent was only chosen reliably if it had also been chosen in the previous encounter for which it had been present.

Interestingly, 50\% selection was still above chance when it additionally was the case that the $100 \%$ referent had been chosen two to five times during learning $(t(25)=6.43, \mathrm{p}<$ .001). This means that one and the same learner could consider the $100 \%$ referent as the correct referent and still be sensitive to the fact that the $50 \%$ referent was a better candidate than the $17 \%$ objects as long as the $50 \%$ referent, as well, had been considered.

This pattern of results supports the weaker version of the propose-but-verify account: While in fact a referent is only stored as the potential meaning if it has been actively considered before, this consideration does not need to happen in the absolutely previous encounter of the noun but only in the last common encounter of the noun and that referent. This means that learners do not only memorize the last guess they made for a noun but also less recent guesses. Our results are clearly not in line with the hypothesis that learners are equipped with a general multiple co-occurrence memory.

Figure 2: 50\% referent selections in test, Exp. 1
It is possible that the results from Experiment affected by the employed learning procedure: Forcing a selection on each trial may enforce the influence of the learning path (i.e., previous accuracy). We address this possibility in Experiment 2.

## Experiment 2

Experiment 2 investigates whether learning path and conditions have the same effect on memorizing potential referents if learners are not forced to make a choice on learning trials.

## Methods

Participants 39 participants were tested, seven of which had to be excluded due to technical and eye-tracking problems. Data of 32 participants ( 16 Male, average age 23) was analyzed.

Design, Materials, \& Procedure The learning paradigm, design, materials, and procedure were exactly the same as in Experiment 1 except that participants were asked to simply look and listen during learning trials while trying to figure out what the novel nouns mean. As in Experiment 2, however, trial change was self-paced (elicited by button press). Moreover, participants' eyes were tracked using a Tobii 1750 eye-tracker (sampling rate 50 Hz ).

Predictions Hypothesizing that clicking does not influence the learner's behavior predicts that one will find the same results as in Experiment 1. Hypothesizing that clicking enforces previous accuracy to be crucial on the other hand predicts a weaker effect of the learning path on the memory for the $50 \%$ referent.

## Data Analysis, Results, \& Discussion

Selecting the $50 \%$ referent in the test again was significantly more frequent than would be expected by chance ( $22.7 \%$ vs. $12.5 \% ; t(31)=6.07, \mathrm{p}<.001$ ) and than selecting any of the other candidates. As in Experiment 1, confidence ratings were higher $(\chi 2(1)=13.12, p<.001)$ and reaction times were lower $(\chi 2(1)=5.12, p<.05)$ when the $50 \%$ referent was selected than when another object was chosen.

Selection rates were (at least marginally) significantly above chance in all four conditions (PPPAAA: 29.9\%, $t(31)$ $=4.53, \mathrm{p}<.001$; PAPAPA: $18.8 \%, t(31)=1.76, \mathrm{p}=.09$; APAPAP: $22.7 \%, t(31)=3.13, \mathrm{p}<.01$; AAAPPP: $19.5 \%$, $t(31)=1.83, \mathrm{p}=.08$, Figure 3$).$

Figure 3: Selections in test, Exp. 2
To evaluate the effect of the learning path although no choices were made during learning, we used learners' eye movements as a predictor: Specifically, we coded test trials for the frequency of $50 \%$-present learning trials in which the $50 \%$ referent had been fixated more often than any of the three other candidates after the novel noun was presented (i.e., from onset of the noun until the self-paced end of the trial). The rationale of this coding was that looking at a referent most reveals that participants had paid attention to it, indicating that it was selected as the potential referent.

We then included this measurement of Previous 50\% Referent Accuracy as a predictor, together with Condition (Fig-
ure 4). Similar to Experiment 1, we found that choosing the $50 \%$ referent at test was not predicted by Condition $(\chi 2(3)=$ $.96, p=.31$ ) but by Previous 50\% Referent Accuracy ( $\chi 2(1)$ $=7.49, p<.01)$. Again, there was no interaction $(\chi 2(3)=$ $0.89, p=.83$ ). And again the number observations across conditions patterned like in Experiment 1 in terms of how often the $50 \%$ referent was 'selected' (by eye) on its last occurrence during learning ( $\mathrm{N}=22$ for AAAPPP; $\mathrm{N}=44$ for PPPAAA; $\mathrm{N}=24$ for APAPAP; and $\mathrm{N}=23$ for PAPAPA).

Figure 4: 50\% referent selections in test, Exp. 2
Interestingly, however, the $50 \%$ referent was still chosen significantly more often than chance at test if it was not looked at most often in the previous encounter $(t(31)=2.43$, $\mathrm{p}<.05$ ). We therefore also coded test trials for whether the $50 \%$ referent had been looked at most in any (i.e., at least one) learning trial (Any Accuracy). We found that if this was not the case, selecting the $50 \%$ referent was not more frequent than chance $(t(21)=-.21, p=.83)$. Any Accuracy was a marginally significant predictor $(\chi 2(1)=3.44, p=.06)$ whereas Condition was not $(\chi 2(3)=3.45, p=.33)$ and both did not interact $(\chi 2(3)=1.27, p=.74)$.

Similar to Experiment 1, having looked at the $100 \%$ referent most often in two to five learning trials did not change this pattern: The $50 \%$ referent was still chosen significantly more often than chance as long as it was also looked at most at least once $(t(31)=3.80, p<.001)$.

These results suggest that learners' behavior when choices were not forced during learning was similar to their behavior when they were forced to respond (i.e., as in Experiment 1). While it may be less crucial that the $50 \%$ referent was paid particular attention to exactly the last time it was encountered, the data indicates that it is was necessary that it at some point in learning it had been attended to. While this difference could suggest that memory in Experiment 2 was better than in Experiment 1 (i.e., that learners stored all proposals rather than only the last one), the different measurements of Previous 50\% Referent Accuracy cannot be perfectly compared with one another.

Most important, however, is that even if the learner is not forced to make decisions during learning, it is still crucial for a potential referent to be paid particular attention to at some point. We interpret this as a confirmation of our findings from Experiment 1: Learners show no sign of a general multiple co-occurrence memory but they are able to memorize more than one proposal they have made.

## Analyses Experiments 1 \& 2

In order to evaluate a potential difference between Experiments 1 and 2 regarding the influence of Condition, we entered data from both into one analysis. Experiment (Experiment 1: click vs. Experiment 2: no click) and Condition were used as fixed factors. We found a marginal effect of Condition ( $\chi 2(3)=7.61, p=.06$ ), no effect of Experiment $(\chi 2(1)=1.59, p=.21)$, and no interaction $(\chi 2(3)=3.22, p=$ .36 ; Figure 5). We then grouped the four conditions into two: $50 \%$ present in first trial (PPPAAA \& PAPAPA) versus $50 \%$ absent in first trial (AAAPPP \& APAPAP) and repeated the analysis. While selecting the $50 \%$ object was significantly more frequent in the first-trial present than the first-trial absent conditions ( $\chi 2(1)=6.63, p<.05$ ), still neither an effect of Experiment $(\chi 2(1)=1.04, p=.31)$ nor an interaction was found $(\chi 2(1)=2.31, p=.13)$. Within experiments, however, both condition groups differed significantly only for Experiment $1(\chi 2(1)=8.04, p<.01)$ but not for Experiment $2(\chi 2(1)=0.51, p=.47)$. It is therefore not quite clear whether the order of exposure and re-exposure was equally meaningful to both Experiments. Possibly, it was slightly more important in Experiment 1 than Experiment 2 that a referent's first encounter happened early, as also indicated by the missing significance of selecting the 50\% referent in Condition AAAPPP in Experiment 1 (Figure 1). Either way, for both experiments, the effect of Previous Accuracy was a much clearer predictor than Condition.

Figure 5: 50\% referent selections in test, Exp. $1 \& 2$

## Conclusions \& General Discussion

Results from Experiments 1 and 2 reveal that learners successfully learned to differentiate between co-occurrence
frequencies of $50 \%$ versus $17 \%$ and $0 \%$ even though another referent co-occurred perfectly ( $100 \%$ ). However, this was only the case if the $50 \%$ referent was in the learner's attention at least once before (or if it even was actively selected). Importantly, the $50 \%$ referent was also stored even if it was not the only referent that the learner had considered (i.e., when both the $100 \%$ referent and the $50 \%$ referent were in the learner's focus of attention at some point during learning). These findings clearly reveal that while cooccurrences were not generally all stored, 'multiple proposal' memory is possible in observational word learning. This is not in line with the standard cross-situational account whereas it generally supports a propose-but-verify account. Interestingly though, selecting the $50 \%$ referent was above chance in conditions PPPAAA and PAPAPA; unlike a strict propose-but-verify theory would predict, learners can memorize more than the most recent choice they have made.

Asking participants to select a referent during learning trials did not generally suppress memorizing multipleproposals. While it may be the case that it is more important for a forced-choice learning procedure than the non-forced choice one that the $50 \%$ referent is considered exactly in the previous encounter of it, a clear comparison between choosing and looking is impossible. If the difference is real, it would indicate that forcing a choice enhances the role of previous consideration, possibly because a stronger memory trace is built by actively (and physically) making a selection than by mental consideration.

Our results moreover at least indicate that there is a possible influence of the order in which referents are firstly encountered and re-encountered: Early on, when the hypotheses space is still completely open, learners are more willing to memorize co-occurring objects as potential meanings than later, when other hypotheses (or considerations) have already been made for a novel noun. This may be more strongly the case when selections are forced even early on in learning (in Experiment 1).

## Summary

We investigated learners' memory for co-occurrence frequencies in referentially ambiguous observational-word learning situations within two experiments. Our data reveals that while participants were able to recall more than one potential meaning for a noun, this memory was dependent on the person's single considerations during learning: Only if a potential meaning had been proposed before (i.e., selected or paid particular attention to), it was stored. However, learners memorized more than the most recent proposal they had made for a novel word. Moreover, a meaning was more likely to be proposed if it co-occurred with a noun early on the learning path. While this whole pattern was very similar independent of the learning procedure (choice made during learning, Experiment 1, vs. no choices made, Experiment 2), the influence of being proposed early may be enhanced when choices are made. In line with a moderate version of the propose-but-verify account (Medina et al.,

2011; Trueswell et al., 2013), our results can be accounted for by a multiple-proposal memory rather than a multiple-co-occurrence memory. Indeed, such a procedure is logically necessary to explain the learning of words with more than one meaning (i.e., homophones). Future research is necessary to explore the conditions under which ambiguous words are successfully learned, taking into account the mutually exclusive occurrence of appropriate referents (Meaning 1 vs. Meaning 2), which was not modeled experimentally here (i.e., the $100 \%$ referent was simultaneously present alongside the $50 \%$ referent on each " P " learning trial). Moreover, other distinguishing contextual features likely support the differentiation of two meanings for the same word. Finally, future work must examine how well these observations hold for naturally occurring word-learning environments in which referential ambiguity is greater and the contexts of word use are more variable. Artificial stimuli like those used here offer better experimental control and thus allow for closer examination of the learning mechanism but do not address how this mechanism responds to more typical input (Medina et al., 2011; Trueswell et al., 2013).

# Awareness in Decision-Making: Implicit Influences or Measurement Biases? 

Emmanouil Konstantinidis (emmanouil.konstantinidis.09@ucl.ac.uk) \& David R. Shanks (d.shanks@ucl.ac.uk)<br>Department of Cognitive, Perceptual and Brain Sciences<br>University College London<br>26 Bedford Way, WC1H 0AP, London,UK

#### Abstract

Can our decisions be guided by unconscious or implicit influences? According to the somatic marker hypothesis, emotionbased signals guide our decisions in uncertain environments outside awareness. However, evidence for this claim can be questioned on the grounds of inadequate assessments of conscious knowledge. Post-decision wagering, in which participants make wagers on the correctness of their decisions, has been recently proposed as an objective and sensitive measure of conscious content. In the experiments reported here, we employed variations of a classic decision-making paradigm, the Iowa Gambling Task, in combination with wagering in order to investigate the role played by unconscious influences. We also examined biases that affect wagering strategies such as the definition of the optimal strategy and loss aversion. Our results demonstrate the inadequacy of post-decision wagering as a direct measure of conscious knowledge and also question the claim that implicit processes influence decision-making.

Keywords: Iowa Gambling Task; decision-making; postdecision wagering; awareness; implicit learning; loss aversion.

## Introduction

One of the most influential paradigms in the study of decision-making under uncertainty is the Iowa Gambling Task (IGT), a four-armed bandit task which requires participants to sample from decks of cards (labeled A-D) with different monetary payoffs (Bechara et al., 1994). Each card selection yields either a win or a combination of a win and loss. Overall, two of the decks are bad, leading to higher immediate wins but long-term losses (a net loss of $-\$ 25$ per card) whereas the remaining two are good, leading to lower immediate rewards but long-term wins (a net win of $+\$ 25$ per card). Another feature of the task is that the decks differ in the probability of loss with two having infrequent $(p=.1)$ and two decks having frequent $(p=.5)$ losses.

The IGT was initially designed to test empirically the somatic marker hypothesis (SMH), according to which bodily affective signals or markers can assist decision-making processes by marking response outcomes with an emotional signal, thus facilitating the selection of the most rewarding options in situations of uncertainty (see Damasio, 1996). A major assumption regarding somatic markers is that they can inform advantageous decision-making even when participants are not aware of the quality of their decisions.

## Measures of Conscious Knowledge in the IGT

In a highly influential study, Bechara et al. (1997) assessed participants' knowledge by pausing the task every 10 trials and asking them to report whatever they knew and felt about the task. In addition, participants' electrodermal skin conductance responses (SCRs) were measured as an index of emotional arousal. The crucial finding was that participants se-
lected cards from the good decks before they had conscious knowledge that those decks were the best. Importantly, the SCRs were higher prior to selections from the bad decks, suggesting that non-conscious biases (or markers) helped participants to avoid disadvantageous selections.

The assertion that our decisions are guided by implicit influences has been extensively criticized on the basis of weaknesses in the method that Bechara et al. (1997) used to probe awareness. Broad questions often fail to capture the rich spectrum of conscious knowledge, and moreover participants may not fully report their knowledge due to a conservative response criterion (see Newell \& Shanks, in press). Following these methodological considerations, Maia and McClelland (2004) developed a more sensitive test of awareness in the form of a quantitative questionnaire. They asked their participants to rate each deck on a numerical scale, to report the expected wins and losses from each deck, and to indicate which deck they would pick if they could only choose from one deck for the rest of the task. Using this assessment, Maia and McClelland found that optimal performance on the IGT was accompanied by accurate reports of the decks' payoffs, indicating that there is little evidence that implicit or emotional biases are essential for successful learning of the task structure.

## Post-Decision Wagering

Despite the apparent evidence in favor of conscious processing in the IGT, Bechara et al. (2005) suggested that the method of probing awareness used by Maia and McClelland (2004) was intrusive and so may render participants more rapidly aware of the task structure and thus undermine the role of somatic markers. In order to avoid the methodological inconsistencies created by verbal reports and numerical confidence ratings, Persaud, McLeod, and Cowey (2007) developed a novel non-verbal method of assessing awareness in the IGT, in which participants are required to make wagers after their card selections (post-decision wagering; PDW). The rationale is that if a participant maximizes her winnings through advantageous wagering (high wager after a good deck choice or low after a bad deck), then this is taken to indicate conscious knowledge.

Persaud et al. (2007) examined the influence of different types of questioning in combination with wagering in three different groups. In their version of the IGT, participants were instructed to wager $£ 10$ or $£ 20$ after each deck selection. Selections from the bad decks yielded a win of two times the wager whereas selections from the good decks returned the amount of the wager. The net outcome was ei-
ther a win of $£ 75$ (good decks) or a loss of the same amount (bad decks) per 10 cards if participants randomly allocated their wagers. Persaud et al. measured on which trial good deck selection and advantageous wagering began and conjectured that if a significant difference between these measures emerged, with performance revealing a preference for good decks before advantageous wagering emerged, this would indicate an unconscious influence on decision-making. In fact, the groups who were asked no questions or the questions of Bechara et al. (1997) demonstrated a lag between good deck selection and advantageous wagering, indicating a dissociation between performance and awareness. On the other hand, when awareness was probed by the questionnaire of Maia and McClelland (2004), performance and advantageous wagering developed simultaneously. These findings led Persaud et al. to conclude that there are implicit influences on decisionmaking which are masked if the measure of awareness makes participants aware of the nature of the task.

## Overview of the Experiments

Although post-decision wagering holds much promise as a method of measuring awareness, it has received many criticisms (e.g., Clifford, Arabzadeh, \& Harris, 2008; Fleming \& Dolan, 2010; Schurger \& Sher, 2008). In the present study, we will focus on two problematic and rather contradictory aspects of the method: the definition of the optimal strategy and loss aversion. Paradoxically, the optimal strategy is always to wager high as this strategy will give the same outcome if deck discrimination is at chance but will increase winnings if it is greater than chance. In this sense wagering high can be said to be a weakly dominant strategy with Persaud et al.'s (2007) payoff matrix, as it is either no worse than wagering low, or better. Consequently, a rational participant would always wager high, regardless of her knowledge about the task.

A second important issue is the influence of loss aversion in wagering strategies. According to prospect theory (Kahneman \& Tversky, 1979), people have an asymmetric conceptualisation of wins and losses; for example, the prospect of losing $£ 5$ is considered to be of greater psychological magnitude than that of winning the same amount. Subjective measures of awareness require participants to set a criterion about, for example, whether to wager high or low. Hence, any criterion may be modulated by cognitive biases such as loss aversion.

The present study examines the validity and sensitivity of post-decision wagering by looking closely at the two aforementioned problematic aspects and by measuring participants' awareness in combination with Maia and McClelland's (2004) quantitative questions.

## Experiment 1: The Weakly Dominant Strategy

In order to overcome the problem that wagering high is the rational strategy irrespective of the acquired knowledge, Clifford et al. (2008) proposed a solution by modifying the original payoff matrix used by Persaud et al. (2007) (see Table 1). In this modified matrix participants are discouraged

Table 1: Payoff matrices for the different combinations of deck selection and wager.

| Persaud et al. |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Clifford et al. |  |  |  |  |  |  |
| Schurger \& Sher |  |  |  |  |  |  |
| Wager | Good | Bad | Good | Bad | Good | Bad |
| Low | +1 | -1 | +2 | -1 | +1 | -2 |
| High | +2 | -2 | +5 | -5 | +10 | -10 |

from wagering high all the time. This can be shown by computing the expected payoff from wagering low which is $+1 / 2$ $[=(+2-1) / 2]$ when deck selection is random compared to $0[=(+5-5) / 2]$ from wagering high. However, when deck discrimination is better than chance, it is more rewarding to wager high due to a higher payoff with a good-high combination $(+5)$ than a good-low one $(+2)$. Based on this matrix a rational participant (i.e., a participant who seeks to maximize gains) would start to wager high only when her discrimination or level of awareness is $4 / 7$ or .57 . The latter can be computed from the differential loss of wagering on a bad decision $(5-1=4)$ divided by the sum of the differential loss and the differential gain of wagering on a good decision $(5-2=3)$.

We also addressed the question of how sensitive wagering is compared to another measure of awareness by using the quantitative questions of Maia and McClelland (2004).

## Method

Participants Twenty-one volunteers participated (13 females, age $M=23.45, S D=3.56$ ), all of whom were recruited via the departmental subject pool. They were paid $£ 2$ for their participation and an additional amount between $£ 0$ and $£ 3$, dependent on their performance in the task.
Task A probabilistic variation of the original IGT was employed. There were four decks of cards with identical physical appearance, labelled A-D. The payoff structure of each deck was different to the original IGT; the matrix of Clifford et al. (2008) was used as the basis of the payoffs received by participants on each trial, in such a way that the amount won or lost was dependent on card selection and wagering. Based on the contingencies in Table 1, on the majority of trials a payoff of +2 was associated with a good deck selection and a low wager. Similarly, the combination of a bad deck and high wager produced a payoff of -5 . On a minority of trials the signs of the payoffs were reversed (e.g., the payoff was -2 for good deck selection/low wager). For decks A and C, the majority outcome occurred on a randomly-chosen $75 \%$ of trials while for decks B and D, the majority outcome occurred on $60 \%$ of trials, resulting in different overall expected payoffs for each deck. In contrast to the original IGT, the outcome on each trial was either a net win or a loss and participants could win or lose points, which translated into money at the end of the experiment.

The task comprised 100 card selections. After each card selection, participants could place a wager, either High or Low.

They were told that if they were confident that their choice would give them some net winnings, then they should wager high, otherwise, they should make a low wager. Based on the combination of deck selection and wagering, participants were presented with a single amount, either a win or a loss. Along with wagering, participants' conscious knowledge was assessed using a modified version of Maia and McClelland's (2004) questionnaire, which was administered every 20 trials.

## Results

Choice and Wagering In order to examine whether decision-making strategies in the IGT are dissociable from awareness we computed the average proportion of good deck selections (decks C and D) and advantageous wagering (either a high wager after a good deck or a low wager after a bad deck) over successive blocks of 10 trials. If learning of the good decks emerged earlier than awareness (as indexed by wagering) then that would indicate an unconscious influence on decision-making strategies in the IGT. However, performance exceeded the chance level on block 1 for both measures (Choice: $t(20)=2.83, p=.01,95 \%$ CI [0.52, 0.65], Wagering: $t(20)=3.80, p<.001,95 \%$ CI [0.57, 0.73]) (see Figure 1A). It is important to note that even though they use the same scale, the two measures cannot be compared directly because advantageous wagering is dependent on the first-order decision (e.g., deck selection) and this creates the possibility of functional differences between the measurement scales. For example, if a participant always chooses a good deck (with the proportion of good deck selections therefore being 1.0), but decides to make both high and low wagers because she is more confident on some trials than others, then advantageous wagering cannot attain a value of 1.0.

A repeated-measures ANOVA on good deck selections with polynomial contrasts revealed significant linear, $F(1,20)=72.38, M S E=3.12, p<.001, \eta_{g}^{2}=0.41$, and quadratic trends, $F(1,20)=7.34, M S E=1.83, p=$ $.013, \eta_{g}^{2}=0.04$. Wagering performance closely followed the optimal decision-making strategy as demonstrated by a linear effect of block, $F(1,20)=19.57, M S E=4.26, p<$ $.001, \eta_{g}^{2}=0.19$. These results indicate that participants favored the good decks and became gradually capable of maximizing their winnings by placing appropriate wagers. Since choice and wagering displayed similar patterns there is no evidence of a dissociation between learning and awareness of the optimal strategy, a pattern which is at odds with the main claim of Persaud et al. (2007) about learning without awareness in the IGT.

An important feature of our task variant is that each deck yielded different overall expected outcomes. If participants had explicit insight about their choices, they could discriminate not only between good and bad decks but also within each pair of decks (A vs B and C vs D). More selections from the most rewarding of the good decks (deck C) would suggest that participants possess substantial knowledge about the payoff structure of the task. Figure 1B shows that participants indeed selected more cards from the deck with the highest win

Figure 1: (A) Proportion of good deck selections and advantageous wagering across block of trials (lines) and proportion of participants who favored the good decks in the quantitative questions (markers). Error bars are $\pm 1$ SEM. (B) Overall proportion of deck selections. The win probability associated with each deck is depicted on the top of each bar.
probability (.75) and there was a significant preference over the second best deck, $t(20)=3.98, p<.001, d=0.87$.
Questionnaire Two of the questionnaire measures, in which participants provided a rating for each deck and indicated which deck they would select cards from for the remainder of the task (Ratings and Deck Selected in Figure 1), reflect knowledge about the general quality of the decks. The remaining two measures, in which participants reported the average net outcome from each deck (Reported Net), refer to the actual payoffs. Participants also reported the average win and loss and the frequency of losses, based on which a net amount for each deck is obtained (Calculated Net).

Figure 1 (markers) shows the proportion of participants whose answers favored the good decks in each of the questionnaire measures. Participants whose verbal responses did not discriminate between good and bad decks (i.e., they gave the same ratings or same reported net for all decks) do not count towards this proportion. Inspection of the figure shows that participants exhibited substantial knowledge about the quality of each deck even in the first assessment period (trial 20). Not only did they rate the good decks higher than the bad decks, but also they had a firm basis for such an attribution as revealed by their reported and calculated net payoffs.

Another way of examining the two measures is to look at participants' deck selections and wagering in the trials following the administration of the questionnaire (trials 21, 41, 61,81 ) in order to examine whether participants who behaved advantageously had knowledge of the advantageous strategy. Specifically, we are interested in the verbal reports and wagers of those participants who behaved advantageously (i.e., selected good decks) in these trials. Figure 2 shows that the majority of participants who made good deck selections also demonstrated knowledge of the advantageous strategy in all the questionnaire items. However, wagering underestimates the acquired knowledge in all trials following the question-
naire compared to the verbal reports (the figure also shows wagers on trial 100, immediately prior to the final set of questions). Thus, it is evident that the detailed and structured questions revealed higher levels of awareness compared to wagering.

Figure 2: Percentage of participants who showed knowledge of the advantageous strategy in the questionnaire items versus in their wagers. Wagering indicates the percentage of participants who made an advantageous wager (high on a good deck choice) on the trial immediately following the administration of the questionnaire.

## Discussion

The key point of Experiment 1 is that wagering did not lag behind the selection of good decks, with both measures becoming reliably better than chance very early in the task. Under the conditions tested here, awareness as measured by wagering tracked deck selections quite closely. In addition, the results of the quantitative questions revealed that there was actually conscious knowledge that was left undetected by wagering as participants' wagers were less sensitive than their verbal reports. This places a question mark over the validity of post-decision wagering as a valid and sensitive method of assessing awareness.

An interesting finding is the early onset of learning and awareness (Block 1) which can be primarily explained by the probabilistic allocation of wins and losses on each trial. Fellows and Farah (2005) found that in their shuffled IGT version (the order of the decks was changed so that losses from the bad decks occurred immediately at the start of the task) normal controls selected more cards from the good decks even in the first 20 trials and they kept on choosing the good decks throughout the task. This setup of the payoff schedule removes the reversal learning component of the IGT which can delay the learning of the optimal decisions.

## Experiment 2: Dealing with Loss Aversion

Depending on the payoff matrix, participants may employ different response criteria to place high or low wagers which can make detection of acquired knowledge very difficult. This leads to the possibility that the expression of awareness via wagering may be constrained by factors other than knowledge itself. For instance, several studies have shown that loss
aversion affects awareness as indexed by wagering (e.g., Dienes \& Seth, 2010; Fleming \& Dolan, 2010).

Schurger and Sher (2008) proposed that the design of the payoff matrix should take into account participants' tendency to evaluate losses worse than equivalent wins. Unlike Clifford et al.'s matrix, which encourages low wagers when certainty is low, "subjects seem to need precisely quite the opposite sort of encouragement" (Schurger \& Sher, 2008, p. 209). Table 1 shows the matrix devised by Schurger and Sher as a means to counter loss aversion. Specifically when discrimination between good and bad decks is at chance it is more advantageous to wager high due to a negative expected payoff from wagering low $[(+1-2) / 2=-1 / 2]$ compared to a neutral payoff from wagering high $[(+10-10) / 2=0]$. Following this, it can be shown that a rational participant would switch to high wagers even when her discrimination is below chance ( $50 \%$ ), at $8 / 17$ or $47 \%$. Specifically, the differential loss of wagering on a bad decision is $8(=10-2)$ divided by the sum of the differential loss and the differential gain of wagering on a good decision $(10-1=9)$.

Despite the fact that this matrix discourages participants from wagering low under uncertainty, its weights regarding high wagers are two times bigger compared to the matrix of Clifford et al. On the one hand, the larger loss following a low wager after an incorrect decision discourages participants from wagering low, thus overcoming the problem of loss aversion. On the other hand, the bigger weights for high wagers could discourage participants from wagering high, even when knowledge about the quality of the decks exists. Thus, employment of this matrix might reveal that the remedy proposed to counter loss aversion cannot be achieved due to the increased weights associated with high wagering.

## Method

Participants We tested a total of 30 participants ( $24 \mathrm{fe}-$ males, age $M=25.08, S D=4.02$ ), recruited from UCL's psychology subject pool. Participants were rewarded between $£ 1$ and $£ 5$, proportional to their performance on the task.

Task The payoffs of each deck were different to the original IGT, but their overall expected payoffs reflected the ratio of losses to wins of the original task. There were four decks of cards each having 100 associated wins and losses, one for each trial. A randomly drawn (win or loss) value was then computed for each trial, which constituted the payoff on that deck for that trial. Decks A and B were bad decks, with an overall net outcome of -500 points (a net loss of -5 per card). These decks had high rewards (from $15-25$ points), but large losses (from $25-75$ ). Decks C and D were good decks, with an overall net outcome of +500 points (a net win of +5 per card). They had lower rewards (from $5-15$ ), but their losses were smaller too. Decks A, B, and C had a loss on $50 \%$ of trials, whereas Deck D had a loss on $10 \%$ of trials. The characteristics of each deck matched the original IGT, including the probabilities and relative magnitudes of losses, except for deck B. The losses on deck B were dis-
tributed over 50 trials (as against originally 10 trials only). We did this to avoid a major loss if participants were unlucky enough to encounter the deck B loss with a high wager. The post-decision wagers comprised multipliers, with the payoff schedule as proposed by Schurger and Sher (2008). Accordingly, a given IGT trial payoff was multiplied by a factor of 2 when wagering low on decks A and B , and by 1 when wagering low on decks C and D . When wagering high, all deck payoffs were multiplied by a factor of 10 .

## Results

Performance exceeded chance on block 1 for both measures (Choice: $t(29)=2.39, p=.023,95 \%$ CI [0.51, 0.64], Wagering: $t(29)=2.52, p=.018,95 \%$ CI $[0.51,0.61]$ ) (see Figure 3 ). This result indicates that participants' optimal decisionmaking and learning occurred very early in the task, a pattern that is not observed in previous studies which have utilised a payoff schedule similar or identical to the original IGT.

Figure 3: (A) Proportion of good deck selections and advantageous wagering across block of trials. Error bars are $\pm 1$ SEM. (B) Overall proportion of deck selections.

Two separate repeated-measures ANOVAs were conducted to investigate the progression of good deck selections and advantageous wagering across blocks. Polynomial contrasts revealed a significant linear effect of block on the proportion of good deck selections, $F(1,29)=143.40, M S E=2.34, p<$ $.001, \eta_{g}^{2}=0.37$. However, the same trend was not observed on the proportion of advantageous wagers as the linear effect was not significant, $F(1,29)=2.06, M S E=8.44, p=.16$. Even though wagering was above chance even from block 1, it never exceeded 0.7. In a situation where high wagers have much greater stakes than low wagers, participants may wager conservatively throughout the task, independent of learning and awareness, due to an aversion to large losses. Additionally, advantageous wagering was above chance in all blocks of trials.

Figure 3B shows the proportion of deck selections throughout the task. Deck B was not selected as often as in previous studies using the IGT, a fact which reflects the change of the loss probability. When the occurrence of losses is more frequent (.5), the prominent deck B phenomenon is not ob-
served. On the other hand, deck D (loss probability .1) was selected more often than deck C (loss probability .5) even though both decks have the same expected value.

## Discussion

This experiment confirms the hypothesis that loss aversion modulates wagering strategies by making participants more sensitive to losses. While the payoff matrix we used encourages high wagering under uncertainty, the probabilistic IGT variant we employed was found to be easier to learn than the classic IGT and thus participants were able to grasp the payoff schedule in the first 10 trials, indicating that they did not go through a phase of exploration or uncertainty. Having learned the probabilistic structure of wins and losses early in the task, it might be expected that wagering would simultaneously follow the optimal choices. This was the case in the first 2 blocks where participants had learned about the good strategy and made high wagers. Yet a random loss which may occur from the selection of a good deck with a high wager $(\times$ 10) would result in a large amount of points being deducted from the total sum. Hence, a "lose-less" strategy seems to overtake the tendency to maximize winnings, and in this particular case leads to suboptimal wagering. In other words, loss aversion constrains participants from wagering high on their good deck selections. This is indicative of a bias regulating wagering strategies and not lack of awareness. While good deck selections gradually increased to reach the maximum point by the end of the task, it would be unreasonable to argue that this was the effect of an unconscious mechanism.

The present experiment also highlights the inadequacy of post-decision wagering to measure awareness objectively and directly. Small changes in the payoff matrix can dramatically change the expression of awareness as cognitive or response biases overtly influence the reasoning behind participants' wagering strategies.

## General Discussion

The purpose of the present article was twofold: first, to evaluate how sensitive and direct post-decision wagering is as a measure of awareness, and secondly to investigate whether there are implicit influences on decision-making under uncertainty or whether past suggestive results have been the byproduct of use of insensitive measures.

We examined two main response biases, dominance and loss aversion, which arise from the design of the payoff matrix. In both cases, there was a direct effect of the design of the payoff matrix on the wagering strategies that participants employed. In Experiment 1, no delay was observed in the onset of awareness relative to deck selection, as advantageous wagering closely followed learning of the good decks. The early onset of awareness can be accounted for by either of two factors: first, the values in the payoff matrix which may have encouraged low wagers, and secondly, the quantitative questions which might have influenced the development of awareness of the deck values. However, participants' wagering performance was better than chance even
before the first administration of the questionnaire, indicating that the explicit nature of the questions did not make participants more aware of the decks' payoffs.

In Experiment 2, we tried to control for the effects of loss aversion on wagering strategies, mindful of the possibility that the high values in the wagering matrix could make participants reluctant to place high wagers. The matrix proposed by Schurger and Sher (2008) attempts to eliminate loss aversion in situations of uncertainty, that is when knowledge about a response option is weak. Participants were able to discriminate between the decks after a few trials. Although wagering performance was better than chance from the beginning of the task, it did not lead participants to maximize their earnings. One explanation lies in the design of the task: with random losses occurring even on selections from the good decks and wagers treated as multipliers of the actual payoffs, the prospect of losing a significant amount could inhibit the placement of high wagers.

Even though the decision-making paradigms employed in our experiments are not identical to the original IGT, they maintain its key characteristics such as sequential choices, rewards, punishments, and uncertainty, while removing some of its problematic features such as participants' tendency to focus on decks with infrequent losses, the lack of explorationexploitation, and the dual presentation of the outcomes. These latter issues make the interpretation of IGT data quite difficult (see Steingroever et al., 2013). Nevertheless, future work could seek to determine whether advantageous deck selection and wagering develop in parallel when our probabilistic version includes the reversal learning element of the original IGT task.

The claim that unconscious biases are essential for successful performance in the IGT has not been confirmed in either of the experiments reported here. In fact, participants' advantageous selections developed in parallel with their conscious knowledge, as revealed by verbal reports and wagering. Learning of the task contingencies through emotional markers cannot be ruled out, but does not seem to precede conscious evaluation of the experienced outcomes. In other words, the activation of an unconscious emotional system which provides critical information for decision-making processes is not essential or sufficient to explain learning in the IGT. Dunn, Dalgleish, and Lawrence (2006) suggested that there is little evidence to support the view that deck contingencies are consciously impenetrable, and that what needs to be tested is whether participants have an explicit understanding of the payoff schedule or whether they can simply discriminate the quality of the decks. Our questionnaire results demonstrate that participants not only were able to show a general preference for the good decks but that in addition they could justify their preferences by accurately reporting the average wins and losses associated with each deck. This knowledge develops very early in the task, leaving little room for unconscious influences.

## Acknowledgments

We thank Ojas Mehta for his help in collecting the data of Experiment 2 and for his useful comments. This work was supported by a UCL Graduate School fellowship (EK).

# The impact of bottom-up and top-down saliency cues on reference production 

Ruud Koolen (R.M.F.Koolen@uvt.nl)<br>Emiel Krahmer (E.J.Krahmer@uvt.nl)<br>Marc Swerts (M.G.J.Swerts@uvt.nl)<br>Tilburg Center for Cognition and Communication (TiCC), School of Humanities, Tilburg University<br>PO Box 90153, 5000 LE, Tilburg, The Netherlands

#### Abstract

This study investigates to what extent visual saliency cues in realistic visual scenes cause speakers to include a redundant color attribute in their definite descriptions of objects, and in particular how such cues guide speakers in determining which objects in the scene are relevant distractors, and which not. First, regarding bottom-up cues, the results revealed that the presence of clutter positively affected the redundant use of color, but that the distance between a target and a distractor did not have an effect in this respect. Second, an effect of topdown saliency (i.e., whether a target's type was mentioned in the instructions) was only partially borne out by the data. We argue that these findings are problematic for algorithms that aim to generate psychologically realistic object descriptions, since these generally select properties that help to distinguish a target from all distractors that are present in a scene.

Keywords: Definite reference; Overspecification; Bottom-up and top-down saliency; Computational models.

## Introduction

When producing definite object descriptions (such as "the green chair"), speakers must decide on the information that they include in order to make a target object identifiable for the addressee. Many referential tasks require distinguishing a target from one or more distractor objects. The properties that speakers include to make the target identifiable seem to be largely determined by the properties of the distractor objects. For example, consider the two scenes depicted in Fig. 1.

Figure 1: Two simple visual scenes.
Although the target is the same in both scenes (a large brown chair, as indicated by the arrows), the distractor will probably cause a speaker to describe it in different ways. In the left scene, where the distractor is a small brown chair, there is a high chance that a speaker produces a description like "the large chair". However, in the right scene, where the distractor is a large green chair, a description like "the brown chair" is more likely to be uttered.

While the distractor object(s) seem to play a large role in the production of target descriptions in simple visual scenes such as the ones depicted in Fig. 1 (involving comparisons of structurally different minimal pairs of objects), it is the question whether a similar process is at play when speakers refer to target objects in realistic, more complex scenes. For example, imagine a speaker asking her listener to hand her a plate that is lying on a table full of objects. Do speakers then regard all these objects as relevant distractors? Or may there be reasons why certain objects are excluded from the set of distractors? And, most importantly, how does this influence the production of reference? These are the questions that we address in the current paper.

## Background

In recent years, the production of referring expressions has received considerable attention, both from a computational and from a psycholinguistic perspective (van Deemter et al., 2012). In computational linguistics, for instance, researchers have developed several Referring Expression Generation (REG) algorithms, most notably the Incremental Algorithm (IA) introduced by Dale and Reiter (1995). The IA is a computational model that focuses on content planning: the algorithm iteratively selects attributes (e.g., type, color, size) in order to distinguish a target from one or more distractor objects in the distractor set. In order to do this, the IA uses a preference order that contains all attributes that occur in the given domain, where it considers frequently used attributes for inclusion before less frequent attributes. In this paper, we assume that type is at the head of the preference order (before color), since it is needed to generate a proper noun phrase (Levelt, 1989).
So how does the IA define the distractor set? Dale and Reiter (1995) write: "We define the context set to be the set of entities that the hearer is currently assumed to be attending to" (p. 236), where the distractor set consists of all elements that are present in a visual scene except the target. Thus, Dale and Reiter do not explain explicitly how the set of distractors should be determined for a scene, and whether it should be restricted in a certain communicative situation or not. This means that the IA generally selects the content of its object descriptions by searching for properties that help to distinguish the target from all distractors that are present in a visual scene. This might be problematic from a psychological perspective: for example, regarding discourse
structure, Krahmer and Theune (2002) argue that the set of distractor objects may change during a discourse (e.g., when speakers repeatedly refer to the same object), while Kelleher and Kruijff (2006) and Van der Sluis (2005) add that visual salience may play a role in this as well. However, to the best of our knowledge, earlier work that systematically tests how human speakers are driven by visual salience to dynamically restrict the distractor set for a given scene is lacking.
In the current paper, we test three visual saliency cues that may guide speakers in determining the set of distractors. We base our manipulations on Itti and Koch's (2000) model of visual attention, stating that an object pops out of a scene if it is sufficiently salient (Itti and Koch call this bottom-up, perceptual saliency), or if the viewer's attention is guided to it (also referred to as top-down, conceptual saliency).

With regard to bottom-up scene processing, we expect two kinds of cues to guide speakers in determining the distractor set. First, we expect the presence of visual clutter to play a role. We define visual clutter here as a collection of objects that are thematically related to the target object, and assume that the amount of visual clutter is positively correlated to the amount of objects in a scene (Bravo \& Farid, 2008). In previous research, clutter has been shown to affect speakers' response times when describing naturalistic scenes (Coco \& Keller, 2009), with slower reactions for cluttered scenes. In line with this, we expect that since a cluttered scene contains more objects (and may thus be more difficult to process), it is unlikely that speakers 'calculate' for every distractor how it can be distinguished from the target object.

Secondly, again regarding bottom-up scene processing, we expect distractor distance (that is, the distance between the target and a distractor) to guide speakers in determining the distractor set. For reference in dialogue, Beun and Cremers (1998) suggest that a speaker's focus of attention limits the number of relevant distractors: in their experiment, they find that speakers generally consider only visually close objects when referring to targets. In an eye-tracking study, BrownSchmidt and Tanenhaus (2008) have similarly shown that distractors that are visually close to the last mentioned target are most likely to be in the speaker's focus of attention. In this paper, we study if the same goes for reference where no preceding discourse is involved.
Thirdly, related to top-down scene processing, we expect the specificity of the referential task to affect speakers when determining the set of distractors, where we hypothesize that a general task (such as "describe this object") will leave the speaker with a bigger, less restricted set of distractors than a more specific task (such as "describe this plate", where the target's type is mentioned). In the latter case, speakers might leave objects other than plates unattended, while any object that is present in the scene might be regarded as a relevant distractor in the former case.

## The current study

Our experiment was a reference production task, in which participants were presented with realistic scenes on a screen. The scenes contained one target and several distractors, and
the participants were asked to describe the target in such a way that an addressee could uniquely identify it. Crucially, the trials were set up in such a way that color was never needed to do this, enabling us to take the proportional use of redundant color attributes (i.e., color attributes that were not necessary for identification) as our dependent variable. In doing this, we follow Koolen et al. (to appear), who used the redundant use of color to study how speakers differ in their perception of low-variation and high-variation scenes. Our stimuli were designed in such a way that the Incremental Algorithm would not select color to distinguish the target: it would always select type and size, irrespective of any experimental condition.

What do we predict regarding the redundant use of color? Firstly, we expect to find an effect of clutter (with speakers using more color when clutter objects are present), because a cluttered scene contains more distractors and hence might be more difficult to process. Secondly, we expect distractor distance to affect speakers' redundant color use: redundant color attributes might get used more often when a potential distractor is placed close to the target object as compared to when it is distant. Thirdly, we expect to find effects of the specificity of the referential task: we hypothesize that when speakers are instructed in a general way (e.g., "Describe this object"), they will be more likely to redundantly use color as compared to when the instruction includes the target's type (e.g., "Describe this plate").

## Experiment

## Method

Participants. 43 undergraduate students from Tilburg University ( 30 female, 13 male) took part in the experiment. All (mean age 21 years and 1 month, range 18-34 years) were native speakers of Dutch (the language of the study) and participated for course credits.

Materials. The stimulus materials consisted of 80 trials, all of which were photo-realistic pictures of objects on either a kitchen table or an office desk. In the 40 critical trials, there were always at least three objects present on the table: one target object and two distractor objects. Crucially, one of the distractors had the same type and color as the target object (meaning that it could only be ruled out by means of its size), and was always positioned next to the target object (either left or right). The second distractor always had a different type and color as compared to the target, and its positioning varied across conditions. Besides that, two other principal factors were manipulated: one related to the presence of clutter in the scene, and one related to the specificity of the task that was given to the speakers.
The first manipulation was related to whether or not there was clutter present in the visual scene. We define clutter as a collection of all kinds of objects that are thematically related to the target and its two main distractors. The clutter objects were not systematically varied, and were unique in the sense that they all had different types. The color of these

Fig. 2: Examples of critical trials in Experiment 1. The left scenes have a close distractor, whereas this distractor is distant in the right scenes. The upper scenes do not contain clutter, whereas the lower scenes do. Note that both the small and the large plate could be the target in the experiment.
clutter objects was kept as neutral as possible; it was at least made sure that the clutter objects did not have the same color as compared to the target and its two distractors. In the cluttered pictures in Fig. 2, five objects are added that one would expect to see on a breakfast table, where most do not have a salient color: a bag of bread, a newspaper, a piece of cheese, a cheese slicer, and a pack of chocolate sprinkles. Clutter was added in half of the critical trials, and the same clutter objects were used for the scenes with a close and a distant distractor.
The second manipulation (distractor distance) was related to the distance between the target object and the second distractor. This distance was manipulated as follows: in half of the trials, the distractor was positioned close to the target (with the two distractors placed in the same corner of the table), whereas this distance was maximized in the other half of the trials (with the target and the first distractor in one corner of the table, and the second one in the opposite corner). In Fig. 2, the left pictures had a close distractor, and the right pictures had a distant distractor. When a scene had a distant distractor, this object was always positioned in the corner opposite the target. Note that mentioning the target's type and size was sufficient to identify the target in both the close and distant conditions, implying that the use of color would inevitably result in overspecification.

The experiment had eighty trials: forty critical trials and forty fillers. Regarding the critical trials, we used ten scenes: five scenes with objects on an office desk and five scenes with objects on a kitchen table. These ten scenes were all manipulated in a 2 (distance) x 2 (clutter) design, resulting
in four within-conditions as described above: one picture with two close distractors but without clutter, one with a close and a distant second distractor without clutter, one with two close distractors and with clutter, and one with a close and a distant distractor and with clutter. Note that the target object could be positioned in all four corners of the table (and not necessarily in the left bottom corner, as is the case in Fig. 2). Since there were always two similar objects in a scene (one of which being the target object), we marked the small object as the target in half of the scenes, and the large object in the other half of the scenes.
Besides distractor distance and the presence of clutter presence (both manipulated as within participants factors), the experiment also had one between participants variable (hence called specificity of the referential task), which was related to the instruction that was given to the participants. As mentioned earlier, it was the participants' task to describe each target object in such a way that it could be distinguished from the other objects in the visual scene. All participants were presented with the same stimuli, but two kinds of instructions were used. Half of the participants had the task to "describe this object" (which means that they took part in the low specificity condition), whereas the other half of the participants (in the high specificity condition) had a more specific task. In this condition, the target's type was mentioned in the instruction. For example, in Fig. 2, these speakers were asked to "describe this plate".

Table 1: Overview of the experimental design and the number of descriptions within each cell.

|  | No clutter |  | Clutter |  |
| :--- | :---: | :---: | :---: | :---: |
|  | Close | Distant | Close | Distant |
| Low specificity | 210 | 210 | 210 | 210 |
| High specificity | 220 | 220 | 220 | 220 |

The experiment had forty fillers: twenty from the kitchen table domain and twenty from the office desk domain. These fillers were set up in the same way as the critical trials, in the sense that there were scenes containing few objects that were positioned in the same way as those in the critical trials, and scenes containing many different objects (in line with the clutter scenes that served as critical trials). Again, one of the objects was marked as the target and was described by the participants, with the crucial difference that the objects in the filler pictures did not differ in terms of their color. In this way, speakers were discouraged from using color when describing the fillers.

Procedure. The experiment was performed in a lab, and had an average running time of 10 minutes. After participants had entered the lab, they were randomly assigned to one of the two conditions: 21 participants took part in the low specificity condition, and 22 in the high specificity condition. Thereafter, they were seated opposite the listener (who was a confederate of the experimenter), and were instructed so as to describe a target in such a way that their listener could uniquely identify it. For each new trial, the participants were instructed by means of a pre-recorded task (for example: "describe this object" in the low specificity condition and "describe this plate" in the high specificity condition). Speakers could take as much time as needed to describe a target, and their descriptions were recorded with a voice recorder.

The trials were presented to participants on a computer screen. We made one block of eighty trials in a fixed random order (which was presented to one half of the participants), and a second block containing the same trials in the reverse order (which was presented to the other half of the speakers). There were two practice trials. The listener had a paper booklet in front of her, containing - for each trial - separate pictures of all the objects that occurred in that given scene. These pictures were taken from the pictures the speaker was presented with. Based on the speaker's descriptions, the listener marked the object that she thought was referred to on an answering form. In order to prevent speakers from including location information in their target descriptions (e.g., 'The plate in the left bottom corner'), the instructions emphasized that the listener was presented with the same objects ranked in a different order. The listener always acted as though she understood the descriptions, and never asked clarification questions. This was done to enable a focus on content planning of initial descriptions ('first mentions'). Once the listener had identified a target, this was communicated to the speaker, who then went on to describe the next target.

Design and statistical analysis. The experiment had a $2 \times 2$ x 2 design (see table 1) with two within participants factors: distractor distance (levels: close, distant) and clutter presence (levels: no clutter, clutter), and one between participants factor: specificity of the referential task (levels: low, high). The experiment had one dependent variable: the proportion of descriptions containing a color attribute. As described above, we made sure that speakers never needed color in order to distinguish the target object from its distractors: mentioning the target's type and size was always sufficient. Thus, when speakers mentioned color, this always resulted in an overspecified description.
Our statistical procedure consisted of Repeated Measures ANOVAs: one on the participant means $\left(F_{1}\right)$ and one on the item means $\left(F_{2}\right)$. We only report on interactions where these are significant. In order to compensate for departures from normality, we applied a standard arcsin transformation to the proportions before running the ANOVAs. For the sake of readability, we report the untransformed proportions in the results section.

## Results

In total, 1720 target descriptions were produced in this experiment. All of these contained a type attribute, and most ( $85.8 \%$ ) contained a size attribute. In the rest of the cases, other additional attributes were mentioned to distinguish the target object (such as its orientation). All descriptions were fully distinguishing. Speakers redundantly mentioned color in $39 \%$ of the descriptions.

Results for clutter. The first factor that we expected to affect speakers' redundant use of color was the presence of visual clutter in the scene. Fig. 3 displays the proportional use of color as a function of clutter presence.

Fig. 3: The proportional use of color (plus standard deviations) as a function of clutter presence.

As can be seen in Fig. 4, the presence of clutter positively affected the redundant use of the attribute color $\left(F 1_{(1,41)}=\right.$ 13.38, $\left.p=.001 ; F 2_{(1,36)}=3.91, p=.06\right)$. In other words, speakers were more likely to include color when presented with visual scenes containing clutter $(M=.43, S D=.05)$ as compared to when the scene did not contain clutter ( $M=$ $.35, S D=.06$ ).

Results for distractor distance. We also studied the effect of distractor distance on the redundant use of color: whether a distractor was placed close to or far from the target object. The results are shown in Fig. 4.

Fig. 4: The proportional use of color (plus standard deviations) as a function of distractor distance.

As can be seen in Fig. 3, distractor distance did not affect the proportional use of the redundant attribute color $\left(F 1_{(1,41)}\right.$ $\left.=.068, p=.80 ; F 2_{(1,36)}=.00, p=.99\right)$. More specifically, color was mentioned color exactly as many times when the distractor was close $(M=.39, S D=.05)$ as compared to when it was distant ( $M=.39, S D=.05$ ).

Results for specificity of the referential task. The third factor that we manipulated was related to the specificity level of the task that was given to the speakers: for half of the speakers this specificity level was low, while it was high for the other half of the speakers.

Fig. 5: The proportional use of color (plus standard deviations) as a function of the specificity of the instruction.

As reflected in Fig. 5, the specificity of the instructions to some extent affected the use of the redundant attribute color,
but this effect was only significant by items $\left(F 1_{(1,41)}=.355\right.$, $\left.p=.55 ; F 2_{(1,36)}=15.81, p<.001\right)$. More specifically, this means that speakers that took part in the low specificity condition ( $M=.42, S D=.07$ ) did use color more frequently as compared to those taking part in the high specificity condition ( $M=.36, S D=.07$ ), but that we did not find a convincing effect of instruction specificity.

## Discussion

In this paper, we have investigated how bottom-up and topdown saliency cues - as defined by Itti and Koch (2000) guide speakers in determining which objects in a scene belong to the set of relevant distractor objects. In doing this, we have studied how these cues affect speakers' production of object descriptions, and in particular, to what extent they cause speakers to mention a redundant color attribute. On average, $39 \%$ of the object descriptions in our experiment redundantly contained a color attribute, which is more than the proportions reported by, among others, Belke and Meyer (2002), Koolen et al. (to appear), and Pechmann (1989).

Regarding top-down scene processing, we hypothesized that participants in the low specificity condition (who were asked to "describe this object") would be more likely to use a redundant color attribute than participants that took part in high specificity condition (who were asked to "describe this X", e.g., "this plate"), since in the latter case (where the target's type was used in the instruction) only the distractor with the same type would remain to rule out (which could always be done by mentioning size). We indeed found a numerical difference between the conditions in the predicted direction, but this was only significant in the $F_{2}$ analysis. We plan to further study this effect in future research.
Secondly, regarding bottom-up scene processing, we have found that - at least for the visual scenes used here - the distance between the target and a distractor does not affect the redundant use of color. This might be due to an artefact of the experimental setup: given that our speakers knew that the addressee was presented with - for every given scene separate pictures of all objects that were depicted in that scene, this might have caused them to ignore the distance between the target and the distractors in the scene. In future research, we aim to improve our manipulation of distractor distance.
Thirdly, again regarding bottom-up scene processing, our results showed that speakers are more likely to mention a redundant color attribute when there is visual clutter present in the scene as compared to when this is not the case. One explanation for this might be that a scene with clutter simply contains more distractor objects than a scene without clutter. As suggested earlier, the latter might lower the chance that speakers exactly 'calculate' for each distractor how it can be distinguished from the target in the most efficient way. Our results suggest that speakers tend to process cluttered scenes in a 'faster' way: they might rely on heuristics (Tversky \& Kahnemann, 1982) when they have to uniquely describe an object. With regard to reference production, heuristics can be defined as general rules that say, for example, that color
should always be included in the case of a cluttered scene. In recent years, such heuristics have indeed been claimed to influence reference production (e.g., Dale \& Viethen, 2009), since speakers' limited processing capacity might prevent them from calculating the shortest possible description in a given referential task (van Deemter et al., 2012).
As we have explained in the introduction of this paper, for the current REG algorithms (most notably Dale and Reiter's IA introduced in 1995) it is not explained explicitly how the distractor set should be defined for a given scene (Krahmer \& Theune, 2002): such algorithms select the content of their descriptions by searching for those properties that help to distinguish the target from all distractors that are present in the scene. Given that our findings (at least partly) suggest that perceptual and conceptual cues affect speakers' object descriptions, and that there are situations in which speakers do not take all distractors into account, or do not 'calculate' the most efficient way to describe a target because too many objects are present, the question is what the implications of our findings are for REG algorithms such as the IA.
For one thing, our results show that speakers often use a color attribute when algorithms such as the IA would not do this: in our stimuli, the algorithm would select type and size instead of color (assuming that, as explained earlier, type is placed at the head of the preference order, followed by color and other, less preferred attributes such as size). So how can the IA account for this frequent color use? For the specific case of clutter (which delivered us with the most convincing results), we propose that one solution might be to make the algorithm redundantly include color more often when it has to describe a target object in a cluttered scene as compared to a scene without clutter. For example, this could be done by dynamically adapting the preference order to the amount of clutter that is present in a particular scene: when clutter is present, color could be placed at the head of the preference order (causing it to be selected if there is any color variation in the scene), whereas the preference order can remain as we assume it is now (with type before color) for visual scenes that do not contain clutter.

## Conclusion

Bottom-up cues (i.e., the presence of visual clutter, but not distractor distance), and to a lesser extent top-down saliency cues (i.e., specificity of the referential task) influence the redundant use of color in definite object descriptions. This is problematic for Referring Expression Generation algorithms that aim to automatically generate psychologically realistic object descriptions.

## Acknowledgments

The research reported in this paper is part of the NWO VICI project "Bridging the gap between psycholinguistics and computational linguistics: the case of referring expressions" (Grant 277-70-007). We thank Anouk van Helvoort for help in creating the stimuli, Kristel Bartels and Elsa Jonkers for running the experiment and annotating the data, and Jette Viethen for comments on an earlier draft of this paper.

#### Abstract

In naturally occurring speech and gesture, meaning occurs organized and distributed across the modalities in different ways. The underlying cognitive processes are largely unexplored. We propose a model based on activation spreading within dynamically shaped multimodal memories, in which coordination arises from the interplay of visuo-spatial and linguistically shaped representations under given communicative and cognitive resources. An implementation of this model is presented and first simulation results are reported.

Keywords: Speech, gesture, conceptualization, semantic coordination, activation spreading

## Introduction

Gestures are an integral part of human communication and they are inseparably intertwined with speech (McNeill \& Duncan, 2000). The detailed nature of this connection, however, is still a matter of considerable debate. The data that underlie this debate have for the most part come from studies on the coordination of overt speech and gestures showing that the two modalities are coordinated in their temporal arrangement and in meaning, but with considerable variations. When occurring in temporal proximity, the two modalities express the same underlying idea, however, not necessarily identical aspects of it: Iconic gestures can be found to be redundant with the information encoded verbally (e.g., 'round cake' + gesture depicting a round shape), to supplement it (e.g., 'cake' + gesture depicting a round shape), or even to complement it (e.g., 'looks like this' + gesture depicting a round shape). These variations in meaning coordination-in combination with temporal synchrony-led to different hypotheses about how the two modalities encode aspects of meaning and what mutual influences between the two modalities could underlie this. However, a concrete picture of this and in particular of the underlying cognitive processes is still missing.

In previous work (Bergmann \& Kopp, 2009) we explored how the surface form of speech and gesture is determined and how this formulation process can be simulated in a computational model. In this paper we turn to the preceding stage, namely, conceptualization by which meaning is structured, portioned and distributed across the two modalities, yielding different kinds of semantic coordination one can see in reallife natural behavior. We thereby focus on speech along with shape-depicting (iconic) gestures. We start with reviewing the
empirical findings on semantic coordination of speech and gesture, and we discuss mechanisms and models that have been put forward to explain it. We argue that building computational models helps to elucidate the mechanisms and to bridge the gap between descriptive models and observable behavior. We propose the first model to present a detailed cognitive account of how meaning can be organized and coordinated in speech and gesture. It is based on tenets of activation spreading in multimodal memory representations and it entails a number of, now explorable, assumptions about conceptualization of speech and gesture. We describe an implementation of this model and present first results on how it can simulate and explain different cases of semantic coordination reported in the literature.

## Background

## Semantic coordination of speech and gesture

A number of studies have shown that concomittant speech and gesture are coordinated in meaning. One line of evidence coming from cross-linguistic studies suggest that packaging of content for co-speech gestures is influenced by the information packaging for the accompanying speech. For example, Kita and Özyürek (2003) showed that speakers of English who are able to combine manner and path of a movement in a single clause (e.g. 'he rolled down' or 'he swings') accompanied this by a single gesture encoding both semantic features. In contrast, Turkish and Japanese speakers encoded manner and path separately in two clauses (e.g. 'he descended as he rolled') and are more likely to use two separate gestures for these two features. Along the same line, when native speakers of Turkish (L1) speak English as their second language (L2) at different levels of proficiency, their gestures were shown to follow the information packaging strategy they adopt (Özyürek, 2002): Advanced L2 speakers typically encoded manner and path information in one clause and their gestures followed, where as speakers at lower proficiency levels typically used two-clause constructions in speech thus following the structure of Turkish, accompanied by separate gestures for manner and path. A subsequent study (Kita et al., 2007) showed that this effect also occurrs when native speakers of English are forced to produce one- or two-clause descriptions of manner and path.

Other studies have investigated the cognitive factors that influence frequency and nature of gesturing, including its coordination with speech. Bavelas, Kenwood, Johnson, and Philips (2002) found that speakers are more likely to produce non-redundant gestures when their addressees could see them, as opposed to when their gestures are not visible and hence less essential for their partners. Bergmann and Kopp (2006) report results from an analysis of natural gesturing in direction-giving, indicating that supplementary iconic gestures are more likely in cases of problems of speech production (e.g. disfluencies) or when the information conveyed is introduced into the dialogue (and thus conceptualized for the first time). In line with this, recent work has suggested that speakers indeed produce more gestures at moments of relatively high load on the conceptualization process for speaking (Kita \& Davies, 2009), in particular on the linearization and the focusing components of conceptualization (Melinger \& Kita, 2007). Hostetter and Alibali (2007) report findings suggesting that speakers who have stronger visual-spatial skills than verbal skills produce higher rates of depictive gestures than other speakers. In a later study, Hostetter and Alibali (2011) found that the speakers with high spatial skills also produced a higher proportion of non-redundant gesturespeech combinations than other speakers, whereas verbaldominant speakers tended to produce such gestures more in case of speech disfluencies. The authors hypothesize that "non-redundant gesture-speech combinations occur because mental images are more active in speakers minds at the moment of speaking than are verbal codes" [р.45]. Taken together, this suggests that non-redundant gesture-speech combinations are the result of speakers having both strong spatial knowledge and weak verbal knowledge simultaneously, and avoiding the effort of transforming the one into the other.

## Models of speech and gesture production

Different models of speech and gesture production have been proposed. One distinguishing feature is the point where cross-modal coordination can take place. The Growth Point Theory (McNeill \& Duncan, 2000) assumes that gestures arise from idea units combining imagery and categorial content. This combination is unstable and initiates dynamic cognitive events through which speech and gesture unfold. Speech and gesture, in this view, are inseparable and interact throughout the production process.

Assuming that gestures are generated "pre-linguistically", Krauss, Chen, and Gottesman (2000) hold that gesture are generated from a mental representation of a source concept comprising a set of semantic features (size, color, shape etc.) that are encoded in propositional and/or spatial format. While there is no influence of language production onto gesture in this model, the readily planned and executed gesture facilitates lexical retrieval through cross-modal priming.

De Ruiter (2000) proposed that speech-gesture coordination arises from a multimodal conceptualization process that selects the information to be expressed in each modality and assigns a perspective for the expression. A propositional rep-
resentation is transformed into a preverbal message, and an imagistic representation is transformed into a so-called sketch and sent to a gesture planner. Kita and Özyürek (2003) agree that gesture and speech are two separate systems interacting during the conceptualization stage. Based on cross-linguistic evidence, their account holds that language shapes iconic gestures such that the content of a gesture is determined by three factors: (1) a communicative intention, (2) action schemata selected on the basis of features of imagined or real space, (3) bidirectional interactions between speech and gesture production processes at the level of conceptualization, i.e. the organization of meaning. An additional link between the speech formulator and the preverbal message generator allows for feedback from grammatical or phonological encoding to the conceptualizer and thus to gesture.

Hostetter and Alibali (2008) proposed the Gestures as Simulated Action framework that emphasizes how gestures may arise from an interplay of mental imagery, embodied simulations, and language production. According to this view, language production evokes enactive mental representations which give rise to motor activation. Whether a gesture is produced or not depends on the amount of motor activation, the speaker's variable gesture threshold, and the simultaneous engagement of the motor system for speaking.

Inspite of a consistent theoretical picture starting to emerge, many questions about the detailed mechanisms remain open. A promising approach to explicate and test hypotheses are cognitive models that allow for computational simulation. However, such modeling attempts for the production of speech and gestures are almost inexistent. Only Breslow, Harrison, and Trafton (2010) proposed an integrated production model based on the cognitive architecture ACT-R (Anderson, Bothell, Byrne, Lebiere, \& Qin, 2004). This account draws on two major assumptions: (1) on Jackendoff's claim that language representations include some irreducibly spatial components; (2) on Goldberg's approach according to which language processing is based on constructions which consist of both semantic and syntactic components. The authors assume such constructions to prescribe spatial representations for what they call linguistic spatial gestures and which they assume to provide "little information not included in the accompanying language" [p.14]. In this view, constructions are selected first and then words and gestures are determined so as to realize the construction. Accordingly, semantic coordination is predetermined and does not result from a coordination process based on problems with lexicalization or high activation of particular visuo-spatial features. This model hence has difficulties, e.g., to explain gestures that clearly complement or supplement verbally encoded meaning.

## A spreading-activation model

We investigate to what extent semantic coordination of speech and gesture can be explained by cognitive principles of activation-based processing on multimodal memory. This account is embedded in a larger production model (Kopp,

Bergmann, \& Wachsmuth, 2008) that comprises three stages: conceptualization, where a message generator and an image generator work together to select and organize information to be encoded in speech and gesture, respectively; formulation, where a speech formulator and a gesture formulator determine appropriate verbal and gestural forms for this; motor control and articulation to finally execute the behaviors. Motor control, articulation, and formulation have been subject of earlier work (Bergmann \& Kopp, 2009). What is missing is a model for multimodal conceptualization that accounts for the range of semantic coordination we see in real-life speechgesture combinations.

## Basic assumptions

We posit that the semantic coordination of speech and gesture emerges from (1) the communicative goal, (2) the need to activate, retrieve and organize multimodal information to achieve this goal, and (3) the expressive as well as cognitive resources available to the speaker at the moment. To model this process, we make a number of assumptions, partly in line with previous models. First, language production requires a preverbal message to be formulated in a symbolic-propositional representation that is linguistically shaped (Slobin, 1996; Levelt, 1989) (SPR, henceforth). During conceptualization the SPR, e.g. a function-argument structure denoting a spatial property of an object, often needs to be extracted from visuo-spatial representations (VSR), e.g. the mental image of this object. We assume this process to involve the invokation and instantiation of memorized supramodal concepts (SMC, henceforth), e.g. the concept 'round' which links the corresponding visuo-spatial properties to a corresponding propositional denotation. Co-verbal iconic gestures are then shaped by (1) the imagistic content in VSR, (2) the invoked SMCs, and (3) the organization of SPR for linguistic processing. We assume that units or entries of these memory structures can be selectively activated and that activation spreads along links between them. Fig. 1 illustrates the overall relation between the three memory structures.

Figure 1: Multimodal memory structures involed in speechgesture production (activations indicated by bold lines).

## Overall production process

Fig. 2 shows an outline of the overall production architecture. Conceptualization consists of cognitive processes that operate upon the abovementioned memory structures to create a,
more or less coherent, multimodal message. These processes are constrained by principles of memory retrieval, which we assume can be modeled by principles of activation spreading (Collins \& Loftus, 1975). As in cognitive architectures like ACT-R (Anderson et al., 2004), activations float dynamically, spread across linked entities (in particular via SMCs), and decay over time. Activation of more complex SMCs are assumed to decay more slowly than activation in lower VSR or SPR.

Figure 2: Overall production architecture.

Production starts with the message generator and image generator inducing local activations of modal entries, evoked by a communicative goal. VSRs that are sufficiently activated invoke matching SMCs, leading to an instantiation of SPRs representing the corresponding visuo-spatial knowledge in linguistically shaped ways. The generators independently select modal entries and pass them on to the formulators. As in ACT-R, highly activated features or concepts are more likely to be retrieved and thus to be encoded. Note that, as activation is dynamic, feature selection depends on the time of retrieval and thus available resources. The message generator has to map activated concepts in SPR onto grammatically determined categorical structures, anticipating what the speech formulator is able to process (cf. (Levelt, 1989)). Importantly, interaction between generators and formulators in each modality can run top-down and bottom-up. For example, a proposition being encoded by the speech formulator results in reinforced activation of the concept in SPR, and thus increased activation of associated concepts in VSR.

In result, semantic coordination emerges from the local choices generators and formulators take, based on the activation dynamics in multimodally linked memory representations. Redundant speech and gesture result from focused activation of supramodally linked mental representations, whereas non-redundant speech and gesture arise when activations scatter over entries not connected via SMCs.

## Computational simulation

We have implemented the activation-based model of semantic coordination within our larger speech and gesture production architecture (Bergmann \& Kopp, 2009). Newly implemented parts are the VSR, SPR and SMC memory structures, the activation dynamics upon these structures, and the generator modules operating on them.

## Representations

To realize the VSR and part of the SMC, we employ a model of visuo-spatial imagery called Imagistic Description Trees (IDT) (Sowa \& Kopp, 2003). The IDT model was designed, based on empirical data, to cover the meaningful visuo-spatial features in shape-depicting iconic gestures. Important aspects include (1) a tree structure for shape decomposition with abstract object schemas as nodes, (2) extents in different dimensions as an approximation of shape, and (3) the possibility of dimensional information to be underspecified. The latter occurs, e.g., when the axes of an object schema cover less than the three dimensions of space or when an exact dimensional extent is left open but only a coarse relation between axes like "dominates" is given. This allows to represent the visuo-spatial properties of SMCs such as 'round', 'left-of' or 'longish'. Applying SMC to VSR is realized through graph unification and similarity matching between object schemas, yielding similarity values that assess how well a certain SMC applies to a particular visuo-spatially represented entity (cf. Fig. 1). SPR are implemented straight forward as predicate-argument sentences.

## Activation dynamics

Each memory entry in VSR, SPR and SMC has a timedependent activation value $a_{t}$. Activation dynamics results from simple update and spreading rules applied to these values in each iteration of a stepwise cognitive simulation process. At each step all of the following updates are performed:

- Activation update for memory entries: $a_{t+1}=a_{t}-d+r$, with decay $d$, random noise $r$ (order of magnitude $10^{-1}$ )
- Activation spreading within VSR: $a_{t+1}=\frac{a_{t}}{c \cdot l}$, where $c$ is the number of outgoing links (fan-out effect) and $l$ is the depth in the hierarchical IDT structure (fade-out effect)
- Activation spreading from SPR towards VSR via SMC: $a_{t+1}^{v s r}=\frac{a_{t}^{s s r}+t_{t}^{s p r}}{2}+\alpha \cdot\left(a_{t}^{s m c}-a_{t}^{v s r}\right)+r-d$, where $\alpha$ controls the rate of convergence towards the SMC activation.
- Activation spreading from VSR towards SPR via SMC:
$a_{t+1}^{s p r}=\frac{a_{t}^{v s r}+a_{t}^{s p r}}{2}+\alpha \cdot\left(a_{t}^{s m c}-a_{t}^{s p r}\right)+r-d$
The first formula models the decay and random noise of each entry's activation, the second realizes local spreading of activation within VSR, the latter two at a global level between VSR and SPR. Especially the global multimodal activation spreading is important as it ensures that linked visuo-spatial and propositional codes align and mutually stabilize. Fig. 3
(left) shows the activations of two linked entries. At point $t=200$ one entry gets temporarily activated and the activation of the linked entry follows. The second important property of this rule is that activation of the more global SMC $a_{t}^{\text {smc }}$ spreads to both linked entries, such that both are "pulled" towards this value. This can be seen in Fig. 3 (right) where the SMC's activation is increased by 2.0 at point $t=100$. Note that activation of SMCs decays more slowly than activation of VSR and SPR entries. Activations of linked entries thus stabilizes at a higher level, such that stable multimodal information packages emerge for a limited period of time. The duration of this time period depends on the decay rate of SMC activations. Finally, memory retrieval depends on the activation of the entries being retrieved. We adopt the ACT-R approach to map activation onto retrieval probability: $p=1 /\left(1+e^{\frac{-\left(a_{t}-s\right)}{r}}\right)$, where $s$ is a threshold and $r$ the noise in the activation levels.

Figure 3: Activations of two memory entry linked via an SMC: temporary activation of one entry (left); activation of the linking SMC (right).

## Generators

The message generator has to package activated SPR information in a way that the speech formulator can produce an appropriate construction. We employ an LTAG-based (Lexicalized Tree Adjoining Grammar) sentence planner for speech formulation (cf. (Bergmann \& Kopp, 2009)). To make sure that all facts necessary to generate a specific construction are available, the message generator applies networks that reflect the encoding options provided by the speech formulator's LTAG grammar (this conforms the view that the conceptualizer learns to anticipate the formulator's abilities (Levelt, 1989)). These message networks consist of type nodes for entities, properties of entities and relations between them. These are connected via weighted links reflecting the combination of particular linguistic types in a language. For instance, relation nodes are strongly linked to two (or more) entity nodes, while links between entity and property nodes are weaker.The message generator matches the activated propositions in SPR against nodes of possible message networks and determines their initial activations. Activation, again, spreads via the weighted links and finally results in an overall activation pattern of a pre-verbal message. This has been implemented for a limited part of our domain of investigation (corresponding to NPs about buildings and their properties).

The image generator retrieves visuo-spatial information from activated VSR and SMC entries in memory. It is in charge of unifying this information into an imagistic representation, from which the gesture formulator can derive a gesture form specification (based on Bayesian decision networks learned from empirical data (Bergmann \& Kopp, 2009)). For instance, information about shape is combined with information about the object's size or position. Depending on the knowledge encoded here, the gesture formulator is able to plan a shape-depicting gesture or rather a localizing deictic or placing gesture.

## Simulation results

The implemented model offers-and simulates-detailed explanations of how semantic coordination between speech and gesture arises (see next Section). In particular, it allows us to manipulate the interaction between modality-specific production processes. As a first exploration, we report results on how processing time as a cognitive resource affects the observable meaning coordination.

The production process is initiated by setting the communicative intention "introduce churchwindow-1". Upon receiving this goal, the image generator activates visuo-spatial imagery of the church window in VSR, and the message generator activates symbolic representations of non-spatial semantic concepts in SPR. These activations spread through memory and lead to invokation of SMCs for, e.g., 'round' (bound to churchwindow-1) and 'at-top-of' (the church-tower), as well as instantiation of the corresponding SPR entries. SMCs along with their linked entries in VSR and SPR attain highest and most slowly decaying activation values.

After a preset number of processing cycles, both generators retrieve modality-specific information from memory with a probability depending on current activation values, leading to 'round' and 'at-top-of' concepts being encoded in speech and gesture in a less coordinated way: the message generator may retrieve only information about the salient shape of the window, but not about its position relative to other entities. Accordingly, a sentence like "The church has a round window" gets formulated. The image generator, on the other hand, may receive information about the entity's position as well. This can result in shape depicting gestures, like drawing the shape of the window in the air, or a static posturing gesture where the hands becoming a model of the circular shape. As the position of the entity is also available, the gesture would be performed in that part of gesture space. So, the gesture would be non-redundant to speech, supplementing it with the position of the entity.

If more time is available, however, the contents expressed either verbally or gesturally tend to converge. The message generator will start to (re-)activate those entries being retrieved and selected by the speech formulator. This results in multimodal representations being better coordinated when the modality-specific formulators start with their generation work, as it is more likely that both generators receive the same
information about shape and position of the entity. Accordingly, the speech formulator is now enabled to plan a sentence like "The church has a round window at the top" which-like the gesture(s) described previously-encodes both, shape information and the entity's relative position.

To quantify these observations, we ran a simulation experiment in which we manipulated the available time (in terms of memory update cycles) before the model had to come up with a sentence and a gesture. We analyzed the resulting sentences and gestures for semantic redundancy/non-redundancy. We defined two conditions: A time-constrained condition with a certain number $N$ of cycles and a condition with twice as many cycles. We ran the model 100 times in each condition. Fig. 4 shows that non-redundant (supplementary) gestures dominate in those runs with stricter temporal limitations, while redundant ones become more likely when time available is increased. Notably, the information conveyed by gesture was similar in both conditions. So, the higher redundancy in the less time-constrained condition is mostly due to the fact that the verbal utterances were richer in content.

Figure 4: Number of semantic gesture features encoded redundantly vs. non-redundantly with speech in 100 simulation runs in more (left) or less (right) time-constrained conditions (note that a gesture may carry more than one feature).

## Discussion and conclusions

We have presented the first model to explain semantic coordination between speech and gesture in terms of (1) how visuospatial and symbolic-propositional memory entries are dynamically linked, (2) how activation spreads in these concept structures, and (3) how this interacts with modality-specific processes of conceptualization and formulation. We believe that this model offer mechanisms and thus possible explanations for many empirical findings and hypotheses put forth in literature: The hypothesis that gestures are more likely if activation in visuo-spatial memory is higher, is directly explained by the activation-based retrieval probabilities when the image generator accesses memory; the hypothesis that non-redundant gestures are more likely when spatial codes are not transformed into verbal codes is accounted for by entries in VSR and SPR not being linked via SMC, leading to less coordinated conceptual structures and activations. Fi-
nally, the shaping of gesture by speech is accounted for, first, through SPR and SMC schematizing VSR in linguistically shaped ways and, second, through choices in linguistic formulation reinforcing activations in SPR and thus VSR.

Our simulation study showed that the model also offers a natural account for the finding that non-redundant gesture are more likely when conceptualization load is high, based on the assumption that memory-based cross-modal coordination consumes resources (memory, time) and is reduced or compromised when, e.g., time is limited. This examplifies how a model like ours can help to make hypothesis testable by giving rise to predictions that can be explored in computational simulations as well as in appropriately set up empirical experiments. While the model presented here mainly accounts for information distribution, work is underway to extend the model to account also for different ways to package information over multiple clauses, e.g., depending on available linguistic or gestural resources. This will enable to simulate cross-linguistic differences in co-speech gesturing. Another issue for future work will be to go beyond objectrelated gestures accompanying NP constructions, and to address descriptions of action events with a more complex internal structure and thus a more demanding semantic coordination to be achieved by the cognitive processes involved in multimodal conceptualization.

#### Abstract

Time is talked about in terms of space more frequently than the opposite is true. Past experimental evidence suggests that this asymmetry runs deep, with results suggesting that temporal concepts and percepts find structure in spatial representations but not vice versa. However, these studies frequently involve verbal and/or visual stimuli. Because vision makes a privileged contribution to spatial processing it is unclear whether these results speak to a deep asymmetry between time and space, or a modality specific one. The present study was motivated by this ambiguity and a complementary correspondence between audition and temporal processing. In an auditory perceptual task, duration and spatial displacement judgments were shown to be mutually contagious. Irrelevant temporal information influenced spatial judgments and vice versa with a larger effect of time on space. The results suggest that the perceptual asymmetry between domains does not generalize across modalities and that time is not fundamentally more abstract than space.

Keywords: space and time; language and thought; metaphor; embodiment

## Introduction

Time is frequently talked about using the language of space (Clark, 1973; Hasplemath, 1997; Tenbrink, 2007). Events can be long or short, and can occupy a place that is either behind or in front of us in time. Space is used to talk about time not only frequently but also meaningfully. We talk about temporal extent or duration in terms of distance, and the past and future in egocentric locational terms. These ways of talking and thinking about space and time are thought to reflect something about how we experience these domains together. We may talk about duration in terms of length because it takes more time to visually scan or travel through more extended space, and the past as behind
because as we walk forward, objects we pass begin to occupy the unseen space behind our bodies becoming accessible only to memory as part of a temporal past. Experimental studies support the idea that the ways in which we experience space play a role in structuring the semantics of time (Boroditsky, 2000, 2001; Boroditsky \& Ramscar, 2002; Casasanto \& Boroditsky, 2008; Kranjec, Cardillo, Schmidt, \& Chatterjee, 2010; Kranjec \& McDonough, 2011; Matlock, Ramscar, \& Boroditsky, 2005; Miles, Nind, \& Macrae, 2010; Nunez, Motz, \& Teuschner, 2006; Nunez \& Sweetser, 2006; Torralbo, Santiago, \& Lupianez, 2006).

In language, time-space relations are relatively asymmetrical. Not only is time talked about in spatial terms much more frequently than space is talked about in terms of time, but in many ways time must be talked about using the language of space, whereas the opposite is not true. These linguistic patterns have been interpreted to suggest a deeper conceptual organization. According to conceptual metaphor theory (Lakoff \& Johnson, 1999) we think about relatively abstract target domains (like time) in terms of more concrete source domains (like space). This basic organizational principle is purported to serve the functional role of making more abstract concepts easier to talk and think about. It is argued that we depend on such a hierarchy because, for example, we can directly see and touch things "in space" in a way that we cannot "in time." This suggests that thinking about time in terms of space runs cognitively deep, and reflects a mental organization more fundamental than that observed at the relatively superficial level of words.

In a widely cited paper, Casasanto and Boroditsky (2008) sought strong experimental evidence for this theoretical organizational principle. Specifically, they wanted to know if the asymmetry of space-time metaphors in language predicted a similar asymmetry in perception. They reasoned
that low-level perceptual biases demonstrating concordant asymmetry with patterns found in language would provide strong evidence that temporal representations are grounded on more concrete spatial representations.

In their study, participants viewed growing or static lines one at a time on a computer screen. Lines could be of nine durations crossed with nine displacement sizes to produce 81 unique stimuli. After the presentation of each line, participants were randomly prompted to either reproduce a line's spatial extent (by dragging a mouse) or a line's duration (by clicking a mouse). Each line was presented twice: once in each kind of reproduction trial (i.e., displacement or duration estimation).

They found that the remembered size of a line in space concordantly modulated recall for its duration, but not vice versa. That is, (spatially) longer lines were remembered as being presented for longer times, but lines of greater durations were not remembered as having greater spatial extent. The results were consistent with the idea that asymmetrical patterns of space-time mappings in language are preserved further down at the level of perception. They concluded, "these findings provide evidence that the metaphorical relationship between space and time observed in language also exists in our more basic representations of distance and duration" (p. 592).

That we use space to think about time is now widely acknowledged. The idea that time is fundamentally (i.e., ontologically) more abstract than space is regarded as a prerequisite for this relation. However, there are still reasons to question this general view. First, neural data supporting the idea that our temporal concepts are grounded in embodied spatial representations is scarce, partly because it is not entirely clear what an embodied spatial representation is in the first place (Kranjec \& Chatterjee, 2010). Furthermore, recent fMRI evidence suggests that temporal and spatial concepts do not necessarily have privileged relations in the brain (Kranjec, Cardillo, Lehet, \& Chatterjee, 2012). By focusing on space, embodied theories have neglected to investigate temporal conceptual grounding in neural systems that instantiate time perception in the body. Importantly, studies in this area of research tend to rely on visual tasks. This in particular makes it unclear whether observed behavioral asymmetries between time and space reflect (1) general ontological (or even metaphysical) relations dependent on each domain's relative level of "abstractness" or (2) a less general, modalityspecific contribution of visual representations in humans.

To distinguish between these two alternatives, the present study directly probes time-space relations in the auditory domain. Audition was selected because there are intuitive reasons to think that those time-space asymmetries observed in vision might actually be reversed in sound. This is because time, more than space, seems to be an intimate
part of our auditory experience. [But see (Shamma, 2001) for a dissenting view.] For example, whereas spatial relations and visual objects tend to be persistent, sound, like time, is relatively transient (Galton, 2011). While the retina preserves analog spatial relations in early representations, the cochlea does not (Moore, 1977; Ratliff \& Hartline, 1974). Sound localization is less precise than object localization in vision (Kubovy, 1988). And generally, temporal information is more critical and/or salient in common forms of experience grounded in sound perception (e.g., music and speech). In the context of music, "when" a sound occurs matters much more than "where" it does. In speech, the ability to perceive differences in voice onset time is critical for discriminating between phonological categories (Blumstein, Cooper, Zurif, \& Caramazza, 1977). Thus, one might argue that in many critical contexts, relations between sound and time are relatively more concrete than relations between sound and space. The present research directly addresses these issues with a task closely following Casasanto and Boroditsky (2008) but using auditory instead of visual stimuli.

## Methods

Twenty members of the University of Pennsylvania community participated for payment. All participants were right-handed, native English speakers, and between 18-26 years of age. The participants were equiped with headphones and seated at a computer for a self-paced experiment. Participants initiated the beginning of each new trial and the start of each within-trial component. Each trial consisted of two sounds, a target sound followed by a playback sound. In the first part of each trial, the target sound was presented, and participants were instructed to attend to both spatial and temporal aspects of the stimulus. Target sounds consisted of bursts of white noise that changed in location relative to a participant's head position across time. White noise bursts were of nine durations (lasting between 1000 and 5000 ms with 500 ms increments) and 9 distances (moving between .5 and 4.5 m in increments of .5 m ). All durations and distances were crossed to create 81 distinct target sounds. The initial location of the target sound was an average of 2.75 m to the left or right of the listener with a jitter of between .1 and .5 m . Starting locations on the right indicated leftward moving trials and starting locations on the left indicated rightward moving trials. Starting locations were randomly assigned to stimuli with an even number of right and leftward moving trials. The plane of movement was 1 meter in front of the listener. Stimuli were created using Matlab and played using the OpenAL library provided with Psychophysics Toolbox extensions (Brainard, 1997). The OpenAL library is designed to model sounds moving in virtual metric space.

After attending to the target sound, participants were prompted to reproduce either the sound's duration or distance and then instructed to press the spacebar to begin
the playback sound. In this second part of each trial, the playback sound provided the medium for the participant's response. The playback sound began in the final location of the preceding target sound and moved in the reverse direction. So, if a target sound moved rightward, the playback sound moved leftward, and vice versa. On distance trials, participants were instructed to respond when the playback sound reached the start location of the target sound, thereby reproducing the distance from head to start point. In this manner, the participant's head provided a fixed reference point for judging distance. On duration trials, participants were instructed to respond when the playback sound duration was equal to the target sound duration. The playback sound lasted for a fixed 8500 ms and moved 3.5 m past the starting location of the target sound or until the participant responded. The playback sounds were designed in such a manner as to allow participants the possibility to both overshoot and undershoot their estimates. Participants heard each target sound in both duration and distance conditions for a total of 162 trials.

## Results

The results (Fig. 1) demonstrate that actual durations affected estimates of spatial displacement (Fig. 1A: y $=$ $0.0002 \mathrm{x}+1.4208, \mathrm{r}^{2}=.98, \mathrm{df}=7, \mathrm{p}<.01$ ) and that actual spatial displacement affected estimates of duration (Fig. 1B: $\mathrm{y}=128.97 \mathrm{x}+2532.8, \mathrm{r}^{2}=.88, \mathrm{df}=7, \mathrm{p}<.01$ ). On distance trials, for stimuli of the same average duration ( 3000 ms ), sounds shorter in length were judged to be of shorter duration, and sounds longer in length were judged to be of longer duration. On duration trials, for stimuli of the same average displacement ( 2.5 m ) sounds of shorter durations were judged to be shorter in length, and sounds of longer durations were judged to be longer in length. Time and space were mutually contagious in that irrelevant information in the task-irrelevant domain affected participants' estimates of both duration and spatial displacement. Compatible effects were found using multiple regression analyses. Duration was significantly correlated with distance judgments even when variance associated with each trial's actual distance was removed $[\rho r(81)=.81 ; \mathrm{p}<.01]$. Distance was significantly correlated with duration judgments when variance associated with actual duration was removed $[\rho r(81)=.64$; $\mathrm{p}<.01]$. There was no effect of direction (left-moving vs. right moving trials).

Figure 1A-D: (Opposite column) Averaged duration and spatial displacement estimates. The top scatterplots depict between domain effects. The dotted lines represent the line predicted by perfect performance. All space and time intervals were fully crossed. The average of all 9 displacement intervals is 2.5 m at each duration (1A) and the average of the all duration intervals is 3000 ms at each displacement length (1B). The bottom scatterplots (1C and 1D) depict within domain effects. Error bars refer to standard error of the mean.

Participants' overall estimates of duration and displacement were very accurate. The effects of actual duration on estimated duration (Fig. 1C: $\mathrm{y}=0.6805 \mathrm{x}+813.64, \mathrm{r}^{2}=.99$, $\mathrm{df}=7, \mathrm{p}<.001$ ) and actual displacement on estimated displacement (Fig. 1D: $y=0.6374 x+0.4115, r^{2}=.99, \mathrm{df}=$ $7, \mathrm{p}<.001$ ) were also very similar to each other and to analogous analyses of accuracy in Casasanto \& Boroditsky (2008). This suggests that participants were approximately equal in accuracy when making duration and distance judgments within the present experiment and between comparable experiments using auditory and visual stimuli.

The effect of duration on displacement was significantly greater than the effect of displacement on duration (Fig. 2) ( 2 A vs. 2 B : difference of correlations $=0.10 ; z=1.7$ onetailed, $p<.05$ ). However, some caution should be taken when interpreting this result. It is unclear to us whether differences in perceptual judgments between domains can be directly compared at such a fine grain when arbitrarily defined scales, intervals, and ranges (e.g., in seconds and meters) are used to define temporal and spatial aspects of the stimuli. This is a concern even though spatial and temporal judgments focused on identical stimuli. It is possible that other scaled relations could yield different patterns of results.

## Discussion

While strong claims about asymmetrical ontological relations between space and time in the auditory domain are premature, we can report a significant pattern of time-space asymmetry in the auditory domain. This asymmetry is predicted by the temporal nature of auditory processing and runs in the opposite direction of the asymmetry found in the visual domain as predicted by patterns of language use (Casasanto \& Boroditsky, 2008) and the relatively spatial nature of vision.

A prior study using visual stimuli found strong evidence for an asymmetrical relationship between space and time, such
that the remembered size of a stimulus in space modulated recall for its duration, but not vice versa (Casasanto \& Boroditsky, 2008). In contrast, the present study having an analogous design but using auditory stimuli found that space and time are mutually contagious. Furthermore, as predicted by the privileged relation between auditory and temporal processing, the perceived duration of a stimulus had a larger effect on perceived displacement than the reverse. While this is suggestive of a perceptual asymmetry running opposite to that observed in the visual domain, broader claims regarding a deep ontological asymmetry between time and space in the auditory domain are currently unwarranted. Although "in sound," time appears to influence judgments of spatial displacement more than vice versa, these results may not generalize to other scales, intervals, and ranges of time-space relations. And importantly, the effect of spatial displacement on duration estimates was still strong in the auditory domain ( $\mathrm{r}^{2}=.88$ ). In Casasanto and Boroditsky's 2008 study, actual duration had no effect on spatial displacement judgments.

These results demonstrate that time is not necessarily or fundamentally more abstract than space, and suggest that previously observed verbal and mental asymmetries of representing time in terms of space may at least be partially dependent on the human disposition to think visually. The general idea that visuospatial representations are central to how we think and reason in a more general sense about the world is well established (Johnson-Laird, 1986; Tversky, 2005) as is the more specific idea that spatial, visual, and verbal representations are deeply intertwined in giving rise to abstract semantics (Chatterjee, 2001, 2008; Jackendoff, 1996; Talmy, 2000). In the context of previous research demonstrating a strong asymmetry for time-space relations, the results of the present study suggest something very important about the nature of those "embodied spatial representations" that appear to structure patterns in language and thought. That is, such representations are likely visuospatial in nature.

It should be noted that the present results do not refute those reported in Casasanto and Boroditsky's analogous (2008) study. Rather, our results suggest that the hypothesis that time is more abstract than space at the level of a deep ontology and/or basic cognitive architecture may need to be revised. This should not come as a total surprise because "space" is itself a very abstract concept and, like "time," cannot be directly seen, touched, or heard. The present data suggest that what makes certain spatial or temporal relations more or less abstract is the sensory modality in which those relations are processed or experienced. As such, the present results support a refined but intuitive view of embodied cognition that takes into account contributions of a particular sensory modality in processing the abstract qualities of a stimulus. While space and time may be equally abstract, relations between objects immersed in either substrate (whether seen or heard) may be more or less
so depending on a range of species-specific and contextual variables.

#### Abstract

Two experiments in the visual world paradigm investigated competition in sentence processing from dynamic eventrelated information about location. In Experiment 1, listeners viewed visual arrays with container objects like a bowl, jar, pan, and jug, while they heard sentences like "The boy will pour the sweetcorn from the bowl into the jar, and he will pour the gravy from the pan into the jug. But first/And then, he will taste the sweetcorn." While "But first" contexts referred to the "source" location of the discourse-final noun (e.g., "sweetcorn"), "And then" contexts referred to its "goal" location. In Experiment 2, listeners always heard "And then" contexts. We found that listeners rapidly fixated contextrelevant locations. Crucially, they also fixated locations that were context-irrelevant, but related to the discourse-final noun, suggesting object competition, or consistent with abstract location information implied by "But first" (source) or "And then" (goal), suggesting location competition.

Keywords: Competition; Event comprehension; Location; Visual world paradigm.

## Introduction

Everyday, we use language in dynamic real world settings that change along any number of dimensions. One such dimension is location: for example, objects like car keys and TV remotes are routinely involved in actions and events that result in (often frustrating!) changes of location. Findings from the Visual world paradigm (Tanenhaus, SpiveyKnowlton, Eberhard, \& Sedivy, 1995), which presents listeners with spoken language about a visual context, have revealed that listeners' eye movements are rapidly guided by dynamic location information (i.e., information about the multiple instantiations of an object at different locations over event time) during sentence processing.

For example, Chambers and San Juan (2008) instructed listeners to move objects around a visual array, and then they presented listeners with sentences like "Now return the..." They found that listeners anticipatorily fixated previously moved objects, consistent with "return," compared to previously unmoved objects. Similarly, Altmann and Kamide (2009) presented listeners with visual
scenes with objects like a glass (on the floor), table, and bookshelf, followed by a blank screen, and sentences like "The woman will put the glass onto the table. Then, she will pick up the bottle, and pour the wine carefully into the glass." At the discourse-final "the glass," they found that listeners were more likely to fixate the glass's new location (the prior location onscreen of the table), consistent with the sentence context, compared to its initial location on the floor.

## Location-based competition?

Thus, when language comprehenders have dynamic eventrelated information about an object's location (i.e., information about where an object is and/or where it was and/or where it will be), they must resolve which locations are relevant to a sentence context, and which are not. The findings of Chambers and San Juan (2008) and Altmann and Kamide (2009) suggest that language comprehenders rapidly integrate location information with sentence context information, and rapidly retrieve context-relevant locations. Here, we ask a closely related question: do language comprehenders also retrieve context-irrelevant location information? In other words, do irrelevant locations compete with relevant locations?

Hoover and Richardson (2008) addressed this question in a study that used a memory recall task. Their listeners heard spoken facts from a burrowing creature at different locations in a visual display, followed by a question about one of the facts. During the question, they found that listeners were more likely to fixate the location where the queried fact had been presented (compared to distractor locations that the creature had not visited). However, listeners also fixated the location where the non-queried fact had been presented.

Hoover and Richardson (2008)'s findings suggest that location information drives competition effects in eye movements: fixations to locations that are related to target information, but context-irrelevant. This complements competition observed elsewhere: for example, Huettig and Altmann (2005) presented listeners with visual arrays with objects like a trumpet and goat, while they heard words like
"piano." They found that listeners were more likely to fixate trumpet, which was of the same category as "piano" (e.g., musical instrument), compared to distractors (e.g., goat). Hoover and Richardson's findings suggest that in addition to effects based on long-term, semantic knowledge (Huettig \& Altmann, 2005), competition in language also stems from short-term, situated location information.

However, Hoover and Richardson (2008)'s findings also raise a number of new questions. First, evidence for location-based competition is mixed. For example, Altmann and Kamide (2009) observed no competition during "the glass" in their study: listeners were no more likely to fixate the glass's (context-irrelevant) initial location on the floor compared to distractors (e.g., bookshelf). Thus, it is unclear how location-based competition impacts online sentence processing.

Second, and more importantly, Hoover and Richardson (2008)'s findings seem to depend more precisely on object, rather than location, competition. In a second condition in which two different creatures presented their facts, they found no competition effects (i.e., listeners did not fixate the location where the non-queried fact had been presented). Thus, perhaps a more precise way of thinking about their results is that the creature was competing with itself, insomuch as it had to be represented at two locations, rather than that the associated locations were competing. Indeed, this claim is compatible with recent work by Hindy, Altmann, Kalenik, \& Thomspon-Schill (2012): they found that conflict-associated brain regions were activated during sentences that described a state change (e.g., "The squirrel will crack the acorn"). They suggest that event-related changes activate multiple instantiations of an object, and that the representation of the object before the change competes with (and engenders conflict with) the representation of the object after the change.

## Current experiments

In the current study, we tested for location-based and objectbased competition effects in sentence processing. In two experiments, we addressed a critical difference between Altmann and Kamide (2009) and Hoover and Richardson (2008): the predictability of the context-relevant location information. In Altmann and Kamide, the discourse contexts were highly predictable (e.g., the discourse-final "the glass" could be anticipated based on the verb selectional restrictions of "pour"), and consequently they observed strong anticipatory effects (e.g., listeners fixated contextrelevant locations prior to the discourse-final noun). By contrast, Hoover and Richardson (2008) queried facts (and their associated locations) at random. Here, we used discourse contexts that were closely related to Altmann and Kamide (2009), but that did not allow for anticipation. Listeners viewed visual arrays with container objects like a bowl, jar, pan, and jug (Figure 1), while they heard sentence pairs like ( $1 \mathrm{a}, \mathrm{b}$ ).
(1a) The boy will pour the sweetcorn from the bowl into the jar, and he will pour the gravy from the pan into the jug.
(1b) But first/And then, he will taste the sweetcorn.
Two critical referents (e.g., "sweetcorn" and "gravy") were described in (1a), so that listeners could not anticipate the discourse-final noun in (1b) (half of trials re-referred to the first critical referent ["sweetcorn"], and half to the second critical referent ["gravy"]). In Experiment 1, listeners heard both "But first" contexts, which referred to the "source" location (e.g., bowl) of the discourse-final noun (e.g., "sweetcorn"), and "And then" contexts, which referred to its "goal" location (e.g., jar). In Experiment 2, listeners only heard "And then" contexts, which always referred to the "goal" location.

Crucially, our design allowed us to disentangle locationbased and object-based competition. In both experiments, we tested for object-based competition (e.g., competition between sweetcorn and itself) by examining fixations to container objects that were related to the discourse-final noun but inconsistent with "But first/And then" (e.g., jar, the goal location of "sweetcorn," following "But first, he will taste the sweetcorn"). On the other hand, we tested for location-based competition (e.g., competition between source/goal locations, which were not linked via an object) by examining fixations to container objects that were consistent with "But first" (source location) or "And then" (goal location) but unrelated to the discourse-final noun (e.g., pan, the source location of "gravy," following "But first, he will taste the sweetcorn").

## Experiment 1

Figure 1: Example visual array from Experiments 1 and 2.

## Methods

Participants Forty-eight individuals from the University of Dundee community participated for course credit or $£ 4$.

Materials We constructed 48 sentence pairs like (1a,b). The first sentence described the critical contents of two containers moving either from their initial locations into two new locations (1a), or into two new locations from their initial locations. The second sentence referred to either the

Figure 2: Average ( $95 \%$ CI) proportions of fixations to source and goal locations of the sweetcorn (target referent) and gravy (competitor referent) during "But first..." (A) and "And then..." (B) "he will taste the sweetcorn" in Experiment 1.
first (e.g., "sweetcorn") or second (e.g., "gravy") of the critical contents, and either its initial ("But first") or new ("And then") location (1b). Each item had eight forms, reflecting the crossing of movement description (from-into and into-from), conjunction ("But first" and "And then"), and discourse-final noun ("sweetcorn" and "gravy"), which were rotated across participants (see Appendix A). Visual arrays (Figure 1) depicted the container objects in the four corners of the display, but not their contents.

For each critical referent, the "source" location was the location of the object before the described movement (e.g., sweetcorn: bowl; gravy: pan), and the "goal" location was
the location of the object after the described movement (e.g., sweetcorn: jar; gravy: jug).

Procedure We used an SR Research EyeLink II headmounted eye tracker, sampling at 500 Hz from one eye (viewing was binocular). The experiments involved a look-and-listen task: participants were instructed to look carefully at the visual arrays, and to listen carefully to the sentences. The onset of the visual stimulus preceded the onset of the spoken stimulus by $1,000 \mathrm{~ms}$. A trial ended $3,000 \mathrm{~ms}$ after the offset of the sentence.

The eye tracker was recalibrated after every eighth trial. The experiment began with four practice trials, and included

12 filler trials (which described a single critical object, rather than two). The experiment was approximately 40 minutes in length.

## Results

Average proportions of fixations to source and goal locations of the sweetcorn (target referent) and gravy (competitor referent) in the visual array are plotted during "But first, he will taste the sweetcorn" in Figure 2A and during "And then, he will taste the sweetcorn" in Figure 2B. Eye movements were resynchronized at the onset of each of the plotted windows ("But first/And then," "he will taste the," "sweetcorn").

We analyzed eye movements during three time windows: during "But first/And then, he will taste the," at the offset of "sweetcorn," and between sentence offset and 500 ms following sentence offset. These windows directly precede, and follow, the critical discourse-final noun. Average proportions of fixations to each region of interest (ROI) are reported within each time window in Table 1 ("But first...") and Table 2 ("And then..."). We submitted proportions of fixations to planned pairwise comparisons (using paired $t$ tests).

Table 1: Average (SD) proportions of fixations to source and goal locations of the sweetcorn (target referent) and gravy (competitor referent) during "But first, he will taste the," at the offset of "sweetcorn," and between sentence offset and 500 ms past sentence offset in Experiment 1.

| ROI | "But" | "sweetcorn" | $\mathbf{+ 5 0 0}$ |
| :--- | :---: | :---: | :---: |
| sweetcorn (source) | $.19(.07)$ | $.35(.13)$ | $.41(.16)$ |
| sweetcorn (goal) | $.25(.08)$ | $.26(.09)$ | $.26(.10)$ |
| gravy (source) | $.20(.06)$ | $.16(.08)$ | $.14(.07)$ |
| gravy (goal) | $.26(.08)$ | $.14(.10)$ | $.11(.07)$ |

Table 2: Average (SD) proportions of fixations to source and goal locations of the sweetcorn (target referent) and gravy (competitor referent) during "And then, he will taste the," at the offset of "sweetcorn," and between sentence offset and 500 ms past sentence offset in Experiment 1.

| ROI | "And" | "sweetcorn" | $\mathbf{+ 5 0 0}$ |
| :--- | :---: | :---: | :---: |
| sweetcorn (source) | $.18(.08)$ | $.23(.10)$ | $.24(.10)$ |
| sweetcorn (goal) | $.26(.08)$ | $.36(.14)$ | $.42(.14)$ |
| gravy (source) | $.19(.08)$ | $.14(.08)$ | $.11(.08)$ |
| gravy (goal) | $.26(.08)$ | $.18(.11)$ | $.14(.09)$ |

"But first." During "But first, he will taste the," fixations to goal locations were reliably greater than to source locations ( $p$ 's $<.001$ ). However, fixations to sweetcorn and gravy source locations did not differ reliably

[^126]( $p=.68$ ), and fixations to sweetcorn and gravy goal locations did not differ reliably ( $p=.60$ ).

At the offset of "sweetcorn," fixations to the (contextrelevant) sweetcorn source location were reliably greater than to the sweetcorn goal location ( $p<.01$ ), gravy source location ( $p<.001$ ), and gravy goal location ( $p<.001$ ); fixations to the sweetcorn goal location were reliably greater than to the gravy source location ( $p<.001$ ) and gravy goal location ( $p<.001$ ), capturing object competition; and fixations to the gravy source location were not reliably different from the gravy goal location $(p=.49)$.

Finally, during the 500 ms time window following sentence offset, fixations to the sweetcorn source location were reliably greater than to the sweetcorn goal location ( $p$ $<.001$ ), gravy source location ( $p<.001$ ), and gravy goal location ( $p<.001$ ); fixations to the sweetcorn goal location were reliably greater than to the gravy source location ( $p<$ .001 ) and gravy goal location ( $p<.001$ ), capturing object competition; and fixations to the gravy source location were reliably greater than to the gravy goal location ( $p<.05$ ), capturing location competition.
"And then." During "And then, he will taste the," fixations to goal locations were reliably greater than to source locations ( $p$ 's < .001). However, fixations to sweetcorn and gravy source locations did not differ reliably ( $p=.66$ ), and fixations to sweetcorn and gravy goal locations did not differ reliably $(p=.81)$.

At the offset of "sweetcorn," fixations to the (contextrelevant) sweetcorn goal location were reliably greater than to the sweetcorn source location ( $p<.001$ ), gravy goal location ( $p<.001$ ), and gravy source location ( $p<.001$ ); fixations to the sweetcorn source location were reliably greater than to the gravy goal location $(p=.05)$ and gravy source location ( $p<.001$ ), capturing object competition; and fixations to the gravy goal location were marginally greater than to the gravy source location ( $p=.08$ ), capturing location competition.

Finally, during the 500 ms time window following sentence offset, fixations to the sweetcorn goal location were reliably greater than to the sweetcorn source location ( $p<.001$ ), gravy goal location ( $p<.001$ ), and gravy source location ( $p<.001$ ); fixations to the sweetcorn source location were reliably greater than to the gravy goal location ( $p<.001$ ) and gravy source location ( $p<.001$ ), capturing object competition; and fixations to the gravy goal location were marginally greater than to the gravy source location ( $p$ $=.08$ ), capturing location competition.

## Discussion

During the discourse-final noun, we found that listeners were more likely to fixate context-relevant locations compared to all other locations (e.g., see fixations to the sweetcorn source location in Figure 2A and sweetcorn goal location in Figure 2B). Consistent with Chambers and San Juan (2008) and Altmann and Kamide (2009), these results suggest that listeners rapidly integrate location and sentence

Figure 3: Average ( $95 \% \mathrm{CI}$ ) proportions of fixations to source and goal locations of the sweetcorn (target referent) and gravy (competitor referent) during "And then, he will taste the sweetcorn" in Experiment 2.
context information. We also found that listeners had a strong bias to fixate goal locations prior to the discoursefinal noun for both "And then" (in which goal information was relevant) and "But first" (in which source information was relevant) contexts. This result suggests that listeners may be biased to track "current" location information: indeed, by the end of the second sentence, the "current" location corresponds to the goal location if one assumes that the description of the events in the language, and the events themselves, are closely time locked.

Crucially, we also found evidence for object-based competition: listeners were more likely to fixate locations that were related to the discourse-final noun but inconsistent with "But first/And then" compared to completely unrelated locations (e.g., see fixations to the sweetcorn goal location vs. gravy goal location in Figure 2A and sweetcorn source location vs. gravy source location in Figure 2B). This result suggests that representations of the sweetcorn at contextirrelevant locations were competing with representations of the sweetcorn at context relevant locations.

Finally, we also found evidence for location-based competition that was independent of object-based competition. Following "sweetcorn," listeners were more likely to fixate the gravy source location compared to the gravy goal location with "But first," which was consistent with source locations, although both gravy locations were unrelated to "sweetcorn." The opposite pattern was also observed with "And then," although the effect was marginal. These results suggest that source locations were competing, based on abstract information about whether a location was a source or a goal of an event, even though no object was present at two source locations.

Next, we asked: can location-based competition be reduced in a setting in which there is less uncertainty about
which referents are relevant? Thus, in Experiment 2 listeners always heard "And then" contexts, in which goal locations were relevant.

## Experiment 2

## Methods

Participants Twenty-four individuals from the University of Dundee community participated for course credit or $£ 4$.

Materials Materials were identical to Experiment 1, except that the second sentence always referred to the goal location ("And then...").

Procedure The procedure was identical to Experiment 1.

## Results

Average proportions of fixations to source and goal locations of the sweetcorn (target referent) and gravy (competitor referent) in the visual array are plotted during "And then, he will taste the sweetcorn" in Figure 3. We performed identical analyses to Experiment 1. Average proportions of fixations by ROI are reported in Table 3.

During "And then, he will taste the," fixations to goal locations were reliably greater than to source locations ( $p$ 's $<.001$ ). However, fixations to sweetcorn and gravy source locations did not differ reliably ( $p=.19$ ), and fixations to sweetcorn and gravy goal locations did not differ reliably ( $p$ $=.50$ ).

At the offset of "sweetcorn," fixations to the (contextrelevant) sweetcorn goal location were reliably greater than to the sweetcorn source location ( $p<.001$ ), gravy goal location ( $p<.001$ ), and gravy source location ( $p<.001$ );
fixations to the sweetcorn source location were reliably greater than to the gravy source location ( $p<.001$ ), capturing object competition, but not the gravy goal location ( $p=.21$ ); and fixations to the gravy goal location were reliably greater than to the gravy source location ( $p<.05$ ), capturing location competition.

Finally, during the 500 ms time window following sentence offset, fixations to the sweetcorn goal location were reliably greater than to the sweetcorn source location ( $p<.001$ ), gravy goal location ( $p<.001$ ), and gravy source location ( $p<.001$ ); fixations to the sweetcorn source location were reliably greater than to the gravy goal location ( $p<.001$ ) and gravy source location ( $p<.001$ ), capturing object competition; and fixations to the gravy goal location were reliably greater than to the gravy source location ( $p<$ .05 ), capturing location competition.

Table 3: Average (SD) proportions of fixations to source and goal locations of the sweetcorn (target referent) and gravy (competitor referent) during "And then, he will taste the," at the offset of "sweetcorn," and between sentence offset and 500 ms past sentence offset in Experiment 2.

| ROI | "And" | "sweetcorn" | $\mathbf{+ 5 0 0}$ |
| :--- | :---: | :---: | :---: |
| sweetcorn (source) | $.16(.06)$ | $.19(.07)$ | $.22(.08)$ |
| sweetcorn (goal) | $.29(.06)$ | $.44(.13)$ | $.48(.14)$ |
| gravy (source) | $.17(.04)$ | $.12(.05)$ | $.09(.05)$ |
| gravy (goal) | $.28(.05)$ | $.17(.07)$ | $.13(.06)$ |

## Discussion

The pattern of results in Experiment 2 was similar to Experiment 1. We found that listeners were more likely to fixate the context-relevant sweetcorn goal location compared to all other locations. Similarly, listeners also fixated the sweetcorn source location based on object competition, and the gravy goal location based on location competition. Further, these results suggest that competition does not depend on mentioning both source/goal locations.

## General Discussion

In two experiments, we found evidence for both locationbased and objects-based competition in sentence processing. While our sentence contexts modulated fixations to contextually-relevant locations, they did not fully inhibit fixations to contextually-irrelevant "competitor" locations. Consistent with Hoover and Richardson (2008) and Hindy et al. (2012), our results suggest that representations of an object (e.g., sweetcorn) before an event-related change compete with representations of the object after the change. In our case, the crucial event-related change was one of location, and the impact of this competition was reflected in eye movements to context-irrelevant locations. Critically, we also found evidence for object-independent location competition (e.g., between goal locations, although they corresponded to different objects [i.e., sweetcorn vs. gravy]). Taken together, these findings suggest that these
two sources of competition - objects and abstract location information - are separable, and have differential effects on sentence processing.

But our findings also diverged from the results of Altmann and Kamide (2009), who did not observe competition during "the glass" (see the Introduction). As we have suggested, a critical difference between the current experiments and their study was the predictability of the context-relevant location. Indeed, they did observe anticipatory competition effects: just prior to "the glass" (i.e., during "the wine carefully into"), listeners were reliably more likely to fixate competitor locations than distractors. Taken together, these findings suggest that location information does compete, and that this competition can precede the mention of the critical referent.

## Acknowledgments

We thank Karl Smith Byrne, Aneta Lisowska, and Robert Petrie for their help with data collection. We gratefully acknowledge support from ESRC Grants RES-062-23-2749 to GTMA and YK and RES-062-23-2842 to YK.

#### Abstract

${ }^{1}$ Accounts of mechanistic explanation require that complex cognitive phenomena can be decomposed into simpler subtasks. We provide a theory of explanation that rationalizes this requirement, and then we use a simple genetic algorithm exercise to demonstrate that evolution can produce designs that violate this functional modularity requirement.

Keywords: mechanism; explanation; evolution; modularity; genetic algorithm

## Introduction

Connectionism, dynamical systems theory, and new robotics have questioned whether the search for informationprocessing mechanisms provides a feasible approach to the study of biologically evolved cognitive systems such as the human mind. Whereas approaches that have their origins in classical AI tend to conceive of cognition as a set of computational operations to be mapped onto physiological parts according to functional decompositions inspired directly by the programmer's intuitions about possible efficient subroutines, the alternative research programs emphasize that biological evolution is likely to produce unintuitive designs of such complexity that renders heuristics based on decomposability and programming intuitions unusable.

In this paper we analyze the problems that evolved solutions raise to the mechanistic understanding of cognitive phenomena. The problem of understanding non-intuitive designs produced by natural selection is well-known in philosophy of psychology (e.g., Clark 1997, Ch. 5), philosophy of biology (Wimsatt 2007), and now even in popular psychology (Marcus 2008), but it has proved to be difficult to articulate without a clear idea of what exactly it is that evolutionary tinkering is supposed to hinder. The main challenge for scientific understanding is often framed and explained by pointing to the path-dependent nature and the resulting unfamiliarity of the evolved design (Jacob 1977). We argue that this is not the whole story. The aim of this paper is to provide an explicit theory of mechanistic explanation and understanding that will move us beyond intuitions towards a more systematic analysis of the nature of these challenges. We also combine our theory of explanation with a computational application of

[^127]evolutionary design: problem-solutions generated by genetic algorithms. By analyzing the nature of solutions that genetic algorithms offer to computational problems, we suggest that evolutionary designs are often hard to understand because they can exhibit non-modular functionality, and that this creates problems for strategies of mechanistic explanation.

## Mechanistic Explanation in the Cognitive Sciences

According to the proponents of the mechanistic approach to explanation (Bechtel 2008; Craver 2007; Piccinini \& Craver 2011), a central goal of the cognitive sciences is to provide understanding of system-level properties of the cognitive system in terms of the properties of its physical component parts and their organization. The most developed philosophical account of strategies for reaching such mechanistic understanding is Bechtel and Richardson's (2010) study of the heuristics of decomposition and localization (DL). The DL procedure goes roughly as follows. First, the different phenomena that the system of interest exhibits are differentiated. Then the phenomenon of interest is functionally decomposed, i.e., analyzed into a set of possible component operations that would be sufficient to produce it. One can think of this step as the formulation of a preliminary set of simpler functions that, taken together, would constitute the more complex input-output relation (the system-level phenomenon). The system is also structurally decomposed into a set of component parts. The final step is to try to localize the component operations by mapping them onto appropriate structural component parts. If this cannot be done, the fault may lie with the functional and structural decompositions or with the very identification of the phenomenon, and these may then have to be rethought. The identification and decomposition procedures will in the beginning be guided by earlier theories and common sense, but empirical evidence can always suggest that a thorough reworking of the basic ontology and the form of the possible explananda may be in order.

What the schema of Bechtel and Richardson lacks is an explicit theory of explanation providing an account of what makes such decomposition and localization exercises explanatory. Whereas cognitive theories of explanation (Churchland 1989; Thagard 2012; Waskan 2006) focus on the internal models and processes of the individuals engaged in explanation-related tasks, such conceptualization is
misleading when thinking about the goal of research: understanding. We use the term 'understanding' in order to shift our focus from single explanations to a broader collective epistemic goal. Scientific understanding proper is not what happens inside individual heads, but is constituted by the collective abilities of the scientific community to reason about and to manipulate the objects of investigation. To conceptualize scientific understanding directly based on models of individual explanatory cognition is to commit a fallacy of composition.

We therefore approach understanding as a public, behavioral concept. Understanding is a regulative label, which is attributed with regard to manifest abilities in action and correctness of reasoning. Suitable cognitive processes (comprehension), and possibly the possession of right mental models, taking place in the privacy of individual minds, are a causal prerequisite for possible fulfillment of these criteria, but these processes themselves are not the facts in virtue of which something is understood or not. They are not the criteria of understanding in the sense that we would have to know them in order to say whether somebody really understands something. The correctness of internal mental models is judged according to manifest cognitive performance, not the other way round (Ylikoski \& Kuorikoski 2010).

We take the principal criterion of understanding to be inferential performance: whether someone understands a phenomenon is assessed based on whether he or she can make correct inferences related to it. Thus our view of understanding can be linked to Woodward's (2003) widely accepted account of scientific explanation, which tells us more specifically what kinds of inferences are constitutive of specifically explanatory understanding (see also Craver 2007). Explanation consists in exhibiting functional dependency relations between variables. This is the connection between explanation and understanding: knowledge of explanatory relationships grounds understanding by implying answers to what-if-things-had-been-different questions concerning the consequences of counterfactual or hypothetical changes in the values of the explanans variable. This is the important difference between explanatory information and purely descriptive information. Whether someone understands a phenomenon is evaluated according to whether he or she can make inferences not only about its actual state, but also about possible states of the phenomenon or system in question.

## Modularity and Understanding

According to Bechtel and Richardson, decomposability is a regulative ideal in mechanistic model construction because complex systems are psychologically unmanageable for humans. Decomposition allows the explanatory task to be divided into parts that are manageable for cognitively limited beings, thereby rendering the system intelligible (Bechtel \& Richardson 2010). The idea comes originally from Simon (1962), who claimed that complex systems have to be nearly-decomposable in order to be
understandable for finite cognitive agents. Neardecomposability means that the system can be decomposed into parts in such a way that the intrinsic causal properties of the parts are more important for the behavior of the system than their relational causal properties, which are constituted also by their environment and interaction. Neardecomposable systems are thus hierarchical in the sense that the complex whole can be seen as made from a limited set of simpler parts and interactions. Hierarchical systems are more manageable for cognitively limited beings because their 'complete description' includes recurring or irrelevant elements describing similar recurring parts and nonimportant interactions. The removal of such descriptions does not hamper our understanding of the system and thus eases cognitive load.

Although there are a number of arguments that conclusively show that such informational economy by itself is not constitutive of understanding, ${ }^{2}$ we agree with Simon (and Bechtel and Richardson) in that a property closely related to near-decomposability, namely modularity, is a necessary condition for mechanistic explanations. In the case of causal-mechanistic explanations, the explanatory dependencies track the consequences of interventions (Woodward 2003; see fig. 1) and causal knowledge thus enables the goal-directed manipulation of the object of explanation. These answers are the basis of the inferential performance constitutive of causal understanding.

$$
\begin{aligned}
& X=f(U) \\
& Z=g(X) \\
& Y=h(Z, U)
\end{aligned}
$$

$$
\begin{aligned}
& X=f(U) \\
& Z=Z \\
& Y=h(z, U)
\end{aligned}
$$

Figure 1. Invariance under exogenous interventions distinguishes "deep", causal, dependencies from mere correlations. $\mathrm{P}(\mathrm{Y} \mid \mathrm{Z}=\mathrm{z})$ is not the same as $\mathrm{P}(\mathrm{Y} \mid \operatorname{set}(\mathrm{Z}=\mathrm{z}))$.

Such answers to what-if questions are derived from internal or external representations of the object of understanding. In order for these answers to be well defined, the dependencies grounding the answers have to possess some degree of independence such that a local change in an aspect of the phenomenon under study cannot ramify uncontrollably or intractably. If local modifications in a part of a system disrupt other parts (dependencies) in a way that is not explicitly specified (endogenized) in the (internal or external) representation of the system according to which the what-if inferences are made, the consequences of these changes are impossible to predict and counterfactual assertions impossible to evaluate (Woodward 2003, 333).

[^128]Therefore, a necessary condition for a representation to provide explanations, and thus understanding, of a phenomenon is that the modularity in the representation matches the modularity in the phenomenon.

If we intervene on a causal input corresponding to variable $X_{i}$ in a model of the studied system, and the intervention, no matter how surgical, also changes the dependencies within the system, or values of other variables themselves affecting variables causally downstream of $X_{i}$, the model does not give correct predictions about the consequences of the intervention. Hence, the model does not provide correct causal understanding of the system and the causal role of the variable in it. If the system cannot be correctly modeled on any level of description or decomposition so that it is modular in the way described above - if the system itself is not causally modular - no what-if-things-had-been-different questions concerning interventions in the system can be answered. This would mean that every local change brings about intractable changes elsewhere in the system to such an extent that there can be no representation that would enable a cognitively finite being to track these changes and make correct inferences about their consequences.

The problem of understanding causally non-modular systems has received some attention in the philosophy of science literature (e.g., Bechtel and Richardson 2010, Ch. 9). However, according to the DL schema, before we can even start thinking about searching for the causalmechanistic implementation of the complex system behavior, we need to formulate hypotheses about the possible functional decompositions of the behavior (see also Cummins 1983). For example, what kind of simpler subtasks could possibly produce complex cognitive capacities such as language production and comprehension, long-term memory, and visual object-recognition? Importantly, this task is separate, though not independent, from hypotheses concerning the implementation of the capacity. Although the understanding offered by the functional decomposition is not, strictly speaking, causal component operations do not cause the whole behavior because they are constitutive parts of it - the modularity constraint on understandability still applies in the following way. We can only understand the complex behavior by having knowledge of its component operations, if we can make reliable what-if inferences concerning the possible consequences of changes in the component operations for the properties of the more complex explanandum capacity. For example, we provisionally understand working memory if we can infer from possible changes in its hypothesized component operations (such as differences in the properties of the postulated phonological loop or episodic buffer) to changes in the properties of the capacity. These inferences are only possible if the functional decomposition itself is suitably modular, i.e., the consequences of "local" changes in component operations do not ramify in an intractable way, making the behavior of the whole completely holistic. We now argue that genetic algorithms demonstrate that
design-by-selection can lead to such non-modular complex behavior.

## Genetic Algorithms

From the point of view of AI, genetic algorithms (henceforth GAs) are a form of non-exhaustive but massively parallel search in the search space of a problem (Holland 1975; Mitchell 1996). Although GAs are not the only strand of evolutionary programming, they serve our purpose well because their basic principles are easy to understand and they are the most well-known kind of evolutionary programming outside computer science (Clark 1997, 2001; Mitchell 2009). GAs are useful for a number of different purposes, but here we use a simple example originally from Mitchell (2009, Ch. 9), where a GA is used to evolve a behavioral strategy for a simulated agent.

Mitchell's model shows how an algorithm mimicking biological evolution can be used to develop a controlling program for a robot picking up soda cans on a 10x10 grid. Robby the robot can only see the squares adjacent to its location (center, North, South, East, West), and each turn it can either move one step to a particular direction, move at random, try to pick up a can, or do nothing. Each simulation run lasts for a predetermined amount of time steps (originally 200), and Robby's task is to pick up as many randomly situated cans as possible.

Genome G:
$[1,0,3,2,0,2,0,0,3,6,6,6,6,2,2,6,6,6,0,2,5,7,3,8,5,10,8$, $3,0,3,3,2,10,3,0,3,6,6,6,2,2,2,6,6,6,2,8,7,6,4,9,9,6,6$, $2,1,1,2,2,0,7,0,1,6,0,6,6,5,8,4,0,6,7,9,8,9,6,6,2,1,0,1$, $4,1,2,0,2,6,2,7,6,0,6,6,6,6,1,1,3,1,4,8,8,9,4,8,6,9,3,0$, $1,3,2,4,3,2,9,6,6,6,2,2,4,6,1,4,0,7,4,6,3,7,2,2,10,1,4$, $1,5,7,8,9,0,5,6,0,6,2,7,2,7,6,2,10,8,1,1,5,10,0,2,6,2,0$, $3,2,0,7,0,0,9,6,6,4,6,6,1,6,6,8,8,6,7,8,5,5,8,9,4,3,4,9$, $3,3,6,0,10,10,6,0,9,6,10,4,10,3,9,3,10,4,5,5,7,8,7,1,2$, $6,5,8,5,10,7,6,10,6,0,6,2,2,5,9,2,8,2,6,3,1,5,6,8,6,2]$

Figure 2. Each "locus" in the genome G corresponds to one of the possible immediate environmental states of Robby, and each digit (the allele) to a move in that situation (e.g., ' 0 ' $\rightarrow$ 'move north', '5' $\rightarrow$ 'pick up') (see Mitchell 2009, 137).

Initially a random population of software individuals is generated, each with a "genome" consisting of 243 random numbers. Each locus in the genome guides Robby's behavior in a particular situation (Fig 2). The fitness score of each candidate in the population is calculated by running several simulation trials: crudely, the more cans the robot is able to pick up on average, the higher its fitness. Programs with the highest fitness are then used to form the next generation: they are paired randomly, and the genomes of the two parents are crossed over at a randomly chosen point to create the genomes of new individuals. Finally, for each locus of a descendant's genome, there is a small probability (.005) that a mutation occurs in it. As a result, the new generation is based on the most successful variants among the previous generation, and the process loops back to the fitness-calculation phase. Thus the GA continues searching
for efficient solutions by charting new regions of the search space.

After a few hundred generations, the evolved strategies start to achieve impressive results. As we replicated Mitchell's simulation, we observed that after the $800^{\text {th }}$ generation, the best strategies among evolved Robbys started to have higher fitness scores than a Robby programmed by a human designer (ultimately 480 vs. 440 points). ${ }^{3}$ However, although solutions found with GAs are efficient, their behavior is often hard to understand. The ingenious behavioral strategies that the programs employ cannot be deciphered by simply looking at individual genes or sets of genes. Instead, it is necessary to look holistically at the broad phenotypic behavior of the robot. A nice illustration of this impenetrability of such evolved solutions is the fact that in some cases when a high-fitness Robby is in the same square with a can, it decides not to pick it up, but rather moves away from the square. While this behavior seems prima facie irrational, looking at the total behavioral profile of the robot uncovers a clever strategy: Robby uses cans as markers to remember that there are other cans on its side, and it explores the adjacent squares for extra cans before picking up the marker can. Thus by not treating cans only as targets but also as navigational tools, Robby uses its environment to extend its severely limited visual capacities and to compensate for its total lack of memory.

Moreover, by examining the behavior of a highly efficient $1500^{\text {th }}$ generation Robby, it can be seen that this marker strategy manifests in slightly different ways in different environmental situations. It is not a discrete adaptation, but rather a collection of independently evolved sub-strategies. Furthermore, the marker strategy is tightly intertwined with another environment-employing "hack" that the sophisticated Robby uses: when there is already a lot of empty space on the grid, Robby employs a "vacuumcleaner" movement strategy. It follows the walls of the board, departing toward the center when it detects a can, employs the marker strategy if possible, and immediately after cleaning up its local environment, returns directly to the south wall to continue its round around the board. This strategy also includes an ingenious "bounce" feature: when Robby arrives to the corner preceding the wall that is parallel to its default navigation direction in an empty field, it bounces off the wall to increase the range of this search pattern.

Such "kluges" are common to designs created by GAs. Like biological evolution, GAs can come up with solutions that a human designer would not think of. These solutions often offload parts of problem solving to the environment, and thus rely on a tight coupling between the system and its environment. And, as pointed out by Clark (1997, 2001), recurrent circuitry and complex feedback loops between different levels of processing often feature in systems designed by GAs. Such designs are often difficult to understand.

[^129]We suggest that these difficulties in understanding are often created by the lack of modularity in the functional decomposition of the behavior. The high-fitness Robby (genome G in Fig. 1) mentioned in the paragraph above only leaves cans as markers in some specific situations, and only the totality of this selective marking strategy - together with navigational strategies utilizing cans and walls - constitutes the effectiveness of the can-search procedure. Looking at isolated genes in Robby's genome only reveals trivially modular elements corresponding to elementary subtasks in its behavior: one gene corresponds to an elementary move in a specific environmental situation. But we cannot make inferences from local hypothetical changes in these elemental behaviors to consequent effects on fitness. The connection between any single elementary behavioral rule and the strategy is simply too complex and context dependent. A change in a single rule (in situation B; a can present; whether to pick up or not to pick up the can) has consequences for the effectiveness of the other elementary behavioral rules. Explanatorily relevant inferences would require an extra "level" of modular sub-operations between the individual movements and the strategy as a whole.

The marker and vacuum-cleaner strategies mentioned above appear to be examples of such middle-level suboperations, but by themselves they are insufficient to yield understanding of the whole behavior of our most successful Robby. This is because the effectiveness of leaving a can is a result of the evolved coupling between the specific situations in which Robby leaves a can and the rest of the navigation behavior. Therefore, there is no way of independently altering these middle-level strategies. Also "the bounce" is intertwined with the rest of the vacuuming navigation and cannot be independently altered. In general, genetic algorithms do not often produce easily discernible designs. Rather, the interesting heuristics in the system's behavior can only be revealed by simultaneously looking at constellations of different genes, and eventually, the whole genome.

To recapitulate, our example exhibits several distinct (yet related) challenges to understanding:
(1) The discernible middle-level strategies (marker, vacuum-cleaner) do not have dedicated structural bases. Instead, the nature of the design process leaves all atomic structural elements (the 243 DNA elements) open for exploitation by all capacities serving the main goal. Consequentially, the system is neither structurally nor behaviorally nearly-decomposable, but instead has a "flat hierarchy," and strategies are implemented in highly distributed structures.
(2) Challenge 1 above means that the interactions between subtasks tend to be strong: a change in one subtask constituting a part of the marker-behavior also affects the functioning of the vacuum-cleaner navigation. In general, the middle-level strategies can only be discerned and defined in a very abstract way, and the interaction-effect on their contribution to the overall fitness is so large as to make
any inferences about the consequences of partial changes in one strategy next to impossible.
(3) The way in which the strategies contribute to the fitness of the individual is highly context-dependent and depends on the properties of the environment as well as the DNA of the agent. Even small modifications to the environment can lead to drastic changes in the performance of a strategy. For instance, we observed that adding only a few randomly placed extra walls on the grid radically collapses the average score of the successful Robby described above.

Extrapolating from this very simple case, we contend that GAs may design behavior that cannot be tidily decomposed into hierarchical and modular subtasks, whose individual contributions would be easy to understand (i.e., we could infer how a change in a sub-routine would affect the behavior of the mother-task). Instead, feedback, many tasks using the same subtasks as resources, and tight systemenvironment coupling lead to holistic design where almost "everything is relevant for everything." The evolved functional architecture is flat in that there are few discernible levels of order between the elementary operations and the complex behavior. The counterintuitiveness of such flat architectures is apparent in the deep mistrust faced by connectionist suggestions for nonhierarchical design of cognitive capacities (see e.g., Rumelhart and McClelland 1986 vs. Pinker and Prince 1988).

Furthermore, GAs underscore the path dependence of evolutionary problem solving. For sufficiently complex computational problems there are often several local maxima in the fitness landscape of the problem, and the population can converge to different maxima in different runs of the simulation. The functional decomposition that a human designer comes up with is just one possible solution among several others. Perhaps our biological evolution actually ended up with a radically different one.

## Lessons for the Study of Mind

Genetic algorithms demonstrate that evolution can, in principle, lead to non-modular functionality. This imposes a limit on our ability to understand such behavior: if we cannot trace the consequences of changes in the suboperations, we cannot answer what-if questions concerning the complex behavior. Such behavior constitutes a thorny problem for mechanistic understanding of the implementation of the said behavioral capacities, since the DL heuristic cannot get off the ground: we do not even know what we are supposed to localize. We can now ask two questions: should we expect to find such non-modular functionality in nature, especially in human cognition, and if so, what attitude should we adopt with respect to this problem. Should the aim of causal-mechanistic understanding of the brain be given up, and be replaced, for example, with non-mechanistic dynamical models often
employing a limited set of instrumentally interpreted macrovariables?
There are important disanalogies between GAs and biological evolution. As is the case with Robby, there is often no genotype-phenotype distinction. In biological evolution, however, genes do not directly cause properties of the phenotype, but rather participate in guiding ontogenesis. It has been suggested that ontogenesis itself favors modular design. GAs may also seem a problematic platform for exploring the possibilities of DL heuristics, since the lowest level of functional organization and the level of implementation are identical (i.e., the genome). However, we see no reasons why this would affect our argument. Moreover, the argument developed here is not only about genetic selection, but about selection in general, and failures of functional modularity may in principle also arise in the course of development - at least if the idea of neuronal group selection or "neural Darwinism" is taken seriously.
The recent research on biological control networks (metabolic and gene regulatory networks) suggests that evolved modular organization is in fact the rule rather than the exception: control networks exhibit network modularity and the recurring modules (motifs) have easily discernible modular functions. Therefore, the question in the recent years has rather been to formulate an evolutionary explanation for this modular design. Genetic algorithms have been used to argue that modularity is not selected for, but that it is instead a byproduct of specialization of gene activity (Espinasa-Soto \& Wagner 2010) or of selection against densely connected networks and long connections (Clune, Mouret \& Lipson 2013).

Most interesting for our case, Kashtan and Alon (2005; see also Kashtan et al. 2007) have demonstrated that when the goals themselves are composed of modularly varying sub-goals, evolution tends to produce modular functionality. It seems easy to see why this is the case. If the tasks to which the system has to adapt remain the same, the selection environment does not change, and the peaks in the fitness landscape are stable, then selection favors strategies that offload problem solving to that particular environment as much as possible. But if the task itself is composed of changing subtasks, it makes sense to design the adaptive response in such a way that a particular sub-operation can locally adapt to a local change in a subtask without altering the totality of the otherwise well-functioning behavior.
In their research, Kashtan and Alon evolved several network models to compute complex Boolean functions, with fitness calculated according to how close the network output was to the target. They found that by modularly varying goals, it is often possible to considerably speed up the evolution. In our Robby simulation, we studied the effects of changing environment for the evolution of modularity by allowing the environment to change discretely from an initial no-walls (torus) condition to one with walls, and eventually to one with also random obstacles. Our results suggest that although "modularity in
tasks" does speed up learning, it can often prematurely weed out diversity in the population in such a way that, in the end, the global maximum for the main target task cannot be reached.

It seems likely that our cognition has evolved in at least partly modularly changing selection environment, but the extent to which we should expect to find modular functionality in human cognition is hard to estimate. We suspect that the usefulness of many of the existing computational models investigating the evolution of biological modularity is constrained by the fact that the tasks (e.g. simple categorization, logic circuits) solved by the algorithms are straightforwardly computational and do not really involve any interesting behavioral aspects. This is why the Robby platform has certain advantages for exploring evolved functionality: The dynamic nature of the simulation allows the "emergence" of novel and irreducibly top-level strategies in a way that is lacking in the more static contexts.

Because of the uncertainty related to the actual extent of non-modularity in human cognition, we stress the conditional nature of our argument. Our study of genetic algorithms and our analysis of the properties of the resulting designs only demonstrates that evolution can create designs, which are in principle beyond the understanding of unaided cognitive beings such as us.

Yet there is nothing mysterious in such designs. Simon pondered whether the apparent abundance of hierarchical, nearly decomposable complexity was due to our selective attention to precisely such systems, but we believe this to be a somewhat hasty conjecture. We have no trouble finding and delineating systems, such as Robby, or possibly ourselves, that manifest functionally non-decomposable behaviors sustained by a flat architecture. However, there certainly might be a psychological bias that makes us see hierarchical design also where there is none. One way of coping with this obstacle to understanding is to realize that there are no fundamental reasons to limit the relevant epistemic agent to be an unaided human. Although only a human agent can experience a sense of understanding, this feeling should not be confused with understanding itself. Therefore brute computational approaches can produce understanding as long as the epistemic subject, the cognitive unit whose inferential abilities are to be evaluated, is conceived as the human-computer pair.

#### Abstract

We present an eye-tracking experiment investigating the time course with which listeners derive pragmatic inferences from contextual information. We used as a test case the construction "It looks like an X" pronounced either with (a) a nuclear pitch accent on the final noun, or (b) a contrastive $\mathrm{L}+\mathrm{H}^{*}$ pitch accent and a rising boundary tone, a contour that can support a complex contrastive inference (e.g., It LOOKS like a zebra...(but it is not)). The contrastive intonational contour elicited higher proportions of fixations to non-prototypical target pictures (e.g., a zebra-like animal) during the earliest moments of processing the target noun. Further, when the display only contained a single related pair of pictures, effects of the contrastive accent on "looks" emerged prior to the target noun, indicating that efficient referential resolution is supported by rapidly generated inferences based on visual and prosodic context.

Keywords: Prosody, contrastive accent, pragmatic inferences, eye-tracking.

## Introduction

Few, if any, would question the claim that addressees must make use of context to infer the intentions of a speaker (speaker meaning). Herb Clark (1992) gives a lovely example to illustrate the richness of context-based inferences. Clark describes a situation in which he addressed the utterance, "I'm hot", to his school-age son, Damon. After going through the plausible pre-compiled senses, Clark notes that none captures his intended (and immediately understood) meaning of his utterance, which could only be inferred from the specific context. Herb and Damon were playing poker and Damon was about to make a large bet. Herb was warning Damon that he should think twice about it.

Despite countless everyday examples of this sort, there is also a widely held view that pragmatic inference is external to the core mechanism of language comprehension. For example, this assumption underlies Levinson's (2000) influential proposal that common inferences might be pre-compiled as automatically generated defaults, by-passing the need for making a slow and resource intensive inferences (e.g., Neely, 1977; Posner \& Snyder, 1975; Shiffrin \& Schneider, 1977). This idea receives support from the hypothesis that the remarkable speed and ease of real-time language processing is possible, in part, because of its modularity in the processing system. A syntactic module, for example, performs computations on restricted inputs without appealing to slow

Figure 1: A sample visual display used in Sedivy et al. (1999) for an instruction "Pick up the tall glass"
and resource-demanding processes, such as inference (e.g., Fodor, 1983).

This modularity hypothesis, however, lacks an explanation for cases in which expectations based on context can effectively constrain parsing decisions. In fact, there is now a large body of research demonstrating that listeners rapidly use information from the linguistic and visual context to resolve ambiguity (e.g., Altmann 1998; Chambers, Tanenhaus \& Magnuson, 2004; Snedeker \& Trueswell, 2003). In this constraint-based approach, the context of language use is integral to effective and incremental language processing in guiding expectations (e.g., Levy, 2008). Furthermore, Piantadosi, Tily and Gibson (2012) propose that inherent ambiguity in the linguistic signal is in fact a design feature of an efficient encoding system, given the assumption that listeners can integrate context information to inferentially resolve ambiguity.

Consistent with these accounts, a number of studies using online measures have shown that listeners can, and do, incorporate visual information to process linguistic input incrementally. For example, Sedivy et al. (1999) examined listeners' processing of prenominal adjectives during incremental language processing. They asked participants to manipulate objects based on spoken instructions such as "Pick up the tall glass". In Figure 1, the pitcher on the lower left is the tallest object, but the glass on the upper left is both tall by comparison to glasses in general, and taller than the other glass in the upper right-hand corner. Sedivy et al. found that the partial instruction "Pick up the tall --" elicited fixations to the tall member of the contrast pair (e.g., the tall glass) rather than
the other tall object (e.g., the pitcher) in the display. This suggests that listeners rapidly integrate context-specific contrast information to begin resolving referential ambiguity prior to the head noun.

Nonetheless, it remains to be understood how readily listeners can derive more complex inferences such as conversational implicature. For example, some experimental studies on the English quantifier some (but not all) have concluded that even the basic scalar implicature is indeed slow and costly, compared with computing its logical meanings (i.e., at least one, possibly all) (e.g., Bott \& Novek, 2004; Huang \& Snedeker, 2009). On the other hand, there is a recent body of work (e.g., Grodner et al., 2010, Degen \& Tanenhaus, under review) suggesting that delays arise only when use of some in the particular context is less natural than another rapidly available alternative.

In this current study, we approach this problem by examining the time course of English speakers' comprehension of contrastive prosody. In English, the pitch accent $\mathrm{L}+\mathrm{H}^{*}$ is known to evoke an alternative set of referents and invites a contrastive inference (e.g., Katie did not win a $T R U C K_{L+H *}$ (but won a motorcycle), Ito \& Speer, 2008). Previous work has found that the use of $\mathrm{L}+\mathrm{H}^{*}$ in an appropriate discourse context restricts the domain of reference during incremental language comprehension. For instance, the $\mathrm{L}+\mathrm{H}^{*}$ in "Give me the red ball. Now give me the $\operatorname{GREEN}_{L+H *}$-" triggers anticipatory eye-movements to a green object of the same type as the preceding referent (i.e., a green ball).

While this contrast-evoking function of $\mathrm{L}+\mathrm{H}^{*}$ is known to be robust (Weber et al., 2006), previous experimental work has almost exclusively focused on prenominal adjectives highlighting color or size contrast. Moreover, studies so far have found incremental processing of contrastive prosody only when a member of the relevant contrast set was linguistically mentioned in prior discourse. These limitations make it difficult to scale up previous findings to cases where contrastive accent triggers complex, and hence allegedly costly, conversational implicatures.

To address this, we used a different linguistic construction, "It looks like an X", which can support two opposing pragmatic interpretations depending on its prosodic realization. A canonical declarative prosodic contour, with a nuclear pitch accent on the final noun (as illustrated in Figure 2, left panel, henceforth Noun-focus prosody), typically elicits an affirmative interpretation (e.g., It looks like a zebra and I think it is one). When the verb "looks" is lengthened and emphasized with a contrastive $\mathrm{L}+\mathrm{H}^{*}$ accent and the utterance ends with a rising L-H\% boundary tone (Figure 2, right, Verb-focus prosody), it can trigger a negative interpretation (e.g., It LOOKS like a zebra but its actually not one (Kurumada, Brown, \& Tanenhaus, 2012).

In the current study, we tested if and how the listeners develop the two different interpretations as they receive prosodic information. Specifically, we asked the following questions:

Figure 2: Examples of Noun-focus prosody (left) and Verbfocus prosody (right).

1. Can listeners integrate visually represented contrasts with prosodic information to guide pragmatic interpretation?
2. Do listeners process intonational contours and develop pragmatic expectations incrementally?

## Experiment overview

We examined the time course of pragmatic intonation interpretation using the visual world paradigm (Tanenhaus et al., 1995). Participants listened to the construction "It looks like an X" produced with either Noun-focus or Verb-focus prosody, and they were asked to click on the corresponding referent in a four picture display. In each display, there was at least one pair of visually similar items (e.g., a zebra and an okapi; Figure 3-a, bottom row). We assumed based on previous work that Noun-focus prosody would bias responses toward the more prototypical member of each pair (e.g., a zebra for "It looks like a ZEBRA"), while Verb-focus prosody would bias responses toward the less prototypical member (e.g., an okapi for "It LOOKS like a zebra"). Thus, our first hypothesis is that listeners should integrate the contrasting relation between the prototypical and non-prototypical target pictures in their interpretation of the utterance intonation.

A previous study has shown that listeners can develop a similar contrastive inference in a visual search task (Dennison \& Schafer, 2010). Their study used the construction "X HAD Y" (e.g., "Lisa HAD a bell..." (but she no longer has one)), but they found no evidence of incremental processing. They proposed that the contrastive inference requires both the pitch accent and the boundary tone, and hence occurs only after the sentence offset.

In the current study, we hypothesize that listeners can compute an implicature incrementally, based on the prosodic and visual context. We tested this hypothesis by comparing the time course of eye movements in a display with a single pair of contrasting items, to those in a display with two pairs. In the one-contrast display, we predicted that participants would be able to use the contrastive pitch accent to infer that the likely referent is a member of the contrast pair (more specifically, the less prototypical member) prior to the processing of the target word. In the two-contrast display, the target referent cannot be determined until it has been explicitly mentioned, which should result in effects of prosody emerging later, i.e., during the processing of the target word.

Figure 3: Sample visual displays

## Methods

## Participants

Twenty-four students from University of Rochester were paid (\$10) to take part in the experiment. They were native speakers of American English with normal or corrected-to-normal vision and normal hearing.

## Stimuli

We selected 16 imageable high-frequency nouns and embedded them in the sentence frame "It looks like an X". A native speaker of American English recorded two tokens of each item with the Noun-focus and the Verb-focus prosodic patterns. The same speaker also recorded 44 filler items in which a target referent was described (e.g., "Can you find the one with white fur?").

We selected 16 more items to form pairs with the 16 target nouns. In each pair, the items were visually similar to each other (e.g., a zebra and an okapi) and one item (e.g., a zebra) was always more common. Hereafter, the picture from each pair that is more common (e.g., a zebra, Figure 3, bottom left) is referred to as the prototypical target picture, and the other (e.g., an okapi, Figure 3, bottom left) is referred to as the nonprototypical target picture.
Prototypicality and nameability norming To create visual stimuli, we ran two types of norming studies using Amazon Mechanical Turk, an online crowd-sourcing platform. In the first study, 40 subjects provided names and nameability ratings (on a seven-point rating scale) for each of the $240 \mathrm{im}-$ ages. In a second norming study, we presented 40 subjects with the images along with a label and collected ratings of referential fit for both adult-directed speech and, as a separate response, child-directed speech. The non-prototypical pictures (e.g., okapi) were always presented with the names of their respective prototypical items (e.g., zebra) in order to establish an empirical measure of prototypicality.

Based on this information we constructed 60 visual scenes ( 16 critical trials and 44 filler trials). Each of the scenes consisted of four pictures including one pair of target pictures described in an auditory stimulus. We created two types of visual scenes: a) 1 target pair +2 singletons ( 1 -contrast condition), and b) 1 target pair and 1 distractor pair ( 2 -contrast
condition) (Figure 3). Singletons in 1-contrast trials consisted of one easily nameable picture and one less-nameable picture to equate the complexity of the visual display across trials.

## Procedure

Participants were first presented with a cover story in which a mother and a child are looking at a picture book. The mother is helping the child to identify various objects and animals by verbally commenting on them. Each trial began with the presentation of a visual display containing four pictures. After 1 second of display preview, participants heard a spoken sentence over Sennheiser HD 570 headphones and clicked on a picture described by the sentence. Their mouseclickng responses were collected while their eye movements were tracked using a head-mounted SR Research EyeLink II system sampling at 250 Hz , with drift correction procedures performed after every fifth trial.

Eight lists were constructed by crossing the 1 ) item presentation order, 2) the location of the prototypical and the nonprototypical items on the display, and 3) the prosodic contour (Noun-focus vs. Verb-focus). All lists started with three example items to familiarize participants with the task. The mean duration of the experiment was 12 minutes.

## Results and discussion

We analyzed three dependent measures to obtain converging evidence about the role of prosody and visual display characteristics in the processing of critical items: response choices in the picture selection task, response times, and proportions of fixations to different alternatives within the display. Each variable was assessed with multi-level generalized linear regression models implemented using the lmer function within the lme4 package in R (R Development Core Team, 2010; Bates et al. 2008) ${ }^{1}$.

We first confirmed that participants selected a correct target picture in $96 \%$ of filler trials, indicating that participants did not have difficulty completing or attending to the picture selection task. We then analyzed their responses in the 16 critical trials to ask if they encoded the visual contrasts of items on the screen and associated them with the two prosodic contours. Participants selected the prototypical target picture $65.6 \%$ of the time in the Noun-focus prosody condition, but only $25.5 \%$ of the time in the Verb-focus prosody condition. A multilevel logistic regression model of responses confirmed that depending on the prosodic contour, participants reliably chose either a prototypical or a non-prototypical item

[^130]

Figure 4: Proportions of fixation to pictures in response to the Noun-focus (solid line) and to the Verb-focus (dashed line). The lines are aligned at the onset of the final noun.
( $\beta=6.37, z=4.394, p<.0001$ ). Thus, without any explicit mention of a contrasted item, participants encoded a relevant contrast set in the visual field and developed a contrastive inference based on the Verb-focus prosody.

Response times indicated that Verb-focus prosody elicited slower responses (mean RT=2204 ms) than Noun-focus prosody (mean $\mathrm{RT}=1969 \mathrm{~ms}, \beta=-.242, t=-2.09, p<.05$ ). However, the effect of prosody was dependent on whether the prototypical or non-prototypical target picture was selected ( $\beta=.509, t=2.94, p<.005$ ). On trials with Nounfocus prosody, RTs were significantly faster when a prototypical picture was selected (mean $\mathrm{RT}=1762 \mathrm{~ms}$ ) than when a non-prototypical picture was chosen (mean $\mathrm{RT}=2364 \mathrm{~ms}$, $\beta=-.272, t=-3.20, p<.005$ ). On trials with Verbfocus prosody, however, there was a numerical trend in the opposite direction (mean RT=2540 ms for prototypical target responses vs. 2089 ms for non-prototypical target responses, $(\beta=.201, t=1.10, p>.10)$. This finding suggests that responses deviating from the expected association between prosody and picture type were associated with greater processing difficulty, further supporting the hypothesis that participants were interpreting the prosodic contour based on
the visual contrasts.
Next we analysed the eye-tracking data to examine the time course of processing the contrastive prosody. Our analysis focused on two regions, which were both defined with respect to the point at which segmental information from the target word would be expected to influence processing. The first region, which we termed the pre-target region, was defined as the region beginning at 200 ms after the offset of "looks" and ending at 200 ms after the onset of the target word. This roughly corresponds to the region indicated with the caption "like a" in Figure 4, shifted to the right by 200 ms . Because it takes approximately 200 ms to program and execute an eye movement, fixations within this window should not be influenced by segmental information from the target word. The only information that would be expected to influence eye movements within this window, then, is information from preceding prosody (e.g. the contrastive accent on "looks").

The second region, the early target-word region, began at 200 ms after target word onset and ended at 200 ms after the offset of the first syllable of the target word. This roughly corresponds to the region indicated with the caption "ze-" in Figure 4 , shifted to the right by 200 ms . Fixations within this window were expected to reflect the integration of expectations based on preceding prosody and initial effects of incrementally presented target word information. Within each window, mean proportions of fixations to each picture were calculated and then transformed using the empirical logit function (Cox, 1970) for the purposes of linear regression analysis.

Pre-target fixations We analyzed logit-transformed proportions of fixations averaged across the pre-target region in two linear mixed-effects regression models. The first model examined effects of prosody contour, display type (i.e., onevs. two contrast sets), and trial number on logit-transformed mean proportions of fixations to the distractor pictures vs. either member of the target contrast set (e.g. the zebra and okapi). The goal of this analysis was to assess prosody- and display-wise differences in anticipating the target contrast set. We predicted that Verb-focus prosody would bias participants to fixate members of the target contrast set in one-contrast trials but not in two-contrast trials.

Results from the regression analysis revealed that the predicted three-way interaction between prosody condition, picture type, and display type was significant ( $\beta=.754, t=1.98$, $p<.05$ ). Analyzing proportions of fixations by display type revealed that effects of prosody condition were dependent on picture type in one-contrast trials $(\beta=-.322, t=-2.61$, $p<.01$ ). Participants were no more likely in the Nounfocus condition to fixate the target picture (mean untransformed proportion of fixations=.209) and the distractor pictures (mean=.186, $\beta=.007, t=.068, p>.1$ ), but they exhibited a significant bias toward the target contrast set in response to Verb-focus prosody (mean=. 245 vs. . $167, \beta=$ $-.315, t=-3.34, p<.001$ ). This interaction was not sig-
nificant in two-contrast trials $(\beta=-.058, t=-.529, p>.1)$.
The second linear mixed-effects regression model examined effects of prosody condition, display type, and trial number on logit-transformed mean fixation proportions to prototypical vs. non-prototypical target pictures. We predicted that the difference between fixations to non-prototypical pictures and fixations to prototypical pictures would be greater in response to Verb-focus prosody than Noun-focus prosody. Indeed, the regression model revealed a marginal two-way interaction between prosody condition and picture type ( $\beta=$ $.138, t=1.71, p=.087$ ). In the Noun-focus prosody condition, fixations to bad target pictures (mean=.238) did not differ significantly from fixations to good target pictures (mean=.181, $\beta=-.124, t=-1.20, p>.1$ ). In the Verb-focus condition, however, participants were significantly more likely to fixate the bad target picture (mean=. 300 vs. .190, $\beta=-.243, t=-2.69, p<.01)$.

Taken together, these findings suggest that participants rapidly encode the visual attributes of and relations between potential referents, and rapidly integrate this visual information with the incoming prosodic input. When a single contrast set is present in the display, contrastive Verb-focus prosody biases listeners to fixate members of that set. This trend is illustrated in Figure 4. In the 1-contrast condition (Figure 4-a), the fixation proportions to the non-prototypical target based on the Verb-focus prosody begins to diverge in the pre-target region. On the other hand, such divergence is delayed in the 2-contrast condition (Figure 4-b).
Early target-word fixations For the early target-word region, we again analyzed logit-transformed mean proportions of fixations in two linear mixed-effects regression models, to compare effects of prosody condition, display type, and trial number on (a) target-picture fixations to distractor fixations, and (b) prototypical target-picture fixations to nonprototypical target-picture fixations.

For the analysis comparing logit-transformed mean proportions of fixations to target pictures vs. distractor pictures, we predicted that the three-way interaction between prosody condition, picture type, and display type would no longer be significant. Instead, the main prediction was that fixations to both target pictures would be significantly higher than fixations to distractors across trial types.

The results of the analysis indicated that neither display type nor prosody condition accounted for a significant proportion of variance in target vs. distractor fixations in the early target-word region. Instead, the main finding was that participants were significantly more likely to fixate target pictures (mean $=.280$ ) than distractor pictures (mean $=.127, \beta=-.240$, $t=-4.12, p<.0001$ ), reflecting their early use of incoming segmental information to restrict the referential domain to the two target pictures.

The analysis of fixations to the two target pictures was predicted to show that the difference between non-prototypical target picture fixations and prototypical target picture fixations would continue to be greater in the Verb-focus condi-

Figure 5: Mean fixation proportions to the non-prototypical item in response to the Verb-focus prosody. Error bars represent standard errors.
tion. In addition, display type was no longer predicted to significantly influence patterns of fixations, since the segmental information from the initial sounds of the target word should restrict the domain of reference to the target contrast set.

The second linear mixed-effects regression model indeed revealed a two-way interaction between prosody condition and picture type ( $\beta=-.472, t=-4.02, p<.0001$ ). In the Verb-focus condition, participants were significantly more likely to fixate non-prototypical target pictures (mean=.374) than prototypical target pictures (mean $=.222, \beta=-.335$, $t=-3.97, p<.0001$ ). In the Noun-focus condition, however, there was a non-significant trend in the opposite direction, with more fixations to prototypical target pictures (mean $=.293$ ) than non-prototypical target pictures (mean $=.231, \beta=.138, t=1.49, p>.1$ ). This interaction between prosody condition and picture type suggests that listeners rapidly integrated incoming segmental information from the target word with their pragmatic expectations for a prototypical vs. non-prototypical referent based on preceding prosodic information.

Figure 5 summarizes mean fixation proportions to the nonprotptypical item based on the Verb-focus prosody. Within the pre-target region, participants were looking at the nonprototypical item more when they were in the 1-contrast condition than in the 2 -contrast condition. This trend was even more magnified when the segmentatal information of the target noun becomes available. This demonstrates that the contrastive pitch accent was processed incrementally under the constraints of the visual context.

## Conclusion

The results show that participants generated complex pragmatic interpretations in an incremental manner. In a context with only one contrast pair, listeners began to launch eye movements to a less prototypical target picture even before segmental cues to the final noun become available. This is of particular interest because, unlike in previous studies, the contrastive accent in the current study was used with the verb.

The contrast was not simply based on individual visual features of objects (e.g., color or size); rather, it was mediated by the implicature based on different predicates. Namely, "It LOOKS like an X" is contrasted with "It IS an X", and therefore interpreted as "It is not an X". Our results demonstrate that such complex pragmatic reasoning can develop online.

The results also highlighted the facilitative roles of visual context in intonation interpretation. The early timing of the prosody effect in the 1-contrast condition suggests that listeners made use of visually represented contrast to guide their inference. This enabled us to demonstrate that inferences based on contrastive prosody do not require explicit previous mention of a contrasting item and can be made incrementally on the basis of partial prosodic contour as well as visual information. These findings together advance our knowledge about the remarkably rapid and robust inferential mechanisms supporting online language comprehension and pragmatic communication.

# Contextual inferences over speakers' pragmatic intentions: Preschoolers' comprehension of contrastive prosody 

Chigusa Kurumada<br>kurumada@stanford.edu<br>Department of Linguistics<br>Stanford University

#### Abstract

We investigate pre-schoolers' ability in drawing pragmatic inferences based on prosodic information. Previous work has found that young children are generally oblivious to intonational meaning of utterances. In particular, the ability to comprehend contrastive prosody develops late during language acquisition (after the age of 6). In three experiments, we show that preschoolers can engage in prosody-based pragmatic inferences if the context provides supports for them. Furthermore, we find that preschoolers' interpretation of prosody involves complex counter-factual reasoning ('what the speaker would have said if she had intended another meaning'). The picture emerging from our studies contrasts with previous work: Through rich contextual inferences, four-year olds are able to bootstrap their interpretation of prosodic information, and achieve adult like performance in intonation interpretation.

Keywords: Prosody, language acquisition, contrastive accent, Principle of Contrast, rational inference

## Introduction

In learning new words, young children can make use of pragmatic inference to bootstrap their knowledge about new word-object mapping. For example, in a situation where an adult utters "Give me the TOMA (nonce word)" ${ }^{1}$ when a familiar object (e.g., a spoon) and an unfamiliar object (e.g., a whisk) are present in a visual field, a child as young as two years of age is likely to reach for the whisk. This is considered to be based on a cognitive bias for a unique objectlabel mapping (e.g., Markman and Wachtel (1988)) or the inference that the mother should have used the familiar word (spoon) if she had intended to refer to it (e.g., Clark (1990)).

Such pragmatic dispositions provide immense leverage in word learning because there is inherent uncertainty associated with mappings between speakers' intentions, linguistic signals, and their referents (Frank, Goodman, \& Tenenbaum, 2009). One way to systematically solve this puzzle is to estimate the probability assigned to a possible intention-signal mapping relative to other possible mappings warranted by the same context. For instance, the probability of the signal "Give me the TOMA" expressing the speaker's intention of picking out the non-spoon object is estimated in proportion to probabilities of (1) the signal being generated by the intention of picking out a spoon; and (2) other signals (including [a spoon]) being generated by the intention of picking out the target (non-spoon) object.

[^131]

Figure 1: A schematic representation of a pragmatic model of intention-signal mapping

In the model illustrated in Figure 1, a speaker's intention (to express meaning m 1 ) generates a particular linguistic signal (signal s1); If the speaker had meant to express meaning m 2 , she would have generated a different signal (signal s2). A word learner's job is to work backwards from the observed signal to infer the speaker's intention (as indicated with arrows) while updating her belief about the signal-intention mappings, including any associations newly introduced.

The current study extends this idea to a new domain: Young children's interpretation of contrastive prosody. Just as words are associated with speaker intentions, different prosodic representations are probabilistically mapped onto intentions that had generated them (Figure 2). Compared to words, however, prosodic signals are continuous and variable, which can make the mapping puzzle much harder to solve. Furthermore, the intentions that prosodic representations encode are often very abstract (e.g., contrastiveness) and are not always disambiguated in an observable context. In other words, signal-intention mappings for prosody include much more uncertainty (indicated by the thinner arrows in Figure 2 ) for listeners to overcome. The current study suggests that, despite this additional complexity, the rational inferences attested in word-learning provide leverage in young children's discovery of pragmatic functions of contrastive prosody as well.

Prosodic information is known to encode structural boundaries and phrasing but also speakers' intentions (Pierrehumbert \& Hirschberg, 1990; Ladd, 2008; Büring, 2003). Much attention has been paid to how listeners interpret context-relevant contrast based on a low-high-low (an L+H*) pitch accent. (e.g., KATIE $\left(\mathrm{L}+\mathrm{H}^{*}\right)$ did not win a truck (but LAURA did); Ito \& Speer, 2008). Previous work has generally agreed that inferences based on an $\mathrm{L}+\mathrm{H}^{*}$ accent present great difficulty to preschoolers, and even young school children fail to achieve adult-like performance in experimental settings (e.g., Solan, 1980; Cruttenden, 1985; Wells, Peppe,

Figure 2: A schematic representation of a model for intention-signal mapping in prosodic interpretation

Figure 3: Waveforms (top) and pitch contours (bottom) of the utterance "It looks like a zebra". The affirmative interpretation It is a zebra is typically conveyed by the pattern on the left, while the negative interpretation It is not a zebra is conveyed by the pattern on the right.
\& Goulandris, 2004; Sekerina \& Trueswell, 2012). Since even young infants can use prosodic information for finding word boundaries or affective communication (Cutler \& Swinney, 1987), the difficulty is not usually attributed to their sensitivity to prosodic information per se, but to limited cognitive resources and memory span (Speer \& Ito, 2009). The current study shows a supportive discourse context allows children to comprehend contrastive prosody earlier than previously reported.

Furthermore, we demonstrate that acquisition of contrastive prosody is supported by the same pragmatic inference underlying the word-intention mappings described above. That is, upon receiving a signal, the listener works backward to inferentially identify the intention most likely to generate the particular signal observed. Crucially, a learner can bootstrap her knowledge about a new signal-intention mapping based on other mappings warranted in the same context.

In the three experiments reported below, 4-year-olds and adults were asked to interpret an English construction "It looks like an X", which can evoke different pragmatic meanings depending on its prosodic realization. A canonical accent placement (as illustrated in Figure 3, left panel, henceforth noun-focus prosody) typically elicits an affirmative interpretation (e.g. It looks like a zebra and I think it is one). When the verb "looks" is lengthened and emphasized with a contrastive accent $\left(\mathrm{L}+\mathrm{H}^{*}\right)$ and the utterance ends with a L H\% boundary tone (Figure 3, right, verb-focus prosody), it can trigger a negative interpretation (e.g. It LOOKS like a zebra but its actually not one; see also Dennison \& Schafer, 2010).

The results show that, replicating the previous studies, preschoolers do not show adult-like understanding of con-
trastive prosody provided in an experimental setting (Experiment 1). However, the difficulty is alleviated when the prosodic input is preceded by a question that highlights what the alternative would be (Experiment 2). This suggests that preschoolers have prosodic representations while exhibiting difficulty in evoking a context-relevant alternative. Furthermore, children can use their knowledge about a construction (It's an X) that is more familiar to them to bootstrap their knowledge about contrastive inference (It LOOKS like a zebra...). These data together suggest that preschoolers use contextual information and pragmatic inferences to achieve adult-like performance in understanding contrastive prosody.

## Experiment 1

In Experiment 1, a game-like task was used to elicit preschoolers' interpretations of the two prosodic contours: Noun-focus and Verb-focus prosody. This was done to replicate the past studies' finding that young children fail to derive contrastive inference based on the prosodic information.

## Methods

Participants 12 children acquiring English as their first language ( 6 girls, 6 boys; mean age $4 ; 1$, age range $3 ; 2-4 ; 8$ ) were recruited and tested at a local nursery school in Stanford, California. For a comparison, 20 adults were also tested in the same paradigm using Amazon Mechanical Turk. The adult participants were all self-reported native speakers of American English residing in the United States.

Stimuli Sixteen high-frequency animal names were embedded in the sentence frame [It looks like an X] (e.g., It looks like a zebra). Half of the items were produced with Noun-focus prosody (e.g., "It looks like a ZEBRA!") and the other half were produced with Verb-focus prosody (e.g., "It LOOKS like a zebra"). The pronunciation patterns were counter-balanced between two lists: items pronounced with Noun-focus prosody in List 1 were produced with Verb-focus prosody in List 2 (and vice versa).

Sixteen more animal terms were chosen to form pairs in which the animals resembled each other in visual features (e.g., a zebra and an okapi, Figure 4). In each pair, the target animal named in the input sentence ("it looks like a zebra") was the more common of the two and was more familiar to the children being tested. Hereafter, the target named in a sentence (e.g., a zebra) is referred to as the "mentioned" animal and the paired animal (e.g., an okapi) is referred to as the "unmentioned" animal. The two animals in each pair served as likely referents for one or the other of the two prosodic contours used in the task (e.g., a zebra for "It looks like a ZEBRA!" and an okapi for "It LOOKS like a zebra")

Procedure The experimenter began by introducing a puppet and telling the child that they would play a guessing game together. The game had two parts. The first part was a picturenaming phase, in which the child saw seven pictures on a computer screen and labeled them one by one. This was done to ensure that the names of the objects were familiar to the

Figure 4: Experimental setup: Participants heard the puppet's clue while looking at a picture like (a) and were subsequently asked to guess which of the two pictures (as in (b)) was hidden behind the barrier.
child. In the second part, the test phase, the child and the puppet took part in seven trials (two practice and five critical) of a two-alternative forced-choice task. In each trial, the child and puppet were presented with a picture partially occluded by a gray barrier (Figure 4a). The puppet was then allowed to peek behind the barrier and give the child a clue about what he saw. The puppet's clue took the form of the "it looks like X" construction, pronounced with either Noun-focus prosody or Verb-focus prosody. All the puppet's speech was vocalized during the task by an experimenter who was a native speaker of American English. Following the puppet's clue, the child was presented with two pictures - the mentioned and unmentioned (Figure 4-b) - and asked to point which animal was hidden by the barrier. When the child pointed to a picture, she got feedback about which animal was the target referent. After completing seven trials, the child named five more animals and participated in five more guessing game.

## Results and Discussion

Figure 5 shows the proportion of mentioned animals chosen by the children and adult participants (e.g., choosing a zebra when the input sentence was [it looks like a zebra]). Adults responded to the stimuli in the expected ways: they reliably picked a mentioned animal based on the Noun-focus prosody (e.g., "It looks like a ZEBRA") and an unmentioned animal based on the Verb-focus prosody (e.g., "It LOOKS like a zebra...").

However, the four-year-olds did not differentiate the two patterns $\left(\chi^{2}(1)=1.36, p>.24\right)$. Overall, they showed a weak bias towards the picking an unmentioned animal ( $60 \%$ of all the responses), which might be due to their preference for a new, and often funnier looking, animal. Thus, replicating the previous findings, four-year-olds did not seem to make the contrastive inference based on the prosodic contour.

What makes the comprehension of contrastive prosody difficult for young children? Recall the model presented in Figure 2 . In order to correctly interpret the prosodic contours, a listener needs to be aware that they are mapped onto two distinct speaker intentions. In particular, it is critical to understand that the two prosodic patterns signal two intentions (answers) relevant to a question at hand (e.g., Is the animal a

Figure 5: Proportions of the mentioned animal chosen in Experiment 1 (children and adults) and Experiment 2 (children). Error bars represent standard error of the mean.
zebra or not?) While this reasoning comes naturally to adult listeners, young children might need more contextual support for establishing these assumptions that are plugged into the interpretation of contrastive prosody. To test this prediction, in Experiment 2, additional discourse-contextual information was provided to ensure that the children have better access to the contextual alternatives.

## Experiment 2

In Experiment 2, effects of an explicit guess-question are examined. The puppet asks the child to make a guess about the hidden animal, which establishes a question that needs to be answered (e.g., Is the hidden animal a zebra or not?) If this manipulation has a positive effect on the child's understanding of contrastive prosody, it would mean that the comprehension difficulty observed in Experiment 1 is at least partially attributed to their difficulty in detecting contextual alternatives.

## Methods

Participants 12 children ( 7 girls, 5 boys; mean age $4 ; 2$, age range $3 ; 6-4 ; 6$ ) were recruited and tested at the same nursery school as in Experiment 1.
Stimuli The stimuli were identical to those of Experiment 1.

Procedure The procedure was almost identical to that of Experiment 1 except that the puppet first pointed to the partially occluded picture and provided a guess-question: "What do you think is hiding behind the wall?" When the child did not give an answer, or the child's answer was unrelated to the trial item, the puppet followed up by saying, "I'm gonna guess it's an X (e.g., a zebra). But let me take a peek and give you a clue." This was done to provide an additional cue to ground the current "question under discussion" (Roberts, 2004), namely, whether the identity of the hidden animal was an X or not an X .

## Results and Discussion

A mixed logit regression analysis with the full two (Nounfocus vs Verb-focus prosody) by two (Experiment 1 vs. Experiment 2) design was employed to predict children's likelihood of choosing a mentioned animal for each stimulus sentence (e.g., choosing a zebra when the input sentence was "it looks like a zebra"). The model reported here has a full factorial random effect structure justified by the data, which contains random by-subject and -item slopes. All the predictors were sum-coded and there was no sign of collinearity. The original model contained the item order as a fixed effect, but it was removed from the analysis that follows based on a null effect in model comparison.

Overall, children showed a marginal but non-significant preference for choosing the mentioned animal when they heard the Noun-focus prosody ( $\beta=.62, p<.07$ ). Importantly, children were overall more likely to choose the mentioned animal in Experiment 2, where an explicit guessquestion was present ( $\beta=1.43, p<.003$ ) (Figure 5). There was also a significant interaction term between the prosodic input and the conditions ( $\beta=2.41, p<.001$ ), such that children were more likely to choose a mentioned animal based on the Noun-focus prosody in Experiment 2. That is, the explicit guess-question about a target animal facilitated their comprehension of the pragmatic interpretations of the two prosodic patterns. An additional analysis revealed that there was also an effect of age: older children tended to choose mentioned animals across conditions and input patterns significantly more often ( $\beta=.08, p<.04$ ).

How did the contextual support lead to adult-like judgement patterns? Two follow-up analyses were conducted to test if the presence and the types of guesses could predict children's choice behaviours. In Experiment 2, children were willing to make guesses $79 \%$ of the time, $53 \%$ of which included an animal mentioned in the input sentences. Consequently, the target animal was introduced to the discourse by the child $42 \%$ of the time, and by the puppet $58 \%$ of the time (e.g., "I'm gonna guess it's an X"). The children's responses to the puppet's guess-question were coded as binary predictors: (1) whether the child offered an animal name or not; and (2) whether the child made a correct guess. These predictors were included in two different models of children's choice of a mentioned animal in the Experiment 2. However, neither of these predictors was significant ( $p>.8$ and $p>.7$ respectively). This suggests that the facilitative effect observed in Experiment 2 cannot be reduced to children's expectation about a particular animal. Whether or not the child guessed correctly at the outset, the explicit introduction of the animal name provided support for their prosodic interpretations.

## Experiment 3

Experiment 3 tests a hypothesis based on the model of backward inferencing in prosodic comprehension. A structurally simpler, semantically less ambiguous, sentence "It's an X" was added to test if the presence of a familiar signal-intention
mapping supports children's inferences about a less-familiar signal and its pragmatic meaning. A few novel features were added to Experiment 3. First, pre-recorded speech was used for the input to rigorously control the input children received. Also, physically manipulable props (a picture card, a cardboard box) replaced the computer screen for the stimuli presentation.

## Methods

Participants 36 children acquiring English as their first language ( 24 girls, 12 boys; mean age $4 ; 6$, age range $3 ; 8-5 ; 2$ ) were recruited and tested. They were randomly assigned to one of the three conditions described in Table 1. 60 adults were also tested on-line, using Amazon Mechanical Turk. 3 adult participants were excluded from the data because their participation time was two standard deviation below the mean.

Stimuli 16 high-frequency animal names were embedded in two sentence frames: [It looks like an X] and [It is an X]. Tokens of [It looks like an X] with Noun-focus and Verbfocus prosody, as well as tokens of [It is an X], were recorded by a female native speaker of American English for use in the presentation of each trial.
Procedure Participants took part in a two-alternative forced choice task similar to Experiments 1 and 2. It consisted of a total of 16 trials (two practice trials and 14 critical trials). As in Experiment 1, the child participant was first introduced to a puppet. A mini portable speaker was attached to the puppet in order to play the audio stimuli. The child first participated in a picture-naming task, in which they labeled eight animals one-by-one. Then child and puppet took part in a guessing game where first they were presented with a box and told that it contained many different pictures of animals. Then the puppet was allowed to peek inside the box and give the child a clue. Next, each child was presented with two pictures (e.g., a zebra and an okapi) and prompted to indicate which of the two pictures was hidden in the box. Then the experimenter took a picture card from the box and showed the child which animal the puppet had actually "seen". After the first eight trials, the child was given eight more pictures of animals to name, and participated in eight more test trials.

Manipulation Children are put into one of the three conditions: Prosory-only, Form-only, and Combined conditions. In the Prosody-Only condition, as in Experiment 1, the puppet used either a Noun-focus or Verb-focus contour with [It looks like an X] to give a hint and a warning respectively. Hence the Prosody-only condition is expected to replicate the results from Experiment 1. In the Form-Only condition, the puppet said [It's an $\mathrm{X}!$ ] as a hint when the target animal was an X (e.g., "It's a ZEBRA" when the target picture depicted a zebra), compared to the puppet saying [It looks like an X] also with a focus on the final noun, as a warning when the picture was not an X (e.g., "It looks like a ZEBRA" when the target

Table 1: The between-subject manipulation of Experiment 3. The shaded cells indicate sentence patterns used for the warning function (identifying the hidden animal as not being the mentioned animal)

|  | Prosody-only X | Form-only | Combined |
| :--- | :--- | :--- | :--- |
| It's an X |  | "It's a ZEBRA" | "It's a ZEBRA" |
| Noun-focus prosody | "It looks like a ZEBRA" | "It looks like a ZEBRA" |  |
| Verb-focus prosody | "It LOOKS like a zebra..." |  | "It LOOKS like a zebra..." |

picture depicted an okapi). Notice that this manipulation is done based on the assumption that the Noun-focus prosody is in principle semantically ambiguous and it can be interpreted as it is an $X$ or It is not an $X$ depending on a speaker's preference and a context (Kurumada, Brown, \& Tanenhaus, 2012). It is hypothesized that children can better distinguish the pragmatic intentions based on these formal cues due to their reliance on lexically encoded information over prosodically encoded information in online processing (Snedeker \& Trueswell, 2003).

Finally, in the Combined condition, the puppet used [It's an X] for a hint with Noun-focus prosody, and Verb-focus prosody (e.g., "It LOOKS like an X") for a warning. Recall the word-learning situation with a spoon and a whisk. Presence of a familiar association (the word "spoon" and an intention to pick out a familiar object) results in higher confidence in a novel mapping compared to a situation in which there is no such familiar association. Experiment 3 tests if children can discover pragmatic meaning of contrastive prosody via a similar pragmatic inference: In the Combined condition, compared to the Prosody-Only condition, "It LOOKS like an x" becomes a more likely candidate for conveying the [it is not an X ] meaning because speaker should otherwise have said "It's an X" if she had meant that.

## Results and Discussion

All responses from the 14 critical trials were included in the analysis, as shown in Figure 6 for the children's response patterns. In the Prosody-only condition, which replicated Experiment 1, children's responses did not deviate from chance, and their judgments for each of the two prosodic patterns ("It looks like an X" and "It LOOKS like an X") did not differ significantly. In the Form-only condition, children showed more sensitivity to the contrast intended by the speaker ( $p .<.3$ ): They showed more diverged responses for the two types of sentences intended for a hint and a warning presumably due to their confidence in the interpretation of "It's an X".

In the Combined condition, the children showed nearly categorical and opposing responses for the two types of prompts, reliably choosing the mentioned animal when they heard "It's an X" and the unmentioned one when they heard "It LOOKS like an X". The most interesting comparison can be made between the responses for the Verb-focus prosody in the Prosody-only and the Combined conditions. They are acoustically identical and yet interpreted differently depending on the other sentence type used for a hint function. The difference between the Form-only and the Combined condi-

Figure 6: Proportions of an mentioned animal chosen by 4-year-olds in Experiment 3. Error bars represent standard error of the mean.

Figure 7: Proportions of an mentioned animal chosen by adults in Experiment 3
tion suggests that children were indeed aware of the pragmatic function of the contrastive prosody used in the Verbfocus prosody.

Figure 7 illustrates adults' responses in the three conditions. The most significant difference between the children's and adults' responses can be found in the Prosody-only condition. While children's responses for both of the prosodic patterns are at chance, adult listeners were almost categorically choosing a mentioned and an mentioned animals based on the Noun-focus and the Verb-focus contours respectively. The judgments were less categorical in the Form-only condition, which suggests that the children's and adults' response patterns were similar to each other in the Form-only condition as well as in the Combined condition.

## General Discussion

The results of the three experiments indicate that discourse contexts provide strong support for preschoolers' comprehension of contrastive prosody. In particular, Experiment 2 confirmed that an explicit question in a preceding context helped children to be tuned into the prosodic differences. This was considered to be because the question made it easier for them to derive two distinct speaker intentions (i.e., It is an $X$ and It is not an X ). This is in line with previous findings in which preschoolers' difficulty in computing scalar implicature was alleviated by an explicit depiction of contextual alternatives (Barner, Brooks, \& Bale, 2011).

Experiment 3 provided evidence that children engage in a rather complex probabilistic inferences when interpreting contrastive prosody: they interpret prosodic contours conditionally, depending on what other speech signals are used by the same speaker. When the speaker uses a more familiar, and semantically less ambiguous, sentence (i.e., It's an X), they can effectively infer that the prosodic prominence on LOOKS signals a distinct speaker intention (i.e., It is not an X).

Previous studies have viewed the interpretation of contrastive prosody as part of children's domain-specific knowledge about mappings between specific patterns of acoustic signals (i.e., $\mathrm{L}+\mathrm{H}^{*}$ ) and pragmatic meanings. However, that approach cannot explain how hearing other forms (e.g., "It's an $\mathrm{X}^{\prime \prime}$ ) in the same context affects children's understanding of contrastive prosody. The current results suggest that children are trying to solve a bigger inference problem, where they cope with uncertainty regarding different speech signals, and estimate the likelihood with which prosodic signals are mapped onto different meanings.

These results highlight the possibility that such contextual inferences allow children to process pragmatic interpretations of prosody even before they acquire fully-fledged understanding of the prosody-pragmatics interface. As we saw in Experiment 1 and 3, four-year-olds do not yet exhibit adult-like knowledge about contrastive prosody. In other words, they do not reliably call to mind a contrast set based solely on prosodic minimal pairs (e.g., It looks like an X vs. It LOOKS like an $x$ ) and make an inference about a speaker's intentions. Nevertheless, with more contextual and linguistic information, they engage in inferences that result in adult-like responses. The role of such contextually-supported inferences has been discussed almost exclusively in word-learning while its full implications for language acquisition remain to be understood. The current results suggest that a similar model can explain pre-schoolers' intonational interpretation. A contrastive meaning of prosody LOOKS unattainable for those young children, but it is not in a context.

# Communicatively efficient language production and case-marker omission in Japanese

#### Abstract

Recent studies hypothesize that language production is governed by the principle of efficient information transmission: Speakers tend to omit elements whose information content is contextually predictable, while providing more linguistic signal to convey otherwise less predictable information. However, previous findings in support of this hypothesis are also compatible with alternative accounts based on production difficulty. To distinguish between these competing accounts, we conducted experiments on speaker's preference in optional casemarking in Japanese. The results suggest that Japanese speakers are more likely to omit the object case-marker when an associated noun has properties (e.g., animacy) that are prototypical to a grammatical object. Moreover, case-marker omission was facilitated when other elements in a sentence made the grammatical function assignment more predictable. The results were obtained with all the factors related to production difficulty held constant, and thus provide support for the models of communicatively efficient language production.

Keywords: Case-marker omission, Japanese, language production, efficiency, information transfer

## Introduction

Language often offers multiple options for expressing semantically equivalent or near-equivalent messages. For example, speakers have a choice between different word orders and voice choices (e.g. the ditransitive alternation in English; active vs. passive; scrambling in languages like German, Japanese, and Hindi). Another common type of alternation involves the choice between more or less linguistic form (e.g., phoneme duration, morphemes, phonological alternation) to encode the same meaning. For example, in English sentence like (1), speakers can, but do not have to, produce the complementizer "that". The past psycholinguistic studies have used these alternations as windows into the cognitive processes underlying language production.
(1) My boss said (that) we were absolutely crazy.

Recent psycholinguistics work has proposed that speakers' preferences in such alternations provide evidence that the computational system underlying language production is organized to facilitate efficient information transfer (e.g., Aylett \& Turk, 2004; Levy \& Jaeger, 2007; Jaeger, 2010). This line of work has focused on the observation that it seems to be predictable linguistic material, and hence material that is low in Shannon information, that tends to be reduced or even completely omitted (e.g., Bell, Brenier, Gregory, Girand, \& Jurafsky, 2009; Frank \& Jaeger, 2008; Resnik, 1996). For example, whether English speakers produce the complementizer that depends on how predictable it is for the continuation
of words so far (e.g., My boss said) to take a complement clause, as in (1): when the complement clause is much expected, that is likely to be omitted; when it is less so, that is likely to be inserted (Jaeger, 2010).

Observations like these can be accounted for in terms of communicative efficiency since the reduction/omission of predictable material and lengthening/insertion of less predictable material results in more uniform distribution of information density across the speech signal, which is proven to facilitate efficient -i.e. fast and robust- information transfer (Genzel \& Charniak, 2002) and to minimize processing difficulty (Levy \& Jaeger, 2007). A trade-off between the amount of information and the amount of linguistic signal expended is also expected under models of boundedly rational communication: If speakers are rational and aim to balance production effort with communicative success, they should provide a more perceptual signal when a word or structure is less contextually inferable (the Ideal Speaker Model in Jaeger, 2011, see also Piantadosi, Tily, \& Gibson, 2011).

However, for much of the evidence that has been cited in favor of communicative efficiency accounts, it is an open question to what extent it could be accommodated in competing accounts. In particular, it is well-established that difficulty with the retrieval, processing, or articulation of upcoming material can affect the degree of reduction/omission of (typically immediately preceding) material. This includes effects on phonetic reduction (Fox Tree \& Clark, 1997) and the optional production of "that" (e.g., Ferreira \& Dell, 2000) described above. For example, speakers are more likely to produce the optional "that", if the onset of the complement clause (its subject) is frequent, short and has previously been mentioned (Ferreira \& Dell, 2000; Roland, Elman, \& Ferreira, 2005). We follow previous work and refer to these effects as availability-based effects.

Here we investigate a morpho-syntactic alternation that provides a less ambiguous test case for the communicativeefficiency accounts. We present three production experiments on optional case-marking in Japanese. Japanese is a verb-final language with relatively flexible word order: in a transitive sentence like (2), both SOV and OSV are possible word orders, although the latter is considerably less frequent. Case relations are marked with post-nominal particles (case-markers) as shown in (2), where "-ga" is the nominative marker and "-o" is the accusative marker. Here we focus on the optionality of the accusative case-marker, indicated in () by parentheses.
(2) Taro-ga sushi-(o) tabe-ta.

Taro-NOM sushi-(ACC) eat-PAST.
Taro ate sushi.
Compared to languages like English or Mandarin Chinese, the flexibility in Japanese word order implies higher uncertainty about the grammatical function assignment (henceforth GF-assignment). In other words, it is not immediately obvious what is the subject and what is the object especially when a case-marker is not present. While case-markers are obligatory in written discourse, however, they are frequently omitted in conversational speech - often, like in (2), without change in meaning.

Such optional case-marking has received considerable attention in linguistic work (e.g., Aissen, 2003), but has remained comparatively understudied in psycholinguistics. Here it is of interest because it allows us to distinguish between the predictions of communicative efficiency accounts, specifically the ideal speaker model proposed in Jaeger (2011), and those of availability-based accounts.

The ideal speaker model predicts that speakers should be more likely to produce case-marking when the intended GFassignment is unexpected given the other information provided in the sentence (for details, see Jaeger, 2011). This is the prediction we test here. In the remainder of this paper, we will use the more succinct statement that "speakers should be more likely to mark the unexpected" to refer to this prediction. In Experiment 1, we investigate whether object typicality, manipulated via changes in animacy, affects speakers' preference during production of optional case-marking in Japanese. We compare the production of sentences that only differ in the animacy of the object, which is either a human referent (e.g., the student) or an inanimate referent (e.g., the fire-engine)(Figure 1-a). If speakers are more likely to mark the unexpected, they should be more likely to produce object case markers if the object is human [atypical] compared to if it is inanimate [typical] (Aissen, 2003).

Preliminary evidence for this prediction comes from qualitative work (Lee, 2007), which examined optional casemarking in conversational Korean. She tested the hypothesis suggested by typological work on case-marking systems. Lee found that both definiteness and animacy are significant predictors of Korean speakers' use of subject- as well as object case-markers in the direction predicted here. However, in a similar corpus study in Japanese, Fry (2003) found no effect of animacy in the object-case marking. While inanimate and indefinite (i.e. atypical) subjects were significantly more likely to be case-marked than animate and definite subjects ( $69 \%$ vs. $64 \%$ ), he found no effect of animacy on object case-marking. It is unclear, however, whether this result indicates an actual absence of an effect of animacy, or whether this was simply due to the sparseness of data or confounding factors, not controlled in the corpus study. Experiment 1 addresses this question by manipulating only object animacy. Further, items were constructed such that all materials following the direct object were held constant, so that no differ-
ences in case-marking preferences between the conditions are predicted by availability-based production (Ferreira \& Dell, 2000).

Experiment 2 and 3 put the ideal speaker model's prediction to a stronger test. We investigate if Japanese speakers' case-marking preference can be directly affected by the inferability of GF-assignment, beyond categorical factors like animacy, givenness, or definiteness. To this end we manipulate plausibility of GF-assignments and investigate their effect on the production of case markers.

## Experiment 1

We employ a spoken recall paradigm to test if Japanese speakers' use of the accusative case-marker -o is sensitive to animacy of the direct object. We manipulated the animacy of the direct object and whether the original stimulus contained a direct object case-marker or not. If optional case-marking is affected by a preference for communicative efficiency, speakers should be more likely to produce responses with a casemarker for animate (atypical) objects compared to inanimate (typical) objects.

## Methods

Participants 20 native speakers of Japanese in Stanford area participated in this study. They received $\$ 7$ for their participation.

Materials In a Latin-square design, each list contained 24 items and 48 fillers. As described above, items were transitive sentences with either animate or inanimate direct objects and with or without a case-marker. Sentence patterns for recall stimuli are illustrated in Figure 1. The nominative casemarker was always present, avoiding ambiguity about the intended GF-assignment and hence about the meaning. Additionally, all items were presented in the subject-before-object order, which is hugely more frequent in Japanese.

Fillers were length-matched sentences with intransitive verbs and longer adverbial phrases. There was no lexical overlap between any of the stimuli. Stimuli were grouped into pairs so that there were 24 item-filler pairs and 12 filler-filler pairs, totalling 36 trials. The order of items and fillers within a pair and the order of pairs were held constant across participants. All stimuli were recorded by a female native speaker of Japanese, using the same prosody for all conditions. In addition, the same speaker recorded 72 recall prompts, one for each sentence (always the verb).

Procedure Each trial consisted of an encoding phase and a recall phase. During encoding, participants listened to pairs of sentences and were instructed to remember them. During recall, participants heard the verb of one of the two sentences (the prompt). They then recalled and produced the full sentence corresponding to that verb. Subsequently, the second prompt was played and participants produced the second sentence. In half of the trials, the sentence encoded first was also recalled first. In the other half, the order was reversed. Following standard procedure (Ferreira \& Dell, 2000), target

Table 1: Percentage of recall error for each of the four conditions in Experiment 1.

|  | Animate | Inanimate |
| :--- | :--- | :--- |
| Present | $8.9 \%$ | $8.9 \%$ |
| Absent | $15.6 \%$ | $8.9 \%$ |

items were never recalled directly after encoding. That is, if an item was encoded first, it was recalled either first or second. If it was encoded second, it was always recalled second. Across participants the recall order for each pair of stimuli was held constant.

Scoring All $20 \times 24=480$ recorded items were transcribed and coded by a native Japanese undergraduate research assistant who was unaware of the purpose of this experiment. Sentences with recall errors anywhere in the sentence were excluded ( $11.6 \%$ ), leaving 424 responses for our analysis. The error rate was doubled for sentences with animate objects without case-marker compared to the other three conditions (Table 2, $\chi^{2}(3)=.7, p<.05$ ). Although these sentences are technically not ambiguous (recall that all sentences contained subject case-marking), sentences with animate objects that lack case-marking are the ones we hypothesized to be most confusing. The high error rate indicates that the recall production was in fact difficult with this type of sentences.

We also coded the presence of disfluency ( 88 out of the 424 analyzable sentences contained at least one disfluency). There was no significant difference across sentence types $\left(\chi^{2}(1)=.03, p>.8\right)$.

## Results and discussion

A mixed logit regression analysis with the full 2 (animacy of object) x 2 (presence of case-marker in stimulus) design was employed to predict the presence of a case-marker. We report the results for the model with maximum random effect structure justified by the data based on model comparison (Jaeger, 2008), which contained random by-subject and item intercepts as well as by-item slopes for the presence of case-marker in stimulus. The effect of interest reported below was robustly significant even in the full random effect model (by-subject and by-item slopes for all factors and their interaction). All predictors were contrast coded and there were no signs of collinearity (fixed effect $r s<.07$ ).

Figure 2: Proportion of case-marker use in Experiment 1. The error bars represent $+/-1$ standard error.

Unsurprisingly, participants were more likely to produce a object case-marker if the original stimulus contained a object case-marker ( $\beta=2.3, p<.0001$ ). Crucially, participants were also more likely to produce a case-marker if the object was animate ( $\beta=.45, p<.03$ ). The two factors did not interact ( $p>9$ ). Figure 2 summarizes the two main effects.

In this recall production experiment, we thus found that animacy of direct objects affected Japanese speakers' casemarking preferences. This suggest that the failure to find animacy-based effects on object case-marking in casual speech in previous work is indeed due to a lack of power and confounding effects of other variables that optional casemarking is sensitive to (Fry, 2003). Our results hence replicate for Japanese what has been found in corpus-based studied on Korean speech (Lee, 2007). Our findings are also compatible with the qualitative description of differential casemarking across languages of the world (Aissen, 2003).

Most relevant to the current purpose, the animacy-based effect on case-marking support the ideal speaker model. The effects we observe are expected under the ideal speaker model and cannot be reduced to availability-based production since the material following the direct object was held constant within items. As discussed above, it is also not clear how production-oriented ('accessibility-based') accounts of the type that have been proposed for phonetic reduction (Arnold, in press; Bell et al., 2009) would account for the observed effects. More generally, it seems unlikely that the effects
observed here are reducible to production difficulty. While we found an increase proportion of recall errors in sentence with animate (atypical) objects without case marker, the proportion of recall errors for animate objects with case markers was identical to that of inanimate objects. Furthermore, the interaction observed for recall errors is not observed in our analysis of speakers' case-marker preferences. Finally, as mentioned above, we did not observe any differences in the distribution of disfluencies across the animacy conditions.

## Experiment 2

If the animacy effect we saw in Experiment 1 was indeed due to effect of communicative efficiency on the encoding of GFassignment, the effect should remain when the animacy of the arguments are controlled. Using animate-animate noun pairs, we examined if the plausibility of GF-assignment affects Japanese speakers' use of the accusative case-marker.

In Figure 1-b (right), the GF-assignment is more plausible when the doctor treats the patient rather than the other way around. Hence the ideal speaker model predicts that speakers should be more likely to produce the object case-marker when the doctor is the object of the sentence, compared to when the patient is the object.

## Methods

Participants 32 native speakers of Japanese in Stanford area participated in this study. They received $\$ 7$ for their participation.
Stimuli There were 24 items, consisting of subject, object, adverb, and verb. Each item consisted of eight conditions ( $=192$ stimuli), resulting from crossing 1) the plausibility of GF-assignment based on the order of two noun phrases and the verb, 2) presence/absence of the case-marker, and 3) the identity of the verb. This is illustrated in Figure 1.

In the example in Figure 1-b, plausibility was coded as high in "The doctor treated the patient in a hospital room" and "The patient waited for the doctor in a hospital room" and as low in "The patient treated the doctor in a hospital room" and "The doctor waited for the patient in a hospital room". Below we collapse over the 2-way within-item verb contrast and treat the design as a $2 \times 2$ (plausibility by case-marker presence in the input), since the identity of the verb is of no theoretical interest here (the effects of verbs on plausibility are already capture by our coding of plausibility). Furthermore, the verb identity was balanced within item and within the two plausibility conditions.

As in Experiment 1, the 24 items were combined with 48 length-matched fillers in a Latin-square design that held order of stimuli constant across lists. There was no lexical overlap between any of the stimuli. The grouping of stimuli into pairs was the same as in Experiment 1. All stimuli were recordings of a female native speaker of Japanese. In addition, the same speaker recorded 72 prompts, one for each sentence (always the verb).

Table 2: Percentage of recall error for each of the four conditions in Experiment 2.

|  | Plausible object | Implausible object |
| :--- | :--- | :--- |
| Present | $8.6 \%$ | $16.7 \%$ |
| Absent | $8.6 \%$ | $12.3 \%$ |

Norming studies The stimuli described below were created using an online norming study (40 native speakers of Japanese). Participants were presented the 24 animateanimate noun pairs used in our items (e.g., doctor-patient). Participants first rated the relative naturalness of the two potential patterns of grammatical function assignment on a 10 point rating scale (e.g., The doctor (did something to) the patient vs. The patient (did something to) the doctor). Second, we asked them to provide verbs that would make the most natural continuation of a given pair of nouns for each pattern (e.g, doctor-NOM patient-ACC / patient-NOM doctor-ACC). Among the set of verbs given by the informants, we selected two verbs for each noun pair such that one verb maximizes the object probability of one noun, and the other verb maximizes the object probability of the other noun. For example, for the "doctor-patient" pair, we chose "(to) treat", which makes "patient" as the plausible object, and "(to) wait for", which makes "the doctor" more plausible.

A second norming study (40 native speakers of Japanese; no overlap in participants with first norming study or either of the experiments) asked participants to rate the relative naturalness of the two patterns of GF-assignment when the verb is present (e.g., "doctor-NOM patient-ACC hospital-roomLOC treat" vs. "patient-NOM doctor-ACC hospital-roomLOC treat").

Procedure The procedure was identical to that of Experiment 1. Since some of the stimuli (e.g., The patient treated the doctor.) were meant to be less plausible, participants were instructed to listen to sentences carefully and produce them faithfully to the input even when they were "somewhat surprising".

Scoring All $32 \times 24=744$ responses were transcribed and coded by a native speaker of Japanese. Sentences with recall errors were excluded ( $11.6 \%$ [sic]), leaving 658 responses for our analysis. Numerically, the error rate was higher for sentences with implausible GF-assignments ( $14.5 \%$ vs. 8.6\%) but the difference was not statistically significant $\left(\chi^{2}(1)=\right.$ $.24, p>.62$ ). $13 \%$ of the error free sentences contained at least one instance of disfluency, but the occurrence rate did not differ across conditions ( $\chi^{2}(3)=.80, p>.3$ ). As in Experiment 1, the distribution of disfluencies did not differ across conditions ( $\chi^{2}(3)=.80, p>.3$ ).

## Results and Discussion

Using the same statistical approach as in Experiment 1, we analyzed the remaining $2 \times 2$ design defined by the plausibility of GF-assignment (high vs. low) and case-marker presence

Figure 3: Proportion of case-marker use in Experiment 3 by plausibility of GF-assignment (high vs. low) and presence of the object case marker in the recall stimulus ( $-o$ present vs. absent). The error bars indicate $+/-1$ standard error.
in the originally presented stimuli (presence vs. absence) to predict the presence of a case-marker in the responses. Unsurprisingly, participants were more likely to produce an object case-marker if the original stimulus contained an object case-marker ( $\beta=2.6, p<.0001$ ). More importantly, they were also more likely to produce a case-marker for implausible GF-assignment ( $\beta=0.8, p<.003$ ). The two factors did not interact ( $p<.7$ ). Thus, this model confirmed the predicted effect of object plausibility in the form of categorical factor. The effects are illustrated in Figure 3.

Next, we analyzed the gradient effects of values for the plausibility of GF-assignments as rated in the norming studies described above. The effect of two different plausibility ratings was examined: plausibility of GF-assignment given only the two nouns (Norming Study 1, part 1) or given the full sentence (Norming Study 2). Plausibility ratings for full sentences returned the expected significant effect ( $\beta=-0.43$, $p<.03$ ), namely that the speakers were more likely to use the case-marker when the GF-assignment had been normed to be less plausible. However, the ratings based on only the two noun phrases returned no such effect ( $\beta=-.05, p>.9$ ). This suggests that what speakers assess is the plausibility of an intended message (including the verb information) rather than just the properties of nouns.

## Experiment 3

We replicated Experiment 2 by using the subject noun, instead of the verb, as a recall cue. This allows us to rule out the possibility that the plausibility effect observed in Experiment 2 is an artifact of the recall cue being the verb of a sentence. As Japanese is a SOV language, it is possible that the use of the (sentence final) verb as the recall cue in Experiment 1 and 2 forced participants to adopt task-specific production strategies that do not reflect normal language production.

Figure 4: Proportion of case-marker use in Experiment 3 by plausibility of GF-assignment (high vs. low) and presence of the object case marker in the recall stimulus ( $-o$ present vs. absent). The error bars indicate $+/-1$ standard error.

## Methods

Participants 26 native speakers of Japanese in Stanford area participated in this study. Data from one subject were excluded because of a problem with the recording device.

Stimuli The stimuli and their presentation order were mostly identical to those of Experiment 2. New recall cues (the subject nouns of the target sentences) were recorded by the same speaker who recorded the stimuli sentences for Experiment 2.

## Results and Discussion

Using the same statistical approach as in Experiment 1 and 2 , we analysed the binary predictors of the plausibility of GF-assignment (high vs. low) and case-marker presence in the originally presented stimuli (presence vs. absence of $-o$ ) to predict the occurrence of a case-marker in the responses. We replicated the finding in Experiment 2: the expected effect of the object case-marker presence in the original stimulus ( $\beta=1.83, p<.001$ ), and the low inferrability GFassignments ( $\beta=-1.12, p<.007$ ). The two effects did not interact ( $p>.2$ ). Thus, this model confirmed that the effect of object plausibility (in the form of categorical factor) remains when the recall cue was the subject of the sentence. The effects are illustrated in Figure 4.

Also, we replicated the effects of two different plausibility ratings. Plausibility ratings for full sentences returned the expected significant effect $(\beta=-0.40, p<.05)$ whereas the ratings based on only the two noun phrases returned no such effect ( $\beta=-.03, p>.6$ ). There was a negative interaction term between the plausibility value given the full sentence and the presence of the case-marker: Highly plausible GFassignments were even less likely to be case-marked when the original sentences lacked the object case-marking ( $\beta=-.74$, $p<.01$ ).

## General Discussion

Our results suggest that Japanese speakers prefer to produce an object NP without case marking when grammatical function of a noun is made more predictable given the semantics of the noun (e.g., animacy) and the other linguistic elements in the sentence (e.g., plausibility of GF-assignment given the subject, object, and verb). The plausibility effect we saw in Experiment 2 and 3 strongly suggests that speakers have fine-grained probabilistic knowledge about the plausibility beyond categorical factors like animacy and definiteness. More generally, this is one of the first studies showing a systematic effect of plausibility in the morpho-syntactic encoding of speech.

Recent studies have found that speakers' use and nonuse of case-markers are interacting with the word order as well. Speakers tend to use case-makers when the word order does not conform to an expected pattern (see Lee and Kim (2012) in Korean, Fedzechkina, Jaeger, and Newport (2012) for experiments using an artificial language). This is also predictable by the assumption of efficient communication. An explicit case marking becomes more likely when the non-canonical word order biases against an intended GFassignment pattern.

This body of research including the current study constitutes strong support for the view that language production is optimized to maximize the efficiency of information transmission (Jaeger, 2010; Levy \& Jaeger, 2007), and, in particular, the ideal speaker model (Jaeger, 2011). Unlike most previous work, the current results cannot be accounted for in terms of availability, even if availability-based production is extended to include the availability of upcoming syntactic structures.

Furthermore, our results provide broader implications for studies investigating the effects of communicative pressure on cross-linguistically attested phenomena such as differential case-marking (Aissen, 2003). Our results and Lee's (2007) study in Korean support the hypothesis that the languages with an optional case-marking system are sensitive to the same factors that are known to affect more categorical caseencodings in various languages. This may suggest that the functional pressure for efficient communication underlies at least some of the universal features found across languages.

#### Abstract

Research investigating top-down attentional capture has demonstrated a tight coupling of working memory content with attention and eye movements. By capitalizing on this relationship, we have developed a novel methodology called the Memory Activation Capture (MAC) procedure for measuring the dynamics of working memory content supporting complex cognitive tasks (e.g., decision making, problem solving). By observing which items are preferentially fixated in task irrelevant arrays containing task relevant information, we gain a measure of working memory content as the task evolves through time. The efficacy of the MAC procedure is demonstrated in a hypothesis generation task. Results suggest a two-stage process following hypothesis retrieval whereby it undergoes a brief period of heightened activation before entering a lower activation state while being maintained for output. The present effects are of additional general interest as they represent the first demonstrations of top-down attentional capture driven by participant-established WM content retrieved from long-term memory.

Keywords: attention, memory, decision making, eye tracking, process tracing, hypothesis generation

## Introduction

The considerable interest in understanding the cognitive dynamics of information use over time is underscored by the proliferation of process-tracing methodologies within several domains. Think-aloud procedures, in which a participant provides concurrent verbalization of their cognitive states while performing a task, were among the first of these techniques to be developed (Ericcson \& Simon, 1993; Ford, Schmitt, Schechtman, Hults, \& Doherty, 1989; Montgomery \& Svenson, 1976; Svenson, 1979) and still enjoy widespread use today (Schulte-Mecklenbeck, Kühberger \& Ranyard, 2011). The usage of eye movements as a window to dynamic cognitive processing has flourished as of late with application in several fields including decision making (Franco-Watkins \& Johnson, 2011; Glaholt, Wu, \& Reingold, 2009, Glaholt \& Reingold, 2011, Sutterlin, Brunner, \& Opwis, 2008), problem solving (Ellis, Glaholt, \& Reingold, 2011), categorization (Rehder \& Hoffman, 2005a, 2005b), language comprehension (Cooper, 1974; Tanenhaus, 1995), and diagnostic reasoning (Renkewitz \& Jahn, 2012).

The methodology forwarded here shares the same goal as process-tracing techniques, namely to gain better understanding of cognitive dynamics by measuring information use as the task naturally unfolds. Our method, however, takes a novel approach towards revealing the content of working memory by relying on the recent literature addressing attentional "top-down capture" effects demonstrating a tight coupling between the content of WM and the deployment of attention and eye movements. For instance, Soto, Heinke, Humphreys, and Blanco (2005) and Soto \& Humphreys (2007) provide evidence that attention is automatically captured by the contents of WM (although for contrasting evidence see Woodman \& Luck, 2007). As the presently forwarded methodology relies on eye movement data it is of particular importance that Soto et al. (2005) found eye movements to be sensitive to the spatial congruency of target and WM-matching items. Moreover, Moores, Laiti, and \& Chelazzi (2003) found that first saccades were biased towards WM-matching items as well as semantic associates of items maintained in WM.

As eye movements are biased by the content of WM, it may be possible to capitalize on this bias to develop a measure of WM content deployable in complex cognitive tasks. Specifically, by presenting brief visual arrays containing task related information at various points in time, differences in the oculomotor guidance towards the items contained in such "WM probe arrays" could be taken as evidence regarding the active content of WM at the time of the array presentations. In this way our methodology can be thought of as an effort to capture snapshots of WM across time. We refer to our methodology as the Memory Activation Capture (MAC) procedure. Although the logic of this procedure (as well as its specific advantages) have been treated elsewhere (Lange, Thomas, Buttaccio, \& Davelaar, 2012), the present experiment represents the first deployment of this procedure in a complex cognitive task.

In the present paper, we deploy this procedure in the context of a memory retrieval task to investigate the temporal dynamics of hypothesis generation. We define hypothesis generation as a general case of cued recall in which the observation of one or multiple cues can lead to the retrieval of one or multiple hypotheses (Dougherty, Thomas, \& Lange, 2010; Thomas, Dougherty, Sprenger, \& Harbison, 2008). In our day-to-day lives, we utilize this
process to better understand the occurrences we witness in our environment. For instance, if a friend is acting differently than usual you may generate various explanations for their behavior. A professional example comes to us through medical diagnosis in which a physician observes various symptoms from a patient and retrieves associated diagnoses from long term memory (LTM).

Recently, we have investigated the influences of time and sequence on hypothesis generation by formulating a model addressing the influence of WM dynamics during information acquisition on the retrieval (i.e., generation) of hypotheses and confirmed model predictions (Lange, Thomas, and Davelaar, 2012 Lange, Thomas, Buttaccio, Illingworth, \& Davelaar, 2012, Lange, Davelaar, \& Thomas, In Press). This model assumes that the memory activation associated with each piece of acquired information (i.e., data) undergoes a dynamic rise and fall over time in accordance with 1) competition from other acquired items, 2) bottom-up activation, and 3) its self-recurrent excitation (see Davelaar, Goshen-Gottstein, Ashkenazi, Haarmann, \& Usher (2005) for a fuller treatment and computational details). We hypothesize that the memory activations of acquired data and retrieved hypotheses are subject to the same competitive WM dynamics. We now provide a hypothetical example of how the memory activations of data and hypotheses may trade off in a simplified medical diagnosis task and use this example to illustrate a hypothetical deployment of the MAC procedure.

Figure 1 provides a hypothetical example of the deployment of our procedure in the context of a simplified medical diagnosis task (e.g., hypothesis generation, diagnostic reasoning). The task is initiated with the presentation of a patient symptom (e.g., fever). As this information is acquired, its associated memory representation becomes activated and rises. Shortly after this data has been acquired, the memory activation associated with an associated diagnosis begins to rise and is generated when its memory activation crosses a threshold distinguishing the content of WM. The memory activation of the diagnosis continues to rise while at the same time the activation associated with the symptom decreases due to competitive WM processes. The points labeled T1-T4 represent points at which the WM Probe Array could be presented. In this example, we assume that the probe array (represented visually) contains four items: the diagnosis and three distractor items. At T1, the diagnosis would not be fixated more than the distractors in the probe array. However, at T2, the diagnosis has been retrieved and resides in WM. At this point, we would expect to see the diagnosis being fixated more often than the distractor items, indicating that it is active in WM. Moreover, at time points T3 and T4 we might see a rise and fall in the fixation rate of the diagnosis due to the rise and fall of its associated memory activation. An important aspect regarding our use of topdown oculomotor capture as a measure of WM content is that, unlike any visual search task, the WM Probe Arrays used in the present experiments are completely task
irrelevant. That is, the participant does not have a task to perform on the array and is not instructed for any response to the arrays.

Figure 1: Hypothetical deployment of the MAC procedure in the context of a simplified medical diagnosis task. Time points T1-T4 represent the presentations of the WM Probe Arrays where eye movements are measured.

We now present an experiment deploying the MAC procedure to investigate the time course of memory retrieval in the context of a hypothesis generation task. The task is explained to the participants as a "Cause and Effect learning task" in which they are to learn associations between colors, some representing Causes and some representing Effects emanating from those Causes. Thus, the present task contains the essential structure for a hypothesis generation task in which one reasons from events (Effects) to explanations (Causes).

## Deploying the MAC Procedure

In this experiment we test the efficacy of the MAC procedure to detect the retrieval of a likely hypothesis into working memory and its sensitivity to retrieval timing.

Participants Twenty-three participants from the University of Oklahoma participated for course credit.

Apparatus, Stimuli, and Procedure Eye movements were recorded monocularly (dominant eye) via an Eye Link 1000 (SR Research) at a sampling rate of 1000 Hz and a distance of 60 cm from a 17" monitor. Stimulus presentation and data recording were controlled via Experiment Builder. A ResponsePixx box was used to collect manual responses during the experiment. Eight colors were used during the experiment (blue, green, orange, purple, red, salmon, white, and yellow). Gray was used as the background color throughout the experiment and the fixations were black. Prior to the start of the experiment, the colors were randomly assigned as causes, effects, or distractors.

The experiment consisted of two main phases, a training phase in which the participants learned probabilistic relationships between the Causes and Effects followed by an elicitation phase in which the MAC procedure was deployed. Training consisted of two parts, passive exemplar training and active exemplar training in what could be considered as a "probabilistic paired-associates category
learning task". Participants first went through the passive training portion which was followed by active training and the entirety of the training phase constituted four repeated pairings of passive and active blocks. In passive training, the participant was presented with many individual exemplars in which a single "Cause" and "Effect" pairing with an arrow going from the Cause towards the Effect. Each exemplar appeared for $1,500 \mathrm{~ms}$ after which point the participant pressed the response box to view a new Cause and Effect exemplar. There were four screen configurations in which the pairing could appear and these were randomly selected on each trial to ensure that the Causes and Effects were balanced across spatial locations.

During active training, the participant was presented with an exemplar in which the Cause was absent and the participant had to select the likely Cause with a manual button press. The participant then received feedback (correct/incorrect) for each trial and was shown the correct Cause on incorrect trials. For the first block of active training, participants had $3,000 \mathrm{~ms}$ to respond with the related Cause and this decreased to $1,500 \mathrm{~ms}$ for the second, third, and fourth blocks.

The statistical associations between the Causes and Effects were dictated by the values in Table 1. Note, Effect 1 was highly diagnostic of Cause 1 and Effect 2 was highly diagnostic of Cause 2 (while Effects 3 and 4 were nondiagnostic). For example, there is a $90 \%$ chance that Effect 1 will be present given Cause 1 as described in Table 1, therefore when Effect 1 is observed it is highly likely that Cause 1 is responsible. Additionally, it is important to note that Effect 1 and Effect 2 were complementary with one another as were Effects 3 \& 4. For instance, in medical diagnosis context Effect 1 could represent "fever" and Effect 2 would represent "no fever".

Table 1: The Cause-Effect contingency table governing the associations between the Causes and Effects.

|  | Effect 1 | Effect 2 | Effect 3 | Effect 4 |
| :--- | :---: | :---: | :---: | :---: |
| Cause 1 | 0.9 | 0.1 | 0.9 | 0.1 |
| Cause 2 | 0.1 | 0.9 | 0.9 | 0.1 |

The elicitation phase, in which we deployed the MAC procedure (and recorded eye movements), commenced following the fourth round of active training. In this phase, participants were instructed that on each trial they would be presented with an Effect and would have to respond (manually with left/right button press) to select the most likely Cause given the effect. On $2 / 3$ of trials a WM Probe Array was briefly presented for 396 ms containing four colored disks (top to center $=15 \mathrm{~mm}$ and right to center $=$ 14). Two of the colors were those of the Causes and the two other colors were those assigned as distracter colors at the beginning of the experiment (which had not appeared at any point prior in the experiment). These four colored disks were positioned around a circle (unseen) with a radius of 86 mm . Relative to a clock face one disk appeared at 1 or 2 o'clock, another at 4 or 5 o'clock, another at 7 or 8 o'clock, and the last at 10 or 11 o'clock. Each of the four items
(Causes \& Distractors) were randomly assigned to these four positions in the WM probe array.

Figure 2: Trial schematic demonstrating the sequence of events for trials on which the WM Probe Array appeared.

The focal independent variable was the timing of the WM Probe Array on the trials in which an array appeared. The WM Probe Arrays were manipulated to appear at a variable SOA following the onset of the Effect. For the Short SOA condition, the ISI with a fixation cross was presented for a brief duration ( 48 ms ) and for the Long SOA condition the fixation was presented for a longer duration ( 600 ms ). The relative duration of the second fixation cross was inverted from the duration of the first fixation ( 600 ms for Short SOA trials and 48 ms for Long SOA trials). On the remaining third of trials, no WM Probe Array appeared. These trials were included to limit the expectation of the WM Probe Array's appearance throughout elicitation. On these "no-probe trials", the Effect was followed by a fixation for 1092 ms prior to the selection screen. Thus, total trial time was equal across all trials. Participants completed 36 trials (12 Short SOA, 12 Long SOA, and 12 No-Probe trials). Within each of these conditions, three trials occurred with each Effect. Participants were not informed of WM probe array's appearance nor were they provided instruction for any response when it appeared.

Although Effects 3 and 4 were presented in the elicitation phase, we were not concerned with these trials as these Effects were non-diagnostic. Effects 1 and 2, on the other hand, were highly diagnostic and, accordingly, it is on these trials where our interest and predictions fall. On these trials, the likely hypothesis should be retrieved into WM and bias eye movements towards its matching representation in the WM probe array through top-down capture. Thus, we hypothesized that participants would fixate the likely hypothesis first more often than the unlikely hypothesis and distractors. Additionally, we hypothesized that a difference in the time course of the generation process might emerge between the two SOA conditions as a result of the time pressure applied in the active training.

## Results

For eye movement analyses, regions of interest (ROIs) were centered on each colored disk appearing in the WM Probe Arrays measuring 34.5 mm top to center and 32 mm right to center. A disk was considered fixated when a fixation landed in its corresponding ROI. For analysis we took our primary DV as the first WM Probe Array disk fixated. Only trials in which participants were presented with a diagnostic

Effect (i.e., Effect 1 or 2) were analyzed. Trials on which the participant selected the less likely Cause at the end of the trial were considered as incorrect trials and discarded prior to analysis ( $24 \%)^{1}$. Two additional criteria were applied to each trial for inclusion in the analysis 1) the participant must have been fixating within an ROI at the center of the screen at the beginning of the trial ( 32 mm tall x 34 mm wide) and 2) an item in the array must have been fixated. An additional $8 \%$ of the total trials were discarded for central fixation criterion and an additional $37 \%$ of the total trials were discarded for the array item fixation criterion.

As displayed in Figure 3 the likely Cause was more often fixated first than the unlikely Cause and distractors in the Short SOA condition, $\mathrm{z}=4.3, p<0.001$, and $\mathrm{z}=4.96, p<$ 0.001 , as well as in the Long SOA condition, $\mathrm{z}=1.91, p<$ 0.056 , and $\mathrm{z}=3.45, p<0.001$ (although this difference was marginal between the likely and unlikely Cause). More importantly, logistic regression revealed that the likely Cause was more often fixated first in the Short SOA condition than in the Long SOA condition, $\chi^{2}(1)=5.92, p<$ .05. No such differences were found for the unlikely Cause, $\chi^{2}(1)=1.36, p=.24$, or distractors, $\chi^{2}(1)=2.9, p=.08$.

Figure 3: Proportion of trials on which each item type was the first array item fixated. Results demonstrate increased fixation of the Likely Cause at the Short SOA relative to the
Long SOA and greater fixation rates for the Likely Cause relative to the Unlikely Cause and Distractors.

## Discussion

We have developed a novel methodology to non-intrusively measure the content of WM in complex cognitive tasks as they unfold over time. Here we deployed the MAC procedure in the context of a hypothesis generation task in which participants retrieved a hypothesis from LTM based on the presentation of an associated cue. Our procedure shares the aims of the multitude of process tracing approaches that have been developed over the last thirty years - to assess moment by moment cognitive dynamics

[^132]and changes in the representations utilized en route to final task output. By capitalizing on the tight connection between WM content and attentional allocation via top-down capture (Soto, Heinke, Humphreys, \& Blanco, 2005; Soto \& Humphreys, 2007), we have developed a new method of such assessment. Moreover, by designing our procedure to assess WM content briefly and on task-irrelevant arrays, we have aimed to develop a procedure that will be less interfering to the processes under investigation than traditional processing measures which essentially constrain the participant with a dual-task (see Russo, 1978; Russo, Johnson, \& Stevens, 1989).

Two important effects manifest in the present experiment: 1) The Likely Cause was most often fixated first relative to the other items in the WM probe arrays, and 2) There was an effect of SOA such that the likely Cause was more likely to be fixated at the shorter SOA. It has previously been suggested (Makovski \& Jiang, 2008) that biases towards WM matching content, as revealed through RTs, are sensitive to the representational strength of the WM content. Additionally, Lange, Thomas, Buttaccio, \& Davelaar (2012) provide preliminary evidence that eye movements are sensitive to WM activation. We interpret the present effect of SOA for the likely hypothesis as demonstrating differences in the memory activation (i.e., representational strength) possessed by the likely hypothesis between the short and long SOAs. The present results suggest that shortly after a hypothesis is retrieved into WM, it undergoes a brief period of heightened activation before moving into a decreased state of activation as it is maintained for output.

We refer to this initial heighted stage as a "retrieval input" stage as it is the act of retrieval from LTM that endows the hypothesis with this heightened activation state. We refer to the following stage of decreased activation as a "maintenance" stage as the hypothesis is being maintained in WM for eventual overt output. This account is readily captured by the context-activation model (Davelaar et al., 2005) which we have recently incorporated into a temporally dynamic model of hypothesis generation (Lange, Thomas, \& Davelaar, 2012). In the context-activation model, the memory activation of an item at each time step is determined by the item's activation on the previous time step, self-recurrent excitation that it recycles onto itself, inhibition from the other active items, external input, and noise ${ }^{2}$. Besides external input, the model can also be excited by information retrieved from LTM and the model readily produces the trend we see in the fixation data at the short and long SOAs. As demonstrated in Figure 4, when the model is provided "retrieval input" for 500 iterations, which is then removed for the final 500 iterations, the trend evidenced in the data is produced. Although the focus of this paper is not in modeling the empirical data, it is encouraging to see that a crucial component of our theoretical framework accounts for the data with such ease.

[^133]

Time (model iterations)
Figure 4: Context-Activation Model account of the SOA difference observed in Experiment 2 for the likely
hypothesis. Shortly after retrieval, the hypothesis enjoys a brief period of heightened activation in WM (measured at the short SOA) before moving into a less activated maintenance state (measured at the long SOA) prior to output.

Two related and recently developed methodological approaches deserve further consideration. Mehlhorn, Taatgen, Lebiere, and Krems (2011) used a lexical decision task to measure memory activation of candidate hypotheses in a diagnostic reasoning task. By interspersing the lexical decision task (yes/no response to indicate "hypothesis or not") at different time points in a diagnostic reasoning task they were able to draw conclusions regarding memory activation by assessing the relative speed with which the lexical decision was made for the various hypotheses of interest. This procedure and the MAC procedure share an emphasis on quickly assessing the content of memory with a brief "probe" presented to the participant. However, as with traditional process tracing, this modified lexical decision procedure requires a secondary (albeit not entirely concurrent) task in addition to the primary task of interest. Despite this difference, we believe the procedure of Mehlhorn et al. (2011) to be highly complementary to ours.

Also of note is the "memory indexing" technique of Renkewitz and Jahn (2012) capitalizing on the phenomenon of looking-at-nothing (Ferreira, Apel, \& Henderson, 2008). By holding the spatial locations of the task relevant information constant throughout the experiment, they were able to use eye movements relating to the spatial locations of this information in the testing phase as an index of what was actively being considered across time in the task (despite the fact that the screen was mostly blank as this data was collected and the participants were looking at nothing). This procedure has been successfully utilized to investigate multi-attribute choice (Renkewitz \& Jahn, 2012) as well as diagnostic reasoning (Jahn \& Braatz, 2012). Each of these three procedures (memory activation capture, modified lexical decision, and memory indexing) has their own strengths and weaknesses. By coordinating their utilization within the domain of hypothesis generation and diagnostic reasoning we may be well poised to gain a much deeper understanding of the dynamic memorial underpinnings of these tasks.

Lastly, although we have focused primarily on the domain of hypothesis generation and diagnostic reasoning here, it is important to note that the MAC procedure itself is entirely domain general. Although specific procedural details would need to be tailored for deployment in additional tasks (e.g., specific array stimuli), there is nothing in the logic or mechanics of the procedure that exclude it from use in other domains. We are hopeful that the application of the MAC procedure in domains such as problem solving, multiattribute choice, probability judgment, and hypothesis testing will foster additional insights concerning the cognitive dynamics operating in these domains as well.

#### Abstract

The detection and categorization of animate motions is a crucial task underlying social interaction and perceptual decisionmaking. Neural representations of perceived animate objects are built in the primate cortical region STS which is a region of convergent input from intermediate level form and motion representations. Populations of STS cells exist which are selectively responsive to specific animated motion sequences, such as walkers. It is still unclear how and to which extent form and motion information contribute to the generation of such representations and what kind of mechanisms are involved in the learning processes. The paper develops a cortical model architecture for the unsupervised learning of animated motion sequence representations. We demonstrate how the model automatically selects significant motion patterns as well as meaningful static form prototypes characterized by a high degree of articulation. Such key poses are selectively reinforced during learning through a cross-talk between the motion and form processing streams. Next, we show how sequence selective representations are learned in STS by fusing static form and motion input from the segregated bottom-up driving input streams. Cells in STS, in turn, feed their activities recurrently to their input sites along top-down signal pathways. We show how such learned feedback connections enable making predictions about future input as anticipation generated by sequence-selective STS cells. Network simulations demonstrate the computational capacity of the proposed model by reproducing several experimental findings from neurosciences and by accounting for recent behavioral data. Keywords: animated motion representation; implied motion; neural model; unsupervised learning; feedback.

## Introduction

Animated movements in actions, like walking, turning, etc., can be robustly detected from video sequence input and predictions about future occurrences can be derived from such spatio-temporal patterns. Giese \& Poggio (Giese \& Poggio, 2003) proposed a hierarchical feedforward network architecture that aims at explaining the computational mechanisms underlying the perception of biological motion, mainly from impoverished stimuli such as point-light walkers. In this paper, we propose a new learning-based hierarchical model for analyzing animated motion sequences. Prototypes in the form and motion pathways are established using a modified Hebbian learning scheme. We suggest how snapshot prototypes are automatically selected from continuous input video streams utilizing features from the motion pathway which are indicative for the occurrence of specific snapshots with strongly articulated configurations, serving as key
poses. Sequence-selective representations of articulated motions in cortical STS are driven jointly by input activations from both motion and form prototypes. In addition, feedback connections are learned to enable STS neurons predicting expected input from form selective IT and motion sensitive MST. We argue that for inputs presenting articulated postures without continuing motion, STS representations are fed by the corresponding snapshot prototype activations (Jellema \& Perrett, 2003). In turn, STS will send feedback to stages in the segregated pathways for form as well as motion processing. Stationary images which depict articulated postures, consequently generate effects of implied motion, which have been shown in functional magnetic resonance imaging (fMRI) studies (Kourtzi \& Kanwisher, 2000). We will argue here, that this can be accomplished by the proposed model through the action of fusing bottom-up input, driven by snapshot representation only, and the activated sequence representations sending feedback to both form and motion representations, thus amplifying motion representations even if no direct motion input is present.
Several computer vision approaches have been proposed for performing action recognition using different processing strategies of combining form and motion information. These approaches build upon the hierarchical architecture proposed by Poggio and coworkers which aims at defining a framework for form processing in the cortical ventral pathway (Riesenhuber \& Poggio, 1999). Extensions of the form processing model to analyze motion information responses in a separate pathway, like the Giese-Poggio model, have been suggested in e.g. (Schindler \& Van Gool, 2008). Here, the relative contributions of form and motion features to the classification of actions have been investigated. Details of the motion processing cascade alone have been studied in more detail in (Escobar \& Kornprobst, 2012). Here the authors contributed further evidence that detecting motion contrasts in sequences of animated motion is useful to distinguish action classes. In all these proposed models, the mechanisms for hierarchical motion (and form) processing are predefined and learning only occurs at the level of a final classifier to distinguish given categories. It still remains unclear to a large extent, how the motion and form prototypes (e.g., in cortical areas MST and IT, respectively) and the sequence-selective pattern representations in STS interact and which features are

Figure 1: Overview of the model architecture. The model consists of two separate processing streams, the motion and the form pathway, both converging into model area STS. Static form prototypes in area IT, as well as optic flow patterns in area MST are learned using an unsupervised Hebbian mechanism. A motion driven reinforcement signal between the two pathways is used to steer the learning of the IT prototypes. After the suppression of cells with low activities, IT and MST cells propagate into area STS, where sequenceselective cells learn corresponding spatio-temporal activity patterns using a similar Hebbian learning rule. In addition, the sequence-selective cells learn the output weights back to the segregated form and motion prototypes, that stabilizes the input processing and activity fusion.
used for learning. How can feature representations be learned automatically from given input streams at different levels of the distributed action sequence representations? Also no topdown influences have been considered so far and how such connectivity patterns may transfer different information between pathways to generate proper predictions concerning future input configurations.

## Model Architecture

The hierarchical model proposed here consists of two separate visual pathways for segregated form and motion processing as inspired by the work of (Giese \& Poggio, 2003) and extends it by combining it with models for the hierarchical feedforward and feedback processing of motion and form along the dorsal and the ventral pathway (Bayerl \& Neumann, 2004; Weidenbacher \& Neumann, 2009). Intermediate level form representations (in model IT) and prototypical optical flow patterns (in model MST) are established using a modified competitive Hebbian learning scheme with convergent weight dynamics. The two separate hierarchical learning approaches are influenced partly by the work of Rolls and
collaborators (Rolls \& Milward, 2000), in which the authors have suggested that layered neuronal structures arranged in a hierarchy with increasingly larger connectivity kernels can learn invariant representations of objects and specific motion patterns. Here, we propose how such learning in a hierarchy can be utilized for learning sequence-selective representations of animated movement prototypes from convergent form and motion input. In addition, we suggest how a motiondriven reinforcement mechanism automatically selects relevant snapshots in the form path from video input streams. The activities of the prototypical form and motion cells converge in the model complex STS, where correlated temporal activations for specific sequences are learned. Sequence-selective representations are established by combined bottom-up and top-down learning, both based on modified Hebbian mechanisms. An overview of the model is shown in Fig. 1. The details are outlined below.

## Form and Motion Processing

Processing the raw input data utilizes an initial stage of orientation and direction selective filtering (in model area V1). These responses are fed into separated pathways which are selective to static form representations (areas V2 and IT) and characteristic optical flow patterns (areas MT and MST). We use single compartment model neurons with gradual activation dynamics. The membrane potential of individual model neurons is calculated by conductance-based mechanisms of feed-forward integration of excitatory and inhibitory feeding input and a passive leakage. The potential can be enhanced by a gating mechanism to amplify the efficacy of the current potential by a matching top-down feedback signal. The membrane potential is finally regulated by a gain control mechanism that leads to activity normalization for a pool of neurons through mutual divisive inhibition. These mechanisms are summarized in a three-stage hierarchy of processing that includes input filtering, modulatory feedback, and pool normalization. The output of a cell is defined by a signal function which converts the membrane potential into a firing rate, or activity. Such model cells are grouped into layers which form abstract models of cortical areas.

## Learning of Form and Motion Prototypes

First, we investigated how intermediate level feature representations can be learned in a biologically plausible fashion by exposing the network architecture with realistic input sequences. In order to generate feature representations of complex form and motion patterns we employ an unsupervised learning mechanism based on a modified Hebbian learning scheme. The modification stabilizes the learning such that the growing of weight efficacies is constrained to approach (bounded) activity levels of the input or the output activation. Motivated by the invariance properties observed by (Wallis \& Rolls, 1997) we combined the modified Hebbian learning mechanism with a short-term memory trace of prolonged activity of the pre- or the post-synaptic cells (trace rule). The adaptation of weightings is controlled by post-synaptic cells
which, in turn, mutually compete for their ability to adjust their incoming connection weights. The particular details as well as the particular variations of the core architecture are explained below.

Hebbian learning in the form and motion pathways. In order to select the image regions that are fed to the learning of prototype representations a region of interest (ROI) is defined which represents a bounding box around the target object. Features within the target region are selected for learning feedforward connection weights in the form and the motion pathway, respectively. We employ the modified Hebbian learning rule

$$
\begin{equation*}
\Delta w_{j i}^{F F, s}=\eta_{s} \cdot \bar{v}_{i}^{p o s t} \cdot\left(u_{j}^{p r e}-\bar{v}_{i}^{p o s t} \cdot w_{j i}^{F F, s}\right) \tag{1}
\end{equation*}
$$

where $\Delta w_{j i}^{F F, s}$ represents the discretized rate of change in the efficacy of the weighted connections with the learning rate $\eta_{s} ; s \in\{$ form,motion $\}$ indicates that the same core mechanisms are devoted to learning in the form and motion pathway, respectively. The variables $u_{j}^{p r e}=f\left(x_{j}\right)$ and $v_{i}^{\text {post }}=f\left(y_{i}\right)$ are the firing rates driven by the membrane potential of pre- and post-synaptic cells, henceforth denoted as activity. The activity $\bar{v}_{i}$ of the post-synaptic cell is calculated by the temporal trace rule $\bar{v}_{i}^{t}=(1-\lambda) \bar{v}_{i}^{t-1}+\lambda v_{i}^{t}, 0<\lambda<1$ (Földiák, 1991). The trace rule (see also (Wallis \& Rolls, 1997; Rolls \& Milward, 2000)) has been proposed to incorporate a short-term memory function for the cells to keep their activation over a short temporal window while adapting their weights. The term in brackets on the r.h.s. of learning equation 1 serves as a biologically plausible mechanism to bound the growth of the cells' input synaptic weights (Oja, 1982). The post-synaptic cells (with activity $\bar{v}_{i}^{\text {post }}$ ) which gate the learning of their respective input weights are arranged in a competitive layer of neurons competing for the best matching response and their subsequent ability to adapt their kernel of spatial input weights. In a nutshell, the layer of post-synaptic neurons competes to select a winning node for a given input presentation which, in turn, is allowed to automatically adapt their incoming (instar) synaptic weights. The temporal trace (or short-term memory) establishes that categories learn their average input over a short temporal interval thus allowing small pertubations for the changing input signals.

Reinforcing snapshot learning. The Giese-Poggio model (Giese \& Poggio, 2003) suggests that sequence selectivity for biological motion recognition is driven by sequences of static snapshots. While the original model relies on snapshots that were regularly sampled temporally, we suggest a mechanism of how snapshots corresponding to strongly articulated poses can be selected automatically. Such snapshot representations are learned in the form channel by utilizing a gating reinforcement signal which is driven by the complementary representation of motion in the dorsal stage MT/MST. Formally, the weighted integration of motion energy over a given neighborhood is calculated by

$$
\begin{equation*}
m_{e}=\int_{\Omega} u_{\phi}(\mathbf{x}) \cdot \Lambda(\mathbf{x}) d \mathbf{x} d \phi \tag{2}
\end{equation*}
$$

Figure 2: IT prototypes trained using disabled and enabled reinforcement signal. Minima and maxima in motion energy correspond to articulated and non-articulated postures (bottom left). Continuous learning of IT prototypes leads to activation profiles with low selectivity (top right). Motion driven reinforcement leads to IT prototypes which signal snapshot poses in synchrony with the gait (bottom right; for details, see text).
with $\Lambda(\bullet)$ denoting a spatial kernel for weighting the relative contribution of motion responses $u_{\phi}(\bullet)$ at spatial locations $\mathbf{x}$ in the 2-D image plane and with direction selectivity $\phi .{ }^{1}$ The motion energy signal itself is a function of time which is used to steer the instar learning in the form pathway. We suggest that different subpopulations of static form, or snapshot, representations can be learned that correspond to either weakly or strongly articulated postures. Here, we focus on snapshot poses corresponding to highly articulated postures with signatures of maximum limb spreading. Motion energy at limbs drops during phases of high articulation when their apparent direction of motion reverses. We incorporate the function $g(\bullet)$ to control a vigilance in snapshot learning to favor form inputs which co-occur with local motion energy minima, i.e. when $\partial_{t} m_{e}=0$, given that $\partial_{t t} m_{e}>0$. In the weight adaptation, $\Delta w_{j i}^{F F, f o r m}$ in Eqn.1, the learning rate is now gated by the motion dependent reinforcement, $\eta_{\text {form }} \cdot g\left(m_{e}\right)$ which leads to the revised learning rule

$$
\begin{equation*}
\Delta w_{j i}^{F F, f o r m}=\eta_{\text {form }} \cdot g\left(m_{e}\right) \cdot \bar{v}_{i}^{p o s t} \cdot\left(u_{j}^{p r e}-\bar{v}_{i}^{\text {post }} \cdot w_{j i}^{F F, \text { form }}\right) . \tag{3}
\end{equation*}
$$

## Learning of Sequence-Selective Representations

Categorial representations in the form and motion pathway, namely in IT and MST, which were learned at the previous stage, feed forward their activations to the stage of STS. In order to stabilize the representations and activity distributions, even in the case of partial loss of input signals, the STS sequence-selective representations send top-down signals to their respective input stages.

[^134]

Figure 3: Response behavior of IT snapshot neurons, MST motion pattern neurons, and sequence-selective STS cells trained by video input for a walker moving from left to right. Activations in the model areas are shown for different input conditions for recall of the training sequence (top), opposite walker movement (middle), and walker displayed in reverse motion (bottom). Line styles and colors encode the input test cases on the right. For details and brief discussion, see text.

Learning of feedforward connections. Prototypical representations with spatio-temporal sequence selectivity are suggested to exist in the cortical STS complex where both form and motion pathways converge. The selectivities of model STS neurons are learned by again using a modified Hebbian instar learning mechanism similar to the separate learning of form and motion prototypes (Eqn.1),

$$
\begin{equation*}
\Delta w_{j i}^{i n, F F}=\eta_{s e q F F} \cdot \bar{v}_{i}^{p o s t} \cdot\left(u_{j}^{p r e}-\bar{v}_{i}^{p o s t} \cdot w_{j i}^{i n, F F}\right) . \tag{4}
\end{equation*}
$$

The weighting kernel $w_{j i}^{i n, F F}$ represents convergent IT $\rightarrow$ STS and MST $\rightarrow$ STS bottom-up input to a post-synaptic STS cell (instar). $\eta_{\text {seqFF }}$ denotes the learning rate and $u_{j}$ and $v_{i}$ are the firing rates of the pre- and post-synaptic neurons, respectively (the post-synaptic activity is again calculated via a temporal trace mechanism). The pre-synaptic activity for the receiving model STS cells are generated by concatenating form and motion output activations, namely $\mathbf{u}=\mathbf{u}^{I T} \cup \mathbf{u}^{M S T}$.

Learning feedback connections. An important component is that sequence-selective prototypes in STS in turn learn the output weights back to the segregated form and motion prototype representations, namely STS $\rightarrow$ IT + MST. Unlike the FF learning mechanisms, the learning here is gated by the pre-synaptic cell (in STS) for their top-down weights, which reads

$$
\begin{equation*}
\Delta w_{j i}^{o u t, F B}=\eta_{s e q F B} \cdot \bar{v}_{i}^{p r e} \cdot\left(u_{j}^{\text {post }}-w_{j i}^{\text {out }, F B}\right) \tag{5}
\end{equation*}
$$

with the same components as in the bottom-up learning formalism in Eqn.4. Bottom-up and top-down learning schemes slightly differ in the definition of the competitive terms (in brackets). In the feedback learning we employ a difference term between post-synaptic activity and the weighting, $u_{j}^{\text {post }}-w_{j i}^{\text {out }, F B}$, omitting the additional weighting of the connectivity strength via the pre-synaptic activity as in the Oja
rule. In steady-state each of the connection strengths emanating from STS cells assumes a value corresponding to the post-synaptic activity distribution, which defines the current input activation. Given an STS cell with attraction $\bar{v}_{i}^{p r e}$, the top-down weight vector approaches $\mathbf{u}^{\text {post }}=\mathbf{w}_{i}^{\text {out }, F B}$, thus learning the expected average input. Combined with the temporal trace, this establishes a representation in which each STS sequence-selective prototype encodes and memorizes in its weight pattern the expected driving input activity pattern configuration from the form and motion pathway. Such a topdown weighting pattern can then be used to generate predictions concerning the expected future input given the current maximally activated prototype at the STS level.

## Results

The model has been tested in various computational experiments, not all of which we can present here. In a first experiment, we probed the properties of snapshot selection from the input streams and their signature concerning static articulations. The latter property has been motivated by the fact that extremal articulation indicates configurations of implied motion, in turn, predictive for future motions. Results shown in Fig. 2 demonstrate that input activations (in V2) with strongly articulated shapes cohere with local motion minima. Such minima drive the reinforcement signal for learning whole body form prototypes. Temporal response signatures for IT prototypes are shown for disabled reinforcement $\left(g\left(m_{e}\right)=1\right.$, and when it is enabled ( $g\left(m_{e}\right)$ monotonically decreasing function of $m_{e}$ ).
We studied the response properties of STS representations and their motion sequence selectivity. There, a prototypical sequence-selective representation is learned for a walker that is traversing from left to right. After training of form, motion and sequence representations, the network is probed by

Figure 4: Response tunings of models cells in area IT (snapshots), MST (motion patterns), and STS (sequence-selective patterns) after training. Category representations have been learned for a walker moving along horizontal direction for $\phi=0^{\circ}$. Activities of prototypical cells are shown (bottom) which were probed by different inputs with varying movement directions, i.e. walkers approaching or receding at different angles with respect to the horizontal reference axis (top). Data has been summarized into box plots showing the response variabilities of models cells as well as the monotonic decline in response for deviations from the target tuning. The tuning width at half maximum response is around $\pm 40^{\circ}$. The variance of the MST / IT prototypes decreases towards larger deviations, depicting the loss of response selectivity of prototypes to different parts of a walkers gait.
three different movement scenarios: a forward moving walker with same profile and movement direction as in the training phase (recall), a forward moving walker traversing from right to left (opposite), and a backward moving walker (reverse). Form/motion prototypes and the sequence representation are triggered maximally in the recall case while in the opposite case form and motion prototypes only respond minimally, and so do the sequence-selective cells. In the reverse case the form prototypes selectively match the input at high articulation configurations, while the motion responses remain minimal. As a consequence, the sequence-selective representations respond at an intermediate level (Fig. 3). This evidence is in line with the experimental findings by (Oram \& Perrett, 1996) and recent observations by (Singer \& Sheinberg, 2010).

We further investigated the direction tuning of the sequence-selective prototypes. Here, we configured different walkers with varying movement directions and speeds with reference to a previously learned representation of a rightward moving walker at a speed of $1 \mathrm{~m} / \mathrm{s}$. Walking directions in the test cases were rotated by $\pm\left\{5^{\circ}, 10^{\circ}, 20^{\circ}, 40^{\circ}\right\}$. Model simulations result in a direction tuning of STS cells with half amplitude of approximately $\pm 40 \mathrm{deg}$ (Fig. 4). IT and MST cells, on the other hand, also show a drop in response but have

Figure 5: Selective removal of interconnections (lesioning). The model was trained using the same walking sequence as in the second experiment (see Fig. $3 /$ forward recall). The model was left untouched to provide a reference (top). Bottom-up (feedforward) connections between area MST and STS were removed, preventing any motion-related signal being propagated to STS (bottom). The amplitude of the IT prototype activities remains almost the same, whereas the sequence-selective STS cell responds only at about halfmagnitude (because of the missing support from the motion pathway). Note the feedback activities propagated from STS to MST optical flow pattern prototypes. We argue that this reflects the induction of increased fMRI BOLD response in human MT+ following the presentation of static implied motion stimuli.
a much larger variability.
In an additional experiment we selectively lesioned of the model architecture, particularly investigating the effects of extinguishing connections between model areas and the activity flow between learned representations (Fig.5). The fully connected model with learned IT / MST and STS feedforward and feedback connections was used as reference. When bottom-up connections from motion input (MST) were cut off the sequence-selective neuron responses in STS drop to approximately half their response amplitude. Feedback from STS invokes an amplification of activities in IT and MST representations. We observe that FF activation from IT alone can drive sequence neurons. Snapshot representations in IT drive the STS sequence neurons which, in turn, send feedback signals to the stages of IT and MST prototype representations. In the motion pathway such feedback elicits an increase in presynaptic activation. We argue that this reflects the induction of increased fMRI BOLD response in human MT+ following the presentation of static implied motion stimuli (Kourtzi \& Kanwisher, 2000).

## Discussion and Conclusion

We propose a biologically plausible model for the learning of animated motion sequences. The model builds upon neurophysiological evidence about the cortical sites and specific neuronal representations which contribute to articulated motion and implied motion perception. The main contributions of the paper are several-fold: First, we suggest how prototype representations in the form and motion pathways, namely in model cortical areas IT and MST, can be established on the basis of probing the model architecture by sequences containing animated motions. Learning mechanisms are based on modified Hebbian schemes which are stabilized through a trace mechanisms and the incorportion of an objective function taking the weight kernel saturation into account. Second, we suggest that sequence-selective cells in model area STS are learned by using the same learning mechanisms but now by combining the responses of intermediate level representations in the form and motion pathways. Third, the learning of articulated poses (snapshots) is controlled by a reinforcement mechanism that enables Hebbian learning in the form pathway through cross-pathway motion-form interaction. Given an animated motion sequence, snapshots are automatically selected as key poses corresponding to strong body pose articulations. Finally, the sequence-selective cells in model STS project to their respective input representations in the form and motion pathways. These feedback connections are again learned by a Hebbian mechanism. Together, the feedforward and the feedback interactions establish a loop of recurrent processing to stabilize the patterns of form, motion, and sequence representation. Via feedback, model STS cells generate a predictive signal through the backward connections' weights to encode the expected matching input that is suitable to match the currently activated sequence pattern. Together with the newly proposed feedback mechanism the model is able to account for various experimental findings, in particular, the ability to infer and predict future motion sequence development from articulated postures (implied motion). Importantly, cells in STS are responsive to both motion as well as static form (Oram \& Perrett, 1996). The model predicts that the presentation of static key poses from previously learned sequences alone leads to enhanced activation in STS sequence selective neurons as observed in (Jellema \& Perrett, 2003). The model also hypothesizes how the presentation of static articulated poses leads to the emergence of predictive motion perception and enhanced neural activations in the motion pathway (Kourtzi \& Kanwisher, 2000). Furthermore, learned sequence-selective prototype representations have direction tunings in response to walkers in the range of $\pm 40$, similar to those reported in (Perrett et al., 1989)). Once again, the model makes a testable prediction that articulated poses represent the snapshot frames that have been suggested by (Giese \& Poggio, 2003) and that have recently been tested experimentally by (Singer \& Sheinberg, 2010).

# Modeling disambiguation in word learning via multiple probabilistic constraints 

Molly Lewis<br>mll@stanford.edu<br>Department of Psychology<br>Stanford University

Michael C. Frank<br>mcfrank@stanford.edu<br>Department of Psychology<br>Stanford University

#### Abstract

Young children tend to map novel words to novel objects even in the presence of familiar competitors, a finding that has been dubbed the "disambiguation" effect. Theoretical accounts of this effect have debated whether it is due to initial constraints on children's lexicons (e.g. a principle of mutual exclusivity) or situation-specific pragmatic inferences. We suggest that both could be true. We present a hierarchical Bayesian model that implements both situation-level and hierarchical inference, and show that both can in principle contribute to disambiguation inferences with different levels of strength depending on differences in the situation and language experience of the learner. We additionally present data testing a novel prediction of this probabilistic view of disambiguation.

Keywords: Word learning; mutual exclusivity; Bayesian models.

## Introduction

A central property of language is that each word in the lexicon maps to a unique concept, and each concept maps to a unique word (Clark, 1987). Like other important regularities in language (e.g. grammatical categories), children cannot directly observe this general property. Instead, they must learn to use language in a way that is consistent with this generalization on the basis of evidence about only specific word-object pairs.

Even very young children behave in a way that is consistent with the one-to-one mapping between words and concepts in language. Evidence for this claim comes from what is known as the "disambiguation" effect. In a typical demonstration of this effect (e.g. Markman \& Wachtel, 1988), children are presented with a novel and familiar object (e.g. a whisk and a ball), and are asked to identify the referent of a novel word ("show me the dax"). Children in this task tend to choose the novel object as the referent, behaving in a way that is consistent with the one-to-one word-concept regularity in language, across a wide range of ages and experimental paradigms (Mervis, Golinkoff, \& Bertrand, 1994; Golinkoff, Mervis, Hirsh-Pasek, et al., 1994; Markman, Wasow, \& Hansen, 2003; Halberda, 2003; Bion, Borovsky, \& Fernald, 2013).

This effect has received much attention in the word learning literature because the ability to identify the meaning of a word in ambiguous contexts is, in essence, the core problem of word learning. That is, given any referential context, the meaning of a word is underdetermined (Quine, 1960), and the challenge for the world learner is to identify the referent of the word within this ambiguous context. Critically, the ability to infer that a novel word maps to a novel object makes the problem much easier to solve. For example, suppose a child hears the novel word "kumquat" while in the produce aisle
of the grocery store. There are an infinite number of possible meanings of this word given this referential context, but the child's ability to correctly disambiguate would lead her to rule out all meanings for which she already had a name. With this restricted hypothesis space, the child is more likely to identify the correct referent than if all objects in the context were considered as possible referents.

What are the cognitive processes underlying this effect? There are broadly two proposals in the literature. Under one proposal, Markman and colleagues (1988; 2003) suggest that children have a constraint on the types of lexicons considered when learning the meaning of a new word - a "mutual exclusivity constraint." With this constraint, children are biased to consider only those lexicons that have a one-to-one mapping between words and objects. Importantly, this constraint can be overcome in cases where it is incorrect (e.g. adjectives), but it nonetheless serves to restrict the set of lexicons initially entertained when learning the meaning of a novel word. Under this view, then, the disambiguation effect emerges from a constraint on the structure of lexicons.

Under a second proposal, the disambiguation effect is argued to result from online inferences made within the referential context (Clark, 1987; Diesendruck \& Markson, 2001). Clark suggests that the disambiguation effect is due to two pragmatic assumptions held by speakers. The first assumption is that speakers within the same speech community use the same words to refer to the same objects ("Principle of Conventionality"). The second assumption is that different linguistic forms refer to different meanings ("Principle of Contrast"). In the disambiguation task described above, then, children might reason (implicitly) as follows: You used a word I've never heard before. Since, presumably we both call a ball "ball" and if you'd meant the ball you would have said "ball," this new word must refer to the new object. Thus, under this account, disambiguation emerges not from a higherorder constraint on the structure of lexicons, but instead from in-the-moment inferences using general pragmatic principles.

These two proposals have traditionally been viewed as competing explanations of the disambiguation effect. Research in this area has consequently focused on identifying empirical tests that can distinguish between these two theories. For example, Diesendruck and Markson (2001) compare performance on a disambiguation task when children are told a novel fact about an object relative to a novel referential label. They found that children disambiguated in both conditions and argued on grounds of parsimony that the same pragmatic mechanism was likely to be responsible for both inferences. More recent evidence contradicts this
view: tests of children with autism, who are known to have impairments in pragmatic reasoning, find comparable performance on the disambiguation task between typically developing children and children with autism (Preissler \& Carey, 2005; de Marchena, Eigsti, Worek, Ono, \& Snedeker, 2011). This result provides some evidence for the view that disambiguation is due to a domain-specific lexical constraint.

We suggest that this competing-alternatives approach to the disambiguation effect should be reconsidered. In a disambiguation task, learners may be making use of both higherorder knowledge about how the lexicon is structured as well as information about the pragmatic or inferential structure of the task. Both of these constraints would then support children's inferences. In other words, these two classes of theories may be describing distinct, but complementary mechanisms that each contribute to a single empirical phenomenon, with their weights in any given task determined by children's age and language experience, the nature of the pragmatic situation, and other task-specific factors.

The model described here explores this proposal computationally. We constructed a Bayesian model that captures effects of both inferences within individual situations and hierarchical inferences about the structure of lexicons. Inferences about individual situations are modeled using an intentional/pragmatic model of word learning (Frank, Goodman, \& Tenenbaum, 2009), while generalizations about the nature of word-concept mappings are modeled as constraints on the set of lexicons that the model considers. We present a set of simulations and a developmental experiment showing that linguistic experience can influence the strength of disambiguation inferences at both levels.

The goal of our model is not to provide an algorithmic description of children's word learning, which we assume depends on psychological factors such as memory and cognitive control. Instead, we aim to provide an ideal observer analysis: to derive normative predictions given a well-articulated set of assumptions (Geisler, 2003). Human behavior can then be compared to this analysis, and deviations can be attributed to differences between the assumptions of the model and the realities of human psychology. Critically, neither our model (nor comparisons between it and human behavior) constitute claims of human optimality: Though our model employs optimal Bayesian inference, there is no implicit claim that human learners also do so (Frank, in press).

## Model

We model a word learner as performing Bayesian inference to infer the structure of a lexicon $l$, which we represent as a (sparse) bipartite graph connecting words $W=w_{1} \ldots w_{n}$ to objects $O=o_{1} \ldots o_{m}$. We write the full possible set of lexicons as $L$. An example enumeration of such lexicons for the case of $n=m=2$ is given in Fig. 2.

We assume a generative structure identical to the the model developed by Frank et al. (2009), with the added complexity of constraints placed on lexicons (described below; see Fig.

Figure 1: The generative process for our model.
1). The critical feature of this existing model is that words are assumed to be generated by intentions. This feature allows the model to jointly solve the problems of mapping a word to an object in ambiguous contexts and learning a long term mapping between a word and concept.

The learner infers a distribution over lexicons, given a corpus $S$ of situations (each consisting of sets of words $\bar{w}_{s}$ and objects $\bar{o}_{s}$ ). From Bayes' rule, the posterior probability of a lexicon is given by

$$
\begin{equation*}
P(l \mid S)=\frac{P(S \mid l) P(l)}{\sum_{l^{\prime} \in L} P\left(S \mid l^{\prime}\right) P\left(l^{\prime}\right)} \tag{1}
\end{equation*}
$$

We first define the likelihood term $P(S \mid L)$ and then return to the prior $P(L)$, which implements hierarchical constraints $C$ on lexicons.

Using the generative process in Fig. 1, we can write the likelihood of a particular situation in terms of the relationship between the objects that were observed in the situation $s$, the speaker's referential intention $i_{s}$ (a choice to speak about one of the objects), and the referring word $w_{s} .{ }^{1}$ As in our prior work, we assume that referential intentions are unobserved and sum across all possible intentions uniformly ${ }^{2}$ :

$$
\begin{equation*}
P(s \mid l)=\sum_{i_{s} \in \bar{o}_{s}} P\left(w_{s}, o_{s}, i_{s} \mid l\right) \tag{2}
\end{equation*}
$$

By the conditional independence of words and objects, we can expand to:

$$
\begin{equation*}
P(s \mid l)=\sum_{i_{s} \in \bar{o}_{s}} P\left(w_{s} \mid i_{s}, l\right) P\left(i_{s} \mid o_{s}\right) \tag{3}
\end{equation*}
$$

Finally, we aggregate across situations by taking the product of each independent situation:

[^135]

Figure 2: The posterior probability distribution over lexicons for our models for Simulation 1. Models were trained with situations establishing the mapping between $w_{1}$ and $o_{1}$ (the familiar word/object pair) and a disambiguation situation including $w_{2}$ and objects $o_{1}$ and $o_{2}$. The four different constraint models are distinguished by color in the main plot, while the 16 possible lexicons are shown on the horizontal axis. Lexicons are marked as links between words and objects, with the correct ( $w_{2}$ and $o_{2}$ ) mapping marked in green and the incorrect ( $w_{2}$ and $o_{1}$ ) mapping marked in red. The noise parameter $\alpha$ was chosen arbitrarily for display purposes and serves only to scale the results.

$$
\begin{equation*}
P(S \mid l)=\prod_{s \in S} \sum_{i \in \bar{o}_{s}} P\left(w_{s} \mid i_{s}, l\right) P\left(i_{s} \mid o_{s}\right) \tag{4}
\end{equation*}
$$

We assume that there is some level of noise in both the choice of word given intention $P\left(w_{s} \mid i_{s}, l\right)$ and the choice of intention given object $P\left(i_{s} \mid o_{s}\right)$, such that the speaker could in principle have been mistaken about their referent or misspoken their word. We implement this decision by assuming a constant probability of random noise for each of these, which we notate $\alpha$. For simplicity, $\alpha$ is assumed to be the same for both terms. The value of $\alpha$ serves only to scale the results we report below, but-as in nearly all probabilistic modelssome level of uncertainty about the individual observations is necessary to make graded predictions.

We now consider the prior distribution over lexicons. We define this prior hierarchically as being the product of a constraint over lexicons $c \in C$ :

$$
\begin{equation*}
P(l)=P(l \mid c) P(c) \tag{5}
\end{equation*}
$$

We consider a hypothesis space of four different constraints placed on the mappings between words and objects within lexicons: one word to one object ( $1-1$ constraint), one word to many objects ( 1 -many constraint), many words to one object (many- 1 constraint), and a null constraint. The 1-many constraint applies a restriction that each object maps to at most
one word in a lexicon. The many- 1 constraint applies a restriction that each word maps to at most one object in a lexicon. The 1-1 constraint applies both of these restrictions, and the null constraint applies neither of these restrictions. ${ }^{3}$ In practice, these hypotheses were implemented such that each lexicon consistent with a constraint was equiprobable, and all inconsistent lexicons had probability 0 . For simplicity, we assumed that $P(c) \propto 1$, although this assumption could easily be modified in future work.

For the simulations below, we were able to infer exact posterior distributions by enumerating all possible lexicons and normalizing (Equation 1).

## Simulation 1: Disambiguation at multiple levels

As a first test of our model on the disambiguation task, we trained the model on a corpus containing two situations. The first was an unambiguous situation in which word $w_{1}$ was associated with object $o_{1}$. This piece of evidence corresponded to the known word in the disambiguation task ("ball" in the example described above). We also included a disambiguation experimental situation, where the previously learned object $o_{1}$ (ball), a new object $o_{2}$ (whisk), and a novel word $w_{2}$

[^136]

Figure 3: Results from Simulation 2. Each panel shows the probability of inferring a 1-1 constraint on the lexicon given a different input corpus, described in text. Horizontal axes varies the overall number of distinct objects presented in the exposure corpus, while the colored lines denote different numbers of exposures to the corpus.
("dax").
Figure 2 shows the posterior distribution over lexicons inferred on the basis of this corpus. Each of the 16 possible lexicons (assuming a world with only two words and two objects) are represented along the x -axis, where lexicons are represented by object and word nodes connected by links.

In this maximally simple simulation of the disambiguation task, all four prior constraints give the highest posterior probability to the lexicon that links the novel word and the novel object. This result emerges from the structure of the inference problem: Given that the learner has already observed an association between $w_{1}$ and $o_{1}$, lexicons that posit a link between $w_{1}$ and $o_{2}$ are less probable than those that posit a link between $w_{2}$ and $o_{2}$. This result comes about because an object with two names ( $w_{1}$ and $w_{2}$ ) can be talked about in two different ways, and each of them is individually less probable than the one way of talking about an unambiguously-named object. (This result echoes the finding of mutual exclusivity in Frank et al., 2009).

These results suggest that disambiguation behavior in children could emerge without a 1-1 constraint on lexicons. On the other hand, prior constraints affected the strength of the disambiguation inference. Constraints barring 1-many and many-1 mappings increased the posterior probability of the correct lexicon; when both were in place, the correct lexicon had by far the highest probability. Thus, probabilistic inference and hierarchical constraints both support disambiguation behavior in the model.

## Simulation 2: Learning constraints on lexicons

Simulation 1 suggested that a learner could behave consistent with a 1-1 constraint on lexicons without assuming a hard constraint on the structure of lexicons. Nevertheless, imposing such a hard constraint raised the probability of a correct answer on the disambiguation task. In this simulation, we show that learners may induce a higher-order constraint on lexicons given the right kind of evidence.

To explore the model's ability to learn a hierarchical 1-1 constraint on lexicons, we trained our model on three corpora. Each corpus consisted of a set of situations with a single word and a single object, but we varied whether these mappings were consistent. The first, the "unambiguous exposure" corpus, showed unambiguous (1-1) mappings between words and objects. The second, the "occasionally ambiguous" corpus, showed the same body of data but with two contradictory mappings appended to the end. The final, "fully ambiguous," corpus consisted of one word that mapped to many objects. We varied both the number of exposures to the corpus (1-4) and the number of objects in the corpus (1-4). We then examined the posterior probability of the 1-1 constraint given these exposure corpora.

The results of this simulation are shown in Figure 3. Given 1-1 evidence, the model induces a 1-1 constraint on lexicons, and this bias becomes stronger as the number of observations increases. The posterior probability of the 1-1 constraint is decreased only slightly by a few ambiguous observations, reflecting the general robustness of this inference. In contrast, in the fully ambiguous condition, the model learns with relatively little data that a 1-1 constraint does not hold.

## Simulation 3: Stronger mappings result in stronger disambiguation

In Simulation 3, we explore whether providing more evidence for a link between the known word and object will in turn strengthen the probabilistic disambiguation effect between words and objects. Recall that the disambiguation effect in Simulation 1 emerged as a result of prior evidence for an association between the known word and object ("ball" and ball). Thus, this model predicts that if the learner receives more evidence for an association between the known word and known object, the disambiguation bias should become stronger.

We trained the model with either 1,2 , or 3 situations in which $w_{1}$ was unambiguously associated with $o_{1}$. We then tested the model in the disambiguation task with a known and

Figure 4: Model predictions under each of the four lexical constraints (left) and experimental results (right) for success in the disambiguation task as a function of the number of labels observed in training. Lower legend shows noise conditions for the model simulations.
unknown object and a novel word, as in Simulation 1, but using a Luce choice rule to compute the probability of a correct choice (Luce, 1963). If more observed associations between the known word and object lead to a stronger bias toward correct lexicons, we should expect the disambiguation bias to increase with the number of training situations.

Assuming a 1-1 constraint, the magnitude of the bias toward correct lexicons increases with number of training situations with the known word-known object association (Fig. 4, upper-left panel). In addition, the magnitude of this increase is sensitive to the noise parameter $\alpha$ that determines the probability that the wrong word was spoken to refer to an object.

## Experiment

We tested the prediction that confidence in the known word mapping leads to a stronger disambiguation inference in preschool children.

## Methods

We recruited 110 children ages $2 ; 1-4 ; 11$ from the floor of the Boston Children's Museum. In each one-year age group, we collected data from 35-38 children.

Each child completed four trials. Each trial consisted of a training and a test phase in a "novel-novel" disambiguation task (de Marchena et al., 2011). In the training phase, the experimenter presented the child with a novel object, and explicitly labeled the object with a novel label 1,2 , or 3 times ("Look at the dax"), and contrasted it with a second novel ob-
ject ("And this one is cool too") to ensure equal familiarity. In the test phase, the child was asked to point to the object referred to by a second novel label ("Can you show me the zot?"). Number of labels used in the training phase was manipulated between subjects. There were eight different novel words and objects. Object presentation side, object, and word were counterbalanced across children.

## Results

Responses were coded as correct if participants selected the novel object at test. As predicted, children showed a stronger disambiguation effect as the number of training labels increased, and as noise decreased with age (Fig. 4, right panel).

We analyzed the results using a logit mixed model to predict correct responses with age and number of labels as fixed effects, and participant as a random effect. There was a significant effect of age $(\beta=.044, p<.001)$ such that older children showed a stronger disambiguation bias. There was also a significant effect of number of labels, such that more training labels led to stronger disambiguation ( $\beta=.454, p<.001$ ). The interaction between age and number of labels was not significant ( $\beta=.019, p=.16$ ). Children's increased confidence in the disambiguation inference, as a function of number of training labels, is consistent with model predictions.

## General Discussion

The disambiguation effect suggests the presence of underlying cognitive mechanisms that help children solve the difficult mapping problem inherent of early word learning (Quine,
1960). Two classes of mechanisms have been proposed: a constraint on the structure of permitted lexicons, and in-themoment pragmatic inferences about the most likely referent given the context. We used a hierarchical Bayesian model to explore the independent contributions of these two effects and find that neither mechanism is necessary to create a bias, but either is sufficient. Disambiguation is strongest when both mechanisms jointly contribute.

This result has important consequences for attempts to experimentally differentiate between the proposed accounts of disambiguation. Given that both mechanisms can in principle lead to disambiguation behavior, experimental tests of disambiguation cannot distinguish between these two theories (as they are instantiated here). That is, evidence for disambiguation behavior is consistent with both a pragmatic account and a mutual exclusivity constraint account. Furthermore, there may be variability in the weights of these constraints across populations. For example, higher-order lexical constraints may play a larger role in disambiguation for individuals with impaired social-cognitive skills (e.g. autism), relative to typically developing children. Our results suggest that future research in this area should reconsider the assumption that a single mechanism must completely and independently give rise to the disambiguation effect.

Our model may provide useful insight into disambiguation in bilingualism. For bilingual learners, the structure of associations between words and objects in the environment differs from that of monolinguals. Bilingual learners typically observe two basic-level words associated with each object rather than one. To make sense of these associations, they might ultimately form an overhypothesis that there is a $1-1$ constraint on lexicons within each language, but they might nevertheless initially entertain a 1-many constraint as a hypothesis. Indeed, there is evidence that disambiguation behavior is weaker in bilingual and trilingual children (ByersHeinlein \& Werker, 2009).

Finally, it is important to consider the limits of an ideal observer analysis. While our results suggest that both mechanisms could contribute to disambiguation behavior, this finding does not entail that both mechanisms do in fact contribute. It remains possible that disambiguation behavior is the result of a single mechanism. Nonetheless, given evidence from other domains that the mind may simultaneously integrate basic probabilistic inferences with higher-order constraints (Tenenbaum, Kemp, Griffiths, \& Goodman, 2011), it seems likely that disambiguation behavior emerges from multiple underlying cognitive mechanisms.

## Acknowledgements

We gratefully acknowledge Jesse Snedeker for the suggestion that led to the Experiment, as well as for providing materials from de Marchena et al. (2011). We thank Joseph Austerweil for valuable feedback, and Melina Flores for assistance in data collection.

#### Abstract

To learn the meaning of a new word, children must solve two distinct problems: identify the referent under ambiguity and determine how to generalize that word's meaning to new objects. Traditionally, these two problems have been addressed separately in the literature, despite their tight relationship with one another. We present a hierarchical Bayesian model that jointly infers both the referent of a word in ambiguous contexts and the concept associated with a word. As a first step in testing this model, we provide evidence that our model fits human data in a simple cross-situational concept learning task.

Keywords: cross-situational word learning; Bayesian models

## Introduction

Learning a new word requires drawing a link in your mental lexicon between a word and a concept. But, children do not observe associations between words and abstract concepts; they observe associations between words and exemplars of those concepts. Furthermore, the associations between words and objects are ambiguous: a single word uttered in any particular context is consistent with an infinite number of possible interpretations (Quine, 1960). There are thus two problems a child must solve in order to learn the meaning of a new word: Determine which object is referred to by a word in context (the Mapping Problem) and determine the relevant concept of the object (the Generalization Problem; see Figure 1).

To understand these two problems more clearly, suppose you lived in an (impoverished) world with two words, "apple" and "cherry," and three objects, a green apple, a red apple, and a cherry. You hear the word "apple" in the context of a single red apple on the table. You somehow infer that "apple" refers to the red object on the table, and thus correctly solve the Mapping Problem. But you have not yet succeeded in solving the Generalization Problem. To correctly solve the Generalization Problem, you must decide whether "apple" also refers to the green apple, which is similar in shape to your observed apple exemplar, or whether it also refers to the cherry, which is similar in color to your observed apple exemplar. Or, alternatively, whether "apple" refers to neither of these other objects (i.e. a proper name). Thus, to learn the word "apple" in this world, you must infer both that "apple" refers to the red object on the table, and that "apple" should be generalized to other apple-shaped objects.

Separate learning mechanisms and constraints have been proposed to account for each of these problems. In the case of the Mapping Problem, one proposed constraint is crosssituational statistics (Pinker, 1984; Smith \& Yu, 2008; Yu \& Smith, 2007). Under this account, learners are hypothesized to aggregate the statistics of associations between words and

Figure 1: Schema of the two problems associated with learning the meaning of a word. Learning a new word requires that the child both identify which object the word refers to in the referential context (the Mapping Problem) and how to generalize that word to objects of the same kind (the Generalization Problem).
objects across situations. When considered in an isolated situation, the referent of a word may be ambiguous, but when situations are aggregated across, the learner is able to constrain the hypothesis space of likely meanings. There is evidence that children as young as 12-months-old can learn word meanings in this way (Smith \& Yu, 2008).

A second class of constraints on the Mapping Problem are accounts of the disambiguation effect. The disambiguation effect refers to children's tendency to select a novel, as opposed to familiar, object as a referent for a novel word. One account of this phenomenon is the principle of mutual exclusivity (Markman \& Wachtel, 1988; Markman, Wasow, \& Hansen, 2003). Under this proposal, there is a constraint on the types of lexicons considered when learning the meaning of a new word. With this constraint, children are biased to consider only those lexicons that have a one-to-one mapping between words and objects. Thus, when faced with an ambiguous referential context, the child solves the mapping problem by assuming that the novel word refers to the object for which she does not yet have a word in her lexicon. This is the inferred mapping because it is the only referent that allows the learner to maintain a one-to-one structure between words and concepts in the lexicon. Others have proposed that general pragmatic assumptions can also account for this effect (Clark, 1987; Diesendruck \& Markson, 2001).

There are also a range of proposals about how children might solve the Generalization Problem. One proposal is that children have a bias to generalize by shape (Smith, Jones, Landau, Gershkoff-Stowe, \& Samuelson, 2002). With this
bias, a child who has learned that "apple" maps to apple, for example, can generalize "apple" to all apple-shaped things. This bias allows learners to rule out alternative, less probable generalizations strategies, such as generalization along the dimension of color. A second proposal is that children have a bias to generalize to another object of similar kind, rather than to one that is thematically related ("Taxonomic Assumption"; Markman, 1990). For example, upon hearing the word "cherry," a child with this bias would be more likely to generalize the word to another fruit, as opposed to ice cream, despite the fact the ice cream and cherries often go together (see Xu \& Tenenbaum, 2007, for a probabilistic view).

Though theoretically distinct, and investigated separately, these the two problems are intimately related. If a child has solved the Generalization Problem for a particular category, the Mapping Problem becomes much easier. For example, suppose a child is faced with a never-before-seen apple and a novel object, and hears the word "dax". If the child has solved the Generalization Problem, the child can identify the apple as an exemplar of the APPLE ${ }^{1}$ concept, and determine the correct referent by mutual exclusivity. Conversely, if a learner can easily solve the Mapping Problem, the learner will accumulate more correct exemplars of a category, and thus be more likely to infer the correct concept. Thus, existing proposals about how each of these problems is solved takes the other problem for granted. But, importantly, a child acquiring language begins with neither of these problems solved; both must be solved in parallel. That is, a learner must determine both what object a word refers to, and how to generalize that meaning beyond the particular context. And, critically, she must do both at the same time.

There is limited work exploring how children might solve these two problems in parallel. A study by Akhtar and Montague (1999) begins to address this question by asking whether children might use cross-situational statistics to learn the relevant features for generalization. In their task, 2-4 year old children were presented with three novel objects that all shared a common feature (e.g. color), but varied along two other features (e.g. texture and shape). Children were able to correctly infer that the novel word referred to the shared feature. This result provides important evidence that children can infer word concepts cross-situationally. However, it is unclear whether this type of learning generalizes to the real world because the actual learning environment is not structured in a way that perfectly disambiguates word meanings cross-situationally.

Apart from word learning, the Generalization Problem has been well-studied in adults (Laurence \& Margolis, 1999; Rosch \& Mervis, 1975; Rosch, Mervis, Gray, Johnson, \& Boyes-Braem, 1976; Medin \& Ortony, 1989). However, limited research has attempted to extend this body of literature to work with children. One exception is work by Sloutsky and colleagues which adopts models of similarity to explain how

[^137]

Figure 2: The generative process for our model. Shading indicates observed variables
children generalize novel words (e.g. Sloutsky, Lo, \& Fisher, 2001).

We present a hierarchical Bayesian model that solves the Mapping and Generalization Problems in parallel. In modeling the Generalization Problem, we draw on the Boolean concept learning framework in which objects are defined by a set of features with a range of values (Shepard, Hovland, \& Jenkins, 1961). The goal for the word learner is conceptualized as the task of mapping a word to a set of features that define the relevant concept. In modeling the Mapping Problem, we focus on the role of cross-situational statistics. In particular, we build on the model developed by Frank, Goodman, and Tenenbaum (2009) that takes into account the intentions of the speaker in order to identify the referent in ambiguous contexts.

The plan for the paper is as follows. We first describe the design of this extended model, and then describe the results of an experiment that explores adult performance in a crosssituational Boolean concept learning task.

## Design of the Model

The goal of our model is to understand how children arrive at an understanding about the meanings of words, on the basis of limited evidence about the associations between words and objects. That is, the goal is to infer a lexicon - a set of word-concept mappings - on the basis of basis of observations of words and objects. To model this, we consider a set of variables relevant to this learning problem, and assume that they are related probabilistically. We assume an identical dependency structure as the model developed by Frank et al. (2009), with the addition of a concept layer to the generative process (see Figure 2). This model is the same underlying
model as presented in Lewis and Frank (2013) but with the addition of a theory of Boolean concepts. For completeness, we present the full model here, but details are identical except where noted.

We model a word learner as performing Bayesian inference to infer a lexicon $l$, which we represent as a (sparse) bipartite graph connecting words $W=w_{1} \ldots w_{n}$ to concepts $C=c_{1} \ldots c_{m}$. Concepts are written as a vector of features with values 1,2 or $*$. The $*$ notation denotes a feature that is irrelevant to the definition of a concept. For example, $[1 * *]$ represents a concept that is defined only by the value of the first feature. This hierarchical formulation of concepts is substantially similar to the concept learning model proposed by Goodman, Tenenbaum, Feldman, and Griffiths (2010). The full possible set of lexicons is denoted as $L$.

The learner infers a distribution over lexicons, given a corpus $S$ of situations (each consisting of sets of words $\bar{w}_{s}$ and objects $\bar{o}_{s}$ ). From Bayes' rule, the posterior probability of a lexicon is given by

$$
\begin{equation*}
P(l \mid S)=\frac{P(S \mid l) P(l)}{\sum_{l^{\prime} \in L} P\left(S \mid l^{\prime}\right) P\left(l^{\prime}\right)} . \tag{1}
\end{equation*}
$$

The prior $P(L)$ is assumed to be uniform over lexicons that map a concept to at most one word (one word to many concepts). We now define the likelihood term $P(S \mid L)$.

Using the generative process in Figure 2, we can write the likelihood of a particular situation in terms of the relationship between the objects that were observed in the situation $s$, the speaker's referential intention $i_{s}$ (a choice to speak about one of the objects), the concept $c_{s}$ selected by the speaker to represent the intention, and the referring word $w_{s}$. As in our prior work, we assume that referential intentions are unobserved and sum across all possible intentions uniformly:

$$
\begin{equation*}
P(s \mid l)=\sum_{i_{s} \in \bar{\sigma}_{s}} p\left(w_{s}, c_{s}, i_{s}, o_{s}, \mid l\right) \tag{2}
\end{equation*}
$$

By the conditional independence of words and objects, we use the chain rule to expand to:

$$
\begin{equation*}
P(s \mid l)=\sum_{i_{s} \in \bar{o}_{s}} P\left(w_{s} \mid c_{s}, l\right) P\left(c_{s} \mid i_{s}\right) P\left(i_{s} \mid o_{s}\right) \tag{3}
\end{equation*}
$$

Finally, we aggregate across situations by taking the product of each independent situation:

$$
\begin{equation*}
P(S \mid l)=\prod_{s \in S} \sum_{i \in \bar{o}_{s}} P\left(w_{s} \mid c_{s}, l\right) P\left(c_{s} \mid i_{s}\right) P\left(i_{s} \mid o_{s}\right) \tag{4}
\end{equation*}
$$

To find the key term in our concept model, $p\left(c_{s} \mid i_{s}\right)$, we use a noisy Naive Bayes classifier:

$$
P\left(c_{s} \mid i_{s}\right)=\prod_{j=1 \ldots f} \begin{cases}1-\alpha & \text { if }\left(c_{s}^{j}=i_{s}^{j}\right) \vee\left(i_{s}^{j}=*\right)  \tag{5}\\ \alpha & \text { otherwise }\end{cases}
$$

This formulation quantifies the probability of a concept given an intended object in terms of the match between the three features.

Figure 3: Experimental stimuli. Each object is defined by a binary value for each of three features: shape, appendage, and color.

We assume that there is some level of noise in both the choice of word given intention $P\left(w_{s} \mid i_{s}, l\right)$ and the choice of intention given object $P\left(c_{s} \mid i_{s}\right)$, such that the speaker could in principle have been mistaken about their referent or misspoken. We implement this decision by assuming a constant probability of random noise for each of these, which we notate $\alpha$; for simplicity, $\alpha$ is assumed to be the same for both decisions. The particular choice of $\alpha$ values only serves to scale the predictions, and does not influence the relative predictions of the test item types. However, as in nearly all probabilistic models, some level of uncertainty about the individual observations is necessary to be able to make graded predictions.

In the simulations reported here, we did inference by exact inference via full combinatoric enumeration of the space of possible lexicons.

## Experiment

Our model jointly solves the two problems associated with learning the meaning of a new word, the Mapping and Generalization Problems. As a first step in evaluating the model, we compared human and model performance in a crosssituational Boolean concept learning task. Participants were given a situation in which a word is seen in the context of two objects, but in a way that is ambiguous as to which of these objects (either or both) the label refers to. The learner is then presented with a second such situation. While each of these situations is individually ambiguous, the learner could aggregate information across situations to infer the concept associated with the word. As predicted by the model, we found that participants generalized the meaning of the label in a graded manner: the more features the training objects shared with the test object, the more likely participants were to generalize the label to the test object.

## Method and Materials

Participants Two hundred and and sixty-six adults were recruited from Amazon's Mechanical Turk. Twenty-two were

Figure 4: Bets on the probability of "dax bren nes" generalizing to each of the relevant test item types in each condition. Error bars represent $95 \%$ confidence intervals as computed via non-parametric bootstrap. Example items seen in the training situations are given in the top-right box of each plot. Given the particular training items shown here, an item in each of the relevant test item types (defined by the number of features shared with the training items) is shown along the $x$-axis. Actual training items (and thus test items) were counter-balanced across participants.
excluded for either not completing the task appropriately (e.g. by responding with values greater than 100) or failing to provide responses for all 8 test objects. All reported that they were native speakers of English.

Stimuli Each object in our stimulus set was constructed to have three binary features. The features of interest were shape, appendage and color. When fully permuted, this defines a space of eight possible objects (see Figure 3).

Procedure Participants viewed a webpage that showed two situations with two objects each. In the first situation, they were instructed: "Suppose you saw these two objects and heard 'dax bren nes.'" A multi-word novel label was used to avoid biases towards meanings consistent with the grammatical class of the word. In other words, we wanted to avoid participants inferring that because the word was an adjective, it was more likely to refer to a property (e.g. color) than a particular object (i.e. a proper noun), for example. Two more objects were presented below and participants were asked to "Now suppose you saw these two new objects and heard 'dax bren nes' again." They were then asked to "bet whether or not you think each of the objects below could also be called 'dax bren nes." Images of all eight objects (including the training items) were then presented, and participants were asked to provide a bet $0-100$ indicating their judgement.

Across participants, we manipulated the number of features shared within and across situations. ${ }^{2}$ We tested an unambiguous baseline condition in which the same object was paired with a different object in each situation and 5 ambiguous conditions in which the features of the objects were confounded either within or across situations. For the ambiguous conditions, we tested cases in which 1 or 2 features were shared within situations ("confounded within" conditions), 1 or 2 features shared across situations ("confounded across" conditions), and a case in which 3 features were shared both within and across situations (Figure 4).

[^138]

Figure 5: Mean bets in each experiment condition, plotted by predictions for each of the models (model predictions are scaled on the horizontal axis). Error bars represent $95 \%$ confidence intervals, as computed via non-parametric bootstrap. The line of best fit is plotted in red.

## Results and Model Fits

Participants showed a consistent gradient of generalization such that greater number of distinct features resulted in lower bets (weaker generalizations), consistent with previous experiments (Figure 4).

Model fits are shown in Figure 5. Our model fits the data with a correlation of $r=.95$. We compared this fit against a null model in which we calculated the target's total feature distance from objects in the situations. This was calculated by counting the number of features for which the target differed from each situation object (e.g. the feature distance [111] and [122] is 2) and summing across all four objects in the situation. This standard exemplar style model fits the data relatively well ( $r=.89$ ). Nevertheless, our model provides a substantial gain in fit. Using non-parametric bootstrap, the cross-situational concept-learning model fits the data significantly better than the feature distance model $(p<.05)$.

## General Discussion

In this cross-situational Boolean concept learning task, our model performed competitively with a simple feature distance model. Critically, however, our model has the machinery to solve not only this simple concept-mapping problem under minimal ambiguity, but can also deal with more complex worlds in which multiple words are present. Given that no existing model is able to jointly account for both the Mapping and Generalization Problems, this model provides a fruitful theoretical tool for future work to explore how children might solve these problems.

For example, this experiment could be straight-forwardly extended to introduce a more complex Mapping Problem component to the task. This could be done by adding additional words to the cross-situational learning context. In a
minimal version of this experiment, the learner could observe $w_{1}$ with [11] and [12] and $w_{2}$ with [22] and [12]. A learner who assumes that the speaker refers to both objects within each situation, might infer a mapping between $w_{1}$ with $[1 *]$ and a mapping between $w_{2}$ with $[* 2]$, given this referential context. Using situations such as these, this paradigm can be extended to directly explore joint inference of both the Mapping and Generalization problems.

An important underlying assumption of this model is that features are given a priori. This seems like an extreme position given that it is implausible that children acquiring language have an innate "appendage" feature, for example. It is, in a sense, the very goal of this model to explain how children acquire such abstract concepts as APPENDAGE. That is, features are themselves concepts that can be considered as primitives in the construction of more complex concepts. This problem, however, is not specific to the word learning problem, but rather is a challenge more generally to the Boolean concept learning framework. Nonetheless, a complete theory of how children acquire word concepts will need to provide an account for the origin of features.

Given this theoretical point, our model should be understood as a computational level description of the problem of acquiring word-concepts, given some set of concepts (i.e. features). Our model remains agnostic about the origins and nature of these initial concepts but, given some primitive set of concepts, our model describes how a learner might bootstrap from these primitives to infer more and more complex concepts. While it seems unlikely that children have an innate APPENDAGE feature, there is evidence that children may have certain perceptual categories, such as color, very early in development (Bornstein, Kessen, \& Weiskopf, 1976). Primitive perceptual features like color categories may provide the
initial building blocks for the construction of more complex concepts, given experience with the environment.

In sum, our model provides a rich framework for studying the word learning problem at the computational level. Previous research has explored how children might solve the two subproblems associated with word learning - the Generalization and Mapping Problems - separately. Our model contributes to this area by providing a unifed account for both of these problems. The experiment reported here suggests that our model is able to account for participants' behavior in solving one of these problems - the Generalization Problem in a simple cross-situational task. Importantly, our model's contribution to theories of the Generalization Problem is to provide an account of the generalization inferences, given an initial set of primitive concepts. This account, coupled with the ability to explore the Mapping Problem, lays the groundwork for a more cohesive understanding of how children learn the meanings of words.

# Proper Sequencing and Level-Bridging Scaffolding in Learning a Chemical System with Graphical Simulations 

Na Li (nl2284@tc.columbia.edu)<br>Teachers College, Columbia University, $525 \mathrm{~W} .120{ }^{\text {th }}$ street<br>New York, NY 10025 USA<br>John Black (black@exchange.tc.columbia.edu)<br>Teachers College, Columbia University, 525 W. $120^{\text {th }}$ street<br>New York, NY 10025 USA

#### Abstract

Secondary-level students encounter many difficulties in learning complex systems with hierarchical levels. Scaffolding is very critical in teaching complex systems. We have two complementary research questions on scaffolding: 1 . How can we chunk and sequence the learning activities in teaching complex systems? 2. How can we help students make connections across system levels? A simulation-based environment teaching a chemical system was used as the research instrument, and the study was conducted at a middle school setting. The results showed that the sequencing method following the "from concrete to abstract" principle produced better recall and comprehension of the system concepts (knowledge integration), while the sequencing method aligned with the casual structure of the system facilitated the construction of a better causal model for transfer. The results also demonstrated that explicit level-bridging scaffolding had positive effects on both knowledge integration and learning the deep causal structure.

Keywords: Complex systems; sequencing methods; levelbridging scaffolding; secondary-level science

## Research Background

Complex systems have become an important topic in today's science education. It is usually difficult for students to learn complex systems with hierarchical levels and abstract system dynamics (Jacobson \& Wilensky, 2006). Complex systems can be difficult from different perspectives. 1). Spatialtemporal extension of a system, e.g., there are many system levels with complex formation and interactivity 2). Abstract system levels and causal structures in a system, e.g., higherlevel patterns emerging from lower-level dynamics (Baryam, 1997). Although two types of difficulties always coexist in various complex systems, one may define the complexity more than the other in a specific context or at a certain learning stage. Biological and natural systems often have many system levels, diversified local behaviors and interactivity (Hmelo-silver \& Azevedo, 2006). For example, the human circulatory system has a "downward tree" structure with a large number of elements, and varied local element interactivity. Effective knowledge integration is a learning difficulty students have to conquer before learning the emergent processes involved in this type of system. Abstract levels and causal structures are often found in
chemical and physics systems (Stieff, 2011). For example, it is difficult to visualize "voltage in an electric circuit" emerging from electrons' behaviors and "gas pressure" from gas molecular activities.

Agent-based modeling and visualizing tools can create visual acuity of system levels and demonstrate cross-level dynamics (Levy \& Wilensky, 2009). However, given the complex nature of the learning content, mere perceptual grounding is not sufficient for effective learning. Scaffolding is a critical factor in learning complex systems (Jacobson et al., 2011). The first research question of this study: How can we chunk and sequence the learning activities in teaching complex systems? There have been contradictory findings to this question. However, analyzing the learning difficulties from different perspectives may address the debate over the sequencing methods.

Knowledge integration refers to students connecting scientific concepts and normative ideas, and providing coherent explanations to scientific phenomena (Linn, 2006). From the perspective of knowledge integration, the "topdown" approach starting from the concrete macro-level function of a system is effective. In Liu \& Hmelo-Silver (2009)'s study, participants learned the respiratory system with either the "top-down" or the "bottom-up" sequencing method, and the results showed that starting from the systemwide function ("how do we breathe") was better than starting from the lower-level substructures and entities. As can be seen, in this type of biological system, a higher-level function is concrete and easy to understand. And a function is often realized by the interactivity of a large number of diverse lower-level substructures. "Making science accessible" as a knowledge integration guideline informs us that concrete levels of a topic should come before abstract ones (Linn, 2006). Additionally, a top-down function-oriented sequencing method provides a good conceptual structure for knowledge integration (Liu \& Hmelo-silver, 2009).

Many studies demonstrate that the "bottom-up" approach is effective in teaching the implicit and abstract causal structure (e.g., emergence) of a complex system (Wilenky \& Stroup, 2002). This sequencing method allows students to experience the causal process of how the small effects of the micro-level elements can lead to the macro-level patterns. For example, in the Connected Chemistry Curriculum (Levy \& Wilensky, 2009), the approach is to let students manipulate and articulate the micro-level entity behaviors (e.g., how a
single gas molecule collide with the walls), and then gradually expand to the emergent processes and phenomena. It is claimed that the "bottom-up" approach help students conceptually understand the implicit linkages between the micro and macro level of the gas phenomena (Levy \& Wilensky, 2009).

While we are chunking and sequencing the tasks, we need to provide extra scaffolding for students to make connections across learning activities. Inter-level experience is critical in learning complex systems (Levy \& Wilensky, 2009). Thus the second research question of this study is: How can we help students make connections across system levels? Scaffolding that elicits self-explanation could significantly improve learning (Chi et al, 1994). Explicit level-bridging scaffolding such as inter-level questions facilitates selfexplanation, and is an effective strategy in teaching complex systems (Stieff, 2011). In this study, the effect of explicit level-bridging scaffolding was tested.

## Learning Materials and Instrument

Ideal gas law is a complex chemical system. A concrete phenomenon such as "an aerosol can explodes when it is thrown into the fire" can be defined as the "system-wide" or "pattern-level" function. This level is concrete, observable, and without complex dynamics. Temperature-pressurevolume relationship is an abstract macro level, which is analogous to and explains the observable pattern-level function, thus we define this level as the "mechanism level." This level depicts the mechanism of the "can explosion phenomenon"; meanwhile, this level emerges from the lower-level molecular activity defined as the "entity level".

A simulation-based environment with two simulations was used as the research instrument. The first simulation visualized the pattern-level function. Students could drag the fire icon towards the can and observe the can explodes (see Figure 1). The second simulation (see Figure 2) visualized the mechanism level (Temperature-pressure-volume relationship) and the entity level (molecular activity). The two simulations could be displayed separately on two pages. Students could switch to either simulation by clicking an arrow button, or they could be displayed on the same page and dynamically linked (see Figure 3). The dynamic link technique can facilitate information integration from multiple representations (van der Meji \& de Jong, 2006), and in this study, it was a part of the manipulation of the explicit levelbridging scaffolding condition.

Figure 1: Aerosol can simulation

Figure 2: Gas container simulation

Figure 3: Two simulations dynamically linked

## Variables \& Hypotheses

Two variables were tested in this study: 1. Sequencing methods; 2. Level-bridging scaffolding.

## Sequencing Methods

Three sequencing methods were compared in this study. The sequencing methods variable was manipulated by changing the delivery order of the three levels of the chemical system.

F-M-E sequencing method Starting from the function level to the mechanism level, and then to the entity level (F-M-E). This sequencing method followed the "from concrete to abstract" principle. It was function-oriented thus provided a good conceptual framework for knowledge integration.

E-M-F sequencing method Starting from the entity level to the mechanism level, and then to the function level (E-M-F). This sequencing method followed the "from cause to effect" principle because it was aligned with the causal structure of the ideal gas law system

M-E-F sequencing method Starting from the mechanism level to the entity level, and then to the function level (M-EF). This sequencing method did not follow the "from concrete to abstract" or the "from cause to effect" principle, thus it was hypothesized to be less effective than the other two methods.

## Hypotheses on Sequencing Methods

Hypothesis 1 the F-M-E sequencing method produces better knowledge integration when compared to the E-M-F and the M-E-F sequencing method.

Hypothesis 2 the E-M-F sequencing method produces better understanding of the deep causal structure when compared to the F-M-E and the M-E-F sequencing method.

## Hypotheses on Level-Bridging Scaffolding

Explicit level-bridging scaffolding and implicit levelbridging scaffolding were compared in this study.

Hypothesis 3 Explicit level-bridging scaffolding produces better knowledge integration when compared to implicit level-bridging scaffolding

Hypothesis 4 Explicit level-bridging scaffolding produces better understanding of the deep causal structure when compared to implicit level-bridging scaffolding.

## Method

## Participants

129 seventh graders from two inner city public middle schools participated in this study. Six cases were dropped from the sample, as these participants were absent from the second session of the study. The final sample included 123 participants. $78.9 \%$ were Hispanic, $13.8 \%$ Black, $4.1 \%$ white and $3.3 \%$ other. The mean age of this sample was 12.4 ( $\mathrm{SD}=0.53$ ). $48.8 \%$ were male and $51.2 \%$ female.

This study employed a $3 \times 2$ design. See Table 1 for the 6 treatment groups.

Table 1: $3 \times 2$ experimental design

|  | F-M-E | E-M-F | M-E-F |
| :--- | :--- | :--- | :--- |
| Explicit <br> level <br> bridging | Group 1 | Group 3 | Group 5 |
| Implicit <br> level <br> bridging | Group 2 | Group 4 | Group 6 |

## Procedure

Within each classroom, participants were randomly assigned. The data collection within each class was operated on two consecutive days. The total length of the two sessions was around 100 minutes.

Day 1 All participants took a pretest. Within the same classroom, participants were randomly paired up and randomly assigned to a condition. Each pair was assigned a laptop with the simulations; and each participant was assigned a booklet with 6 learning activities. Participants were asked to read the guidance and questions on the worksheets and write down their answers without any group discussion (for better control of extraneous factors). Three research assistants and the science teacher were present to monitor the learning progress, help change the simulation interfaces and solve technical problems. Participants completed 3-4 learning activities on Day 1.

Day 2 Participants were assigned to the same group as Day 1. They were asked to spend around 5 minutes reviewing their work from Day 1. Participants continued learning and completed the rest of the learning activities. Participants completed a posttest after the learning session.

## Manipulation

Sequencing Methods Sequencing methods were manipulated by changing the delivery order of these three system levels. The same learning activities on three system levels were arranged in different orders.

Level-Bridging Scaffolding This variable was manipulated on two aspects. For the explicit level-bridging condition: 1). Inserting inter-level questions among the learning activities 2). Two simulations were dynamically linked for the final learning activity (See Figure 3.). For the implicit levelbridging condition: 1). Inserting intra-level questions among the learning activities 2 ). Two simulations were not dynamically linked for the final learning activity.
The inter-level questions and intra-level questions were manipulated in a way that the same amount of information was delivered. Please see Table 2 for the two sets of questions. Where each question was inserted also depended on the sequencing method condition.

Table 2: Inter-level questions vs. Intra-level questions

| Inter-level questions |  |
| :--- | :---: |
| 1. What is the relationship <br> between temperature and <br> pressure? Use what you learned <br> about temperature and pressure <br> from the gas container <br> presentation, explain why the <br> aerosol can explodes? |  |
| 2. How do gas molecules <br> behave? Use what you learned <br> about gas molecules; explain <br> why as temperature rises, <br> pressure inside the container <br> also rises? |  |

3. Use the knowledge of gas molecules; explain what happens to the gas pressure inside the aerosol can as you drag the fire closer? Explain why the aerosol can explodes?

## Intra-level questions <br> 1.Explain why the aerosol can explodes?

2. Use what you learned about temperature and pressure from the gas container presentation, explain what is the relationship between temperature and pressure?
3. Use the knowledge of gas molecules; explain how do gas molecules behave?
4.Explain what happens to the aerosol can as you drag the fire closer?
5.What did you learn from the aerosol can presentation?
6.As temperature rises, pressure also rises, is this correct?
7.What did you learn about gas molecules?

## Measures

Pretest The pretest included two open-ended questions asking the participants to explain two ideal gas law problems: "using an ice pack to reduce tooth pain" and "car tires are more likely to explode in the summer than in the winter". No extra system information about ideal gas law was provided, as priming the participants with any level of the system might disrupt the manipulation of the sequencing methods.

Posttest. The posttest included four parts. Part I. short answer questions and labeling questions measuring recall of system knowledge. Part II. Two snapshots of the virtual experiment simulation were provided, participants were asked to describe what happened from Time A to time B. This open-ended question measured recall of simulation events; Part III. Four open-ended questions measured comprehension of the system knowledge, e.g., participants were asked to explain their understanding of "gas pressure", and "why the aerosol can explodes". Part IV. The same two ideal gas law problems as in the pretest were used as transfer questions. This part measured understanding of the deep causal structure of the system.

Most of the questions in the pre and posttest were openended questions. Participants' answers were coded on the absence or presence of important system knowledge units. All possible knowledge units were included in the coding scheme (possible maximum scores were high), but participants' actual scores were relatively low.

Two raters blind to the conditions coded the answers independently, and the inter-rater reliability was above $95 \%$ for all parts of the pre and posttest. Disagreement was resolved via discussion between the two raters.

## Results

## Pretest Scores

The possible maximum score of the pretest was 10. Pretest scores did not significantly differ across sequencing methods, $\mathrm{F}(2, \quad 117)=0.674, \quad \mathrm{p}=0,512 ; \quad$ or across level-bridging scaffolding conditions, $\mathrm{F}(1,117)=0.238, \mathrm{p}=0.789$. The pretest scores were used to establish equivalency and used as a covariate in further analysis.

Table 3. Pretest scores

|  | $\mathrm{F}-\mathrm{M}-\mathrm{E}$ | $\mathrm{E}-\mathrm{M}-\mathrm{F}$ | M-E-F | Marginal |
| :--- | :--- | :--- | :--- | :--- |
| Explicit | 1.33 | $\mathrm{M}=1.45$ | $\mathrm{M}=1.16$ | $\mathrm{M}=1.30$ |
| Level- | $\mathrm{SD}=0.65$ | $\mathrm{SD}=1.08$ | $\mathrm{SD}=0.90$ | $\mathrm{SD}=0.89$ |
| bridging | $\mathrm{N}=20$ | $\mathrm{~N}=19$ | $\mathrm{~N}=22$ | $\mathrm{~N}=30$ |

## Posttest Scores

Knowledge integration was measured through recall and comprehension tasks (Part I, II, III), and understanding of the deep causal structure was measured through transfer tasks (Part IV). ANCOVA and helmert contrasts were conducted as inferential tests.

Part I. Recall of system knowledge (possible maximum score=8) Two statistical outliers were converted to the 98percentile value of the sample distribution. Descriptive data of this part please see Table 4 and Figure 4. Pretest scores as a covariate was marginally significant, $\mathrm{F}(1,116)=3.36$, $\mathrm{p}=0.069$. No interaction between sequencing methods and level-bridging scaffolding was found, $F(2,116)=0.212$, $\mathrm{p}=0.847$, indicating the $\mathrm{F}-\mathrm{M}-\mathrm{E}$ sequencing method and explicit level-bridging scaffolding had additive effects on the recall of system knowledge. The Helmert contrasts results showed that the F-M-E sequencing method produced significantly better recall when compared to the average of the other two sequencing methods, $\mathrm{t}(116)=2.56, \mathrm{p}=0.012$; no significant difference was found between the E-M-F and the M-E-F sequencing method, $t(116)=0.13, p=0.894$. This demonstrated that the "top-down" function-oriented sequencing method following the "concrete to abstract" principle (F-M-E) provided a desirable conceptual framework for knowledge integration. Explicit level-bridging scaffolding had significant positive effects on the recall of system knowledge, $\mathrm{F}(1,116)=7.24, \mathrm{p}=0.008$. The results supported Hypothesis 1 and 3.

Table 4. Recall of system knowledge

|  | $\mathrm{F}-\mathrm{M}-\mathrm{E}$ | E-M-F | M-E-F | Marginal |
| :--- | :--- | :--- | :--- | :--- |
| Explicit | $\mathrm{M}=4.30$ | $\mathrm{M}=3.45$ | $\mathrm{M}=3.50$ | $\mathrm{M}=3.77$ |
| Level- | $\mathrm{SD}=1.08$ | $\mathrm{SD}=1.19$ | $\mathrm{SD}=1.53$ | $\mathrm{SD}=1.26$ |
| bridging | $\mathrm{N}=20$ | $\mathrm{~N}=19$ | $\mathrm{~N}=22$ | $\mathrm{~N}=61$ |
| Implicit | $\mathrm{M}=3.45$ | $\mathrm{M}=3.00$ | $\mathrm{M}=3.00$ | $\mathrm{M}=3.14$ |
| level- | $\mathrm{SD}=1.19$ | $\mathrm{SD}=1.65$ | $\mathrm{SD}=1.20$ | $\mathrm{SD}=1.37$ |

|  |  |  |  | $\mathrm{~N}=123$ |

Figure 4. Recall of system knowledge

Part II. Recall of simulation events (possible maximum score=6) One statistical outlier was converted to the 99percentile value of this sample. Descriptive data of this part please see Table 5 and Figure 5. Pretest scores as a covariate was not significant, $\mathrm{F}(1,116)=1.11, \mathrm{p}=0.29$. The $\mathrm{F}-\mathrm{M}-\mathrm{E}$ \& Implicit level-bridging group recalled more simulation events when compared to the other treatment groups. As statistical evidence for that, the interaction between the sequencing methods contrast ( $\mathrm{F}-\mathrm{M}-\mathrm{E}$ vs. other) and the level-bridging scaffolding variable was significant, $\mathrm{t}(116)=2.03, \mathrm{p}=0.045$, meaning that the F-M-E was effective on the recall of simulation events only in the implicit level-bridging condition. The results from Part I and II indicated that the F-M-E sequencing method led to better recall in general. Given explicit level-bridging scaffolding, students were more likely to integrate important system concepts; while in the implicit level-bridging scaffolding condition, participants focused more on superficial simulation events.

Table 5. Recall of simulation events

|  | $\mathrm{F}-\mathrm{M}-\mathrm{E}$ | $\mathrm{E}-\mathrm{M}-\mathrm{F}$ | M-E-F | Marginal |
| :--- | :--- | :--- | :--- | :--- |
| Explicit | $\mathrm{M}=1.75$ | $\mathrm{M}=1.79$ | $\mathrm{M}=1.86$ | $\mathrm{M}=1.80$ |
| Level- | $\mathrm{SD}=0.55$ | $\mathrm{SD}=0.71$ | $\mathrm{SD}=0.83$ | $\mathrm{SD}=0.70$ |
| bridging | $\mathrm{N}=20$ | $\mathrm{~N}=19$ | $\mathrm{~N}=22$ | $\mathrm{~N}=61$ |
| Implicit | $\mathrm{M}=2.30$ | $\mathrm{M}=1.83$ | $\mathrm{M}=1.84$ | $\mathrm{M}=1.98$ |
| level- | $\mathrm{SD}=0.66$ | $\mathrm{SD}=0.83$ | $\mathrm{SD}=0.60$ | $\mathrm{SD}=0.74$ |

|  | $\mathrm{SD}=0.66$ | $\mathrm{SD}=0.77$ | $\mathrm{SD}=0.73$ | $\mathrm{M}=1.89$ |
|  | $\mathrm{~N}=40$ | $\mathrm{~N}=42$ | $\mathrm{~N}=41$ | $\mathrm{SD}=0.72$ |
|  |  |  |  | $\mathrm{~N}=123$ |

Figure 5: Recall of simulation events
Part III. Comprehension (possible maximum score=15) Descriptive data of this part please see Table 6 and Figure 6. Pretest scores were significantly associated with the comprehension scores, $\mathrm{F}(1,116)=8.51, \mathrm{p}=.004$. The interaction between sequencing methods and level-bridging scaffolding was not significant, $\mathrm{F}(2,116)=0.049, \mathrm{p}=.952$, indicating the effects of sequencing methods and levelbridging scaffolding were additive. Although this part showed a similar pattern as Part I, the positive effects of F-M-E sequencing method over the average of the other two
was not significant, $t(116)=1.46, p=0.146$. Significant main effects of the explicit level-bridging scaffolding was found, $\mathrm{F}(1,116)=4.45, \mathrm{p}=0.037<0.05$. When comparing Part I and Part III, we may find that the effects of explicit level-bridging scaffolding on knowledge integration was more sustainable than the $\mathrm{F}-\mathrm{M}-\mathrm{E}$ sequencing method.

Table 6. Comprehension of system knowledge

|  | $\mathrm{F}-\mathrm{M}-\mathrm{E}$ | $\mathrm{E}-\mathrm{M}-\mathrm{F}$ | M-E-F | Marginal |
| :--- | :--- | :--- | :--- | :--- |
| Explicit | $\mathrm{M}=3.97$ | $\mathrm{M}=3.53$ | $\mathrm{M}=3.34$ | $\mathrm{M}=3.60$ |
| Level- | $\mathrm{SD}=1.41$ | $\mathrm{SD}=1.57$ | $\mathrm{SD}=2.01$ | $\mathrm{SD}=1.70$ |
| bridging | $\mathrm{N}=20$ | $\mathrm{~N}=19$ | $\mathrm{~N}=22$ | $\mathrm{~N}=61$ |
| Implicit | $\mathrm{M}=3.20$ | $\mathrm{M}=2.89$ | $\mathrm{M}=2.92$ | $\mathrm{M}=3.30$ |
| level- | $\mathrm{SD}=1.64$ | $\mathrm{SD}=1.27$ | $\mathrm{SD}=1.98$ | $\mathrm{SD}=1.61$ |
| bridging | $\mathrm{N}=20$ | $\mathrm{~N}=23$ | $\mathrm{~N}=19$ | $\mathrm{~N}=62$ |
| Marginal | $\mathrm{M}=3.58$ | $\mathrm{M}=3.18$ | $\mathrm{M}=3.15$ | Total |
|  | $\mathrm{SD}=1.56$ | $\mathrm{SD}=1.43$ | $\mathrm{SD}=3.15$ | $\mathrm{M}=3.30$ |
|  | $\mathrm{~N}=40$ | $\mathrm{~N}=42$ | $\mathrm{~N}=41$ | $\mathrm{SD}=1.68$ |
|  |  |  |  | $\mathrm{~N}=123$ |

Figure 6: Comprehension of system knowledge
Part IV. Transfer tasks (possible maximum score=10) Different from the comprehension questions in Part III, these two transfer questions required participants to recognize the problems as ideal gas law phenomena, and transfer the causal structure of the system to explain the problems. Two statistical outliers were converted to the 98 -percentile value of the sample distribution. Descriptive data of this part please see Table 7 and Figure 7. These two transfer questions were the same as the pretest questions. The mean pre-post gain was $0.68, \mathrm{SD}=1.33$, which was significantly different from 0 , $\mathrm{t}(122)=5.66, \mathrm{p}<.001$. However, the low pre-post gain indicated that transfer was inherently difficult.

The E-M-F sequencing method with explicit level-bridging scaffolding was the most effective treatment in teaching the deep causal structure of the system. As statistical evidence for the claim, the interaction of the sequencing methods contrast (E-M-F vs. other) and the explicit level-bridging scaffolding variable was significant, $\mathrm{t}(116)=2.04, \mathrm{p}=0.044$. This indicated that a "bottom-up" approach aligned with the causal structure was effective only when explicit level-
bridging scaffolding was provided. The results provided evidence to Hypothesis 2 and Hypothesis 4.

Figure 7: Transfer_Understanding of the deep causal structure

## Conclusion

Scaffolding is critical in teaching complex systems. Different sequencing methods as procedural scaffolding were compared in this study. The F-M-E sequencing method which followed the "concrete to abstract" sequencing principle produced better knowledge integration. The E-M-F sequencing method which followed the "cause to effect" principle produced better understanding of the deep causal structure only when explicit level-bridging scaffolding was provided. The M-E-F sequencing which did not follow either principle was not very effective for either knowledge integration or understanding of the deep causal structure. These findings are valuable as they address the "top-down" vs. "bottom-up" debate in teaching complex systems. When teaching systems with many levels and detailed system dynamics, effective knowledge integration is very essential at an early stage, thus the "top-down" approach starting from concrete macro-level functions may produce better performance. While in teaching complex systems with abstract and implicit causal structures, a sequencing method aligned with the causal structure of the system may help learners construct better mental models for transfer. Different sequencing methods can be used in different contexts or at different learning stages.

The results also showed that explicit level-bridging scaffolding had positive effects on both knowledge integration and understanding of the causal structure. From the perspective of knowledge integration, level-bridging scaffolding and the F-M-E sequencing method had additive effects. In learning the deep causal structure, merely delivering the system knowledge in a "bottom-up" approach was not sufficient, and explicit level-bridging scaffolding was necessary in this process. The positive effects of the explicit level-bridging scaffolding are worth emphasizing. We need to explicitly encourage learners to make connections across system levels via inter-level questions and technology-enhanced techniques (e.g. dynamic link of two simulations). Future research is needed to study the separate effects of different level-bridging scaffolding strategies.

#### Abstract

In order to better understand how humans acquire knowledge, one of the essential goals in cognitive science is to build a cognitive model of human learning. Moreover, a cognitive model that better matches student behavior will often yield better instruction in intelligent tutoring systems. However, manual construction of such cognitive models is time consuming, and requires domain expertise. Further, manually-constructed models may still miss distinctions in learning which are important for instruction. Our prior work proposed an approach that finds cognitive models using a state-of-the-art learning agent, SimStudent, and we demonstrated that, for algebra learning, the agent can find a better cognitive model than human experts. To ensure the generality of that proposed approach, we further apply it to three domains: algebra, stoichiometry, and fraction addition. To evaluate the quality of the cognitive models discovered, we measured how well the cognitive models fit to student learning curve data. In two of those domains, SimStudent directly discovers a cognitive model that predicts human student behavior better than the human-generated model. In fraction addition, SimStudent supported discovery of a better cognitive model in combination with another automated cognitive model discovery method.

Keywords: cognitive model, machine learning, simulated student

## Introduction

One of the fundamental goals in cognitive science is to understand human knowledge acquisition. A cognitive model of human learning that fits data would be a significant achievement. This goal also complements with another goal in education, which is to provide individualized instruction based on students' abilities, learning styes, etc. Cognitive models provide intelligent tutoring systems with useful information on the learning task difficulties and transfer of learning among similar problems. A better cognitive model often leads to more effective tutoring. A cognitive model is a system that can solve problems in the various ways human students can. One common way of representing a cognitive model is a set of knowledge components ( $K C$ ) (Koedinger \& McLaughlin, 2010). The set of KCs includes the component skills, concepts, or percepts that a student must learn to be successful on the target tasks. For example, a KC "divide" in algebra encodes how to proceed given problems of the form $N v=N$ (e.g., $-3 x=6$ ), where $N$ stands for a number, and $v$ stands for a variable.

Nevertheless, manual construction of cognitive models remains time consuming and error prone. Traditional ways to construct cognitive models include structured interviews, think-aloud protocols, and rational analysis. Manual construction of cognitive models requires domain expertise, and
important instructional details may still be overlooked. Automated search methods such as Learning Factor Analysis (LFA) (Cen, Koedinger, \& Junker, 2006) are more objective: the algorithm searches through the space of human-provided factors to find a cognitive model that best matches with human data. Although automated search methods have found better models than manual construction, the quality of the discovered model depends on the quality of the human-provided factors. If there is a better model that can not be expressed by known factors, LFA will not be able to uncover it.

In Li, Matsuda, Cohen, and Koedinger (2011), we have proposed to use the state-of-the-art learning agent, SimStudent (Matsuda, Lee, Cohen, \& Koedinger, 2009), to automatically discover cognitive models without depending on human-provided factors. SimStudent learns skill knowledge from demonstration and problem solving experience. Each skill SimStudent acquires corresponds to a KC in the cognitive model. To demonstrate the generality of this approach, we present evaluations of the SimStudent-generated models in three domains: algebra, stoichiometry, and fraction addition. We validate the quality of the cognitive models using human student data as in Koedinger and MacLaren (1997). Instead of matching with performance data, we use the discovered cognitive model to predict human learning curve data. Experimental results show that for algebra and stoichiometry, SimStudent directly finds a better cognitive model than humans. For fraction addition, SimStudent results assist LFA in finding a better cognitive model than a domain expert. We have also carried out an in-depth study using Focused Benefits Investigation (FBI) (Koedinger, McLaughlin, \& Stamper, 2012) to better understand this machine learning approach, and discussed possible ways of further improvements.

## A Brief Review of SimStudent

SimStudent is an intelligent agent that inductively learns skills to solve problems from demonstrated solutions and from problem solving experience. It is a realization of programming by demonstration (Lau \& Weld, 1998) using a variation of the version space algorithm (Mitchell, 1982), inductive logic programming (Muggleton \& Raedt, 1994), and iterative-deepening depth-first search as underlying learning techniques. For more details, please refer to Matsuda et al. (2009). Recently, in order to build a more human-like intelligent agent, we have developed a model of representation learning, and integrated it into SimStudent's skill acquisition mechanism.

Figure 1: Original and extended production rules for divide in a readable format.

## Tutoring Strategy

To learn, SimStudent interacts with a tutor (human or automated). Given a problem, if SimStudent does not know how to solve it, it will ask the tutor to demonstrate a next step. If SimStudent knows how to proceed, it will propose the next step, and ask for feedback from the tutor. For each demonstrated step, the tutor specifies a tuple of $\langle$ selection, action, input $\rangle$ (SAI tuple) for a skill along with a skill label (e.g., divide). For instance, a demonstrated step for skill "divide" is $\langle(-3 x, 6)$, input text, (divide -3$)\rangle$.

SimStudent learns skills as production rules. The left side of Figure 1 shows an example production rule for skill divide in a readable format. A production rule shows "where" to look for useful information (i.e., perceptual information), "when" to apply the skill (i.e., precondition), and "how" to proceed (i.e., operator sequence). To illustrate, consider the rule on the left side of Figure 1. It states that given an equation (e.g., $-3 x=6$ ), if the left side does not have a constant term, then first get the coefficient of the left side (-3), and divide both sides by that coefficient.

Each skill corresponds to a KC. During training, the tutor can provide an initial set of KCs to SimStudent by labeling each demonstrated step with a skill name. The label given to SimStudent in the example production rule (i.e., the left side of Figure 1) is "divide". If no such initial KC is known, the tutor can simply label all of the steps with the same skill name. SimStudent's learning algorithm will automatically create the cognitive model as needed.

## Skill Learning

SimStudent has three learning components - each acquires one part of the production rules. The first component is a perceptual information (i.e., "where") learner that acquires the path to identify the useful information from its environment. In our case, the environment is a graphical user interface, but it could also be a physical world or an educational game. The elements in the environment are organized in a tree structure. SimStudent learns perception by moving from specific to general. That is, SimStudent tries to find the least general path in the perceptual hierarchy that covers all of the selections in the demonstrated steps. In the example skill "divide," the left and right sides of the equation can be found in
the last row that SimStudent entered input.
The second part of the learning mechanism is a precondition (i.e., "when") learner, which acquires the descriptions of desired situations in applying the skill. The learner is given a set of feature predicates to get a basic understanding of the problem. Each predicate is a boolean function that describes relations among objects in the domain (e.g. (has-coefficient $-3 x)$ ). The precondition learner utilizes FOIL (Quinlan, 1990), an inductive logic programming system that learns Horn clauses from both positive and negative examples. The learning process is general to specific, where the precondition learner starts by considering all situations applicable, and then gradually narrows down the condition based on negative examples. The precondition acquired for the example skill divide is (not (has-constant ?var-left)), which returns true if the left side does not have a constant.

The last component is the operator sequence (i.e., "how") learner. The learner is given a set of operator functions as prior knowledge. Operator functions specify (ideally) basic manipulations (e.g. (add 12 ), (get-coefficient $-3 x$ )) that SimStudent can apply to the problem. Given all of the demonstrated steps, the learning mechanism searches for the shortest operator sequence that could explain all of the records, using iterative-deepening depth-first search. For example, given a demonstrated step $\langle(-3 x, 6)$, (divide -3$)\rangle$, the shortest explanation sequence is (bind? coef (get-coefficient ?left-var)) (bind ?output (divide ?coef)).

There are two groups of operator functions, domainindependent operator functions and domain-specific operator functions. Domain-independent operator functions (e.g. (add 12 )) are basic skills applicable across multiple domains. Human students often have knowledge of these simple skills prior to class. Domain-specific operator functions (e.g. (add-term $5 x-25$ ), (get-coefficient $-3 x$ )) are more complicated skills that human students may not know before class. Thus providing such operators to SimStudent may produce learning behavior that is distinctly different from human students (Matsuda et al., 2009). As we will explain in the next subsection, by integrating representation learning with skill learning, we can reduce or remove SimStudent's dependency on domain-specific operator functions.

Finally, let's talk about how the KCs are discovered. SimStudent starts with a given set of skill labels associated with demonstrated steps. SimStudent tries to learn one rule for each label. It will fail when the perceptual information learner cannot find one path that covers all demonstrated steps, or the operator sequence learner cannot find one operator function sequence that explains all records. In that case, SimStudent learns a disjunctive rule just for the last record. This effectively splits the examples into two clusters. Later, for each new record, SimStudent tries to acquire a rule for each of the clusters with the new record, and stops whenever it successfully learns a rule with one of the clusters. If the new record cannot be added to any of the existing clusters, SimStudent creates another new cluster. By the end of learning, the set of

Figure 2: Different parse trees for -3 x and -x .
clusters defines a new cognitive model.

## Integrating Representation Learning with Skill Learning

As we can see, the prior knowledge given to SimStudent (e.g., the perceptual hierarchy, the operator functions) largely affects the cognitive model it discovers. The more knowledge engineering needed, the less human-like SimStudent is. Therefore, to get a better cognitive model, we need to reduce the amount of knowledge engineering required in constructing SimStudent. Previous studies (Chase \& Simon, 1973) have shown that one of the key differences between experts and novices is their different representations of the world. Recently, we have extended SimStudent to support representation learning, and integrated it into skill learning. It has been shown that by integrating representation learning and skill learning, we can automatically learn the tree-structured representation of the problem, and reduce or remove the need of domain-specific operator functions.

The representation learner extends a grammar induction technique to acquire a probabilistic context-free grammar (pCFG) for the problems based on a set of observations (e.g., $-3 x, 2 x+5)$. To integrate representation learning with skill learning, we extend the perceptual hierarchy to further include the most probable parse trees from the learned pCFG in the contents of the leaf nodes. For example, the left side of Figure 2 is a subtree for parsing " $-3 x$ " and is connected to the node associated with $-3 x$ in the perceptual hierarchy. This subtree ensures that the coefficient -3 is explicitly represented in the perceptual hierarchy. Then, the perceptual information learner and the operator function sequence learner determine how to extract the coefficient from the perceptual hierarchy. This path for identifying the coefficient is added to the perceptual information part of the production rules (See Figure 1, right side). Then, the operator function sequence part no longer needs the domain-specific operator function "get-coefficient". For more details, please refer to Li, Cohen, and Koedinger (2012).

## Cognitive Model Discovery Study

In Li et al. (2011), we demonstrated the effectiveness of using SimStudent to discover cognitive models in an algebra domain. In order to evaluate the generality of the proposed
approach, in this paper, we tested SimStudent in three domains, algebra, stoichiometry, and fraction addition.

## Method

In each domain, we compared the SimStudent model with the best human-generated model available, made by domain experts. To generate the SimStudent model, SimStudent was trained by interacting with automated tutors that simulate the automated tutors used by human students in the studies. The video demonstration in the original study was not used in training SimStudent. SimStudent was trained on problems used by humans students. Then, for each step a human student performed, we assigned the applicable production rule as the KC associated with that step. In cases where there was no applicable production rule, we coded the step using the human-generated cognitive model. Each time a student encounters a step using some KC is considered as an opportunity for that student to show mastery of that KC.

To evaluate the quality of the cognitive model, we measured how well the cognitive model fits with human student data using the Additive Factor Model (AFM) (Cen et al., 2006) to validate the coded steps. AFM is an instance of logistic regression that predicts the probability of a student making an error on the next step given each student, each KC , and the KC by opportunity interaction as independent variables.

$$
\ln \frac{p_{i j}}{1-p_{i j}}=\theta_{i}+\sum_{k} \beta_{k} Q_{k j}+\sum_{k} Q_{k j}\left(\gamma_{k} N_{i k}\right) .
$$

Where:
i represents a student i .
j represents a step j .
$\mathbf{k}$ represents a skill or KC k .
$p_{i j}$ is the probability that student i would be correct on step j.
$\theta_{i}$ is the coefficient for proficiency of student i.
$\beta_{k}$ is coefficient for difficulty of the skill or KC k
$Q_{k j}$ is the Q -matrix cell for step j using skill k .
$\gamma_{k}$ is the coefficient for the learning rate of skill k ;
$N_{i k}$ is the number of practice opportunities student i has had on the skill k;

## Domains

We carried out our study in three domains: algebra, stoichiometry, and fraction addition. The domains as well as the setup in each domain vary from one to another. This ensures that the experiment tests the generality of the proposed approach.

In algebra, we analyzed data from 71 students who used an Carnegie Learning Algebra I Tutor unit on equation solving. The students were typical students at a vocational-technical school in a rural/suburban area outside of Pittsburgh, PA. A

Table 1: AIC on SimStudent-Generated models and Human-Generated Models.

|  | Human-Generated <br> Model | SimStudent-Discovered <br> Model |
| :--- | :--- | :--- |
| Algebra | 6534.07 | $\mathbf{6 4 4 8 . 1}$ |
| Stoichiometry | 17380.9 | $\mathbf{1 7 2 1 8 . 5}$ |
| Fraction Addition | $\mathbf{2 1 1 2 . 8 2}$ | 2202.02 |

total of 19,683 transactions between the students and the Algebra Tutor were recorded, where each transaction represents an attempt or inquiry made by the student, and the feedback given by the tutor. We selected 40 problems that were used to teach students as the training set for SimStudent.

The stoichiometry dataset contains data from 3 studies. 510 high school and college students participated in the studies, and generated 172,060 transactions. Instructional videos on stoichiometry were intermingled with the problems. Instructional materials were provided via the Internet. It took students from 1.5 hours to 6.5 hours to complete the study. 8 problems in this study were used in training SimStudent.

In fraction addition, we analyzed data from 24 students who used an intelligent tutoring system as part of a larger study. Approximately half of the students were recruited from local schools. Students were given immediate correctness feedback on each step, and were offered on-demand text hints. Each interaction was logged through Datashop, and the 24 students yielded 4558 transactions. SimStudent was tutored with 20 problems from this study.

## Measurements

We used Akaike Information Criterion (AIC) and a 10 -fold cross validation (CV) to test how well the generated model predicts the correctness of human student behavior. AIC measures the fit to student data and penalizes over-fitting. We did not use BIC (Bayesian Information Criterion) as the fit metric, because based on past analysis across multiple DataShop datasets, it has been shown that AIC is a better predictor of cross validation than BIC is. The cross validation was performed over ten folds with the constraint that each of the training sets must have data points for each student and KC. We reported the root mean-squared error (RMSE) averaged over ten test sets.

## Results

As shown in Table 1 and Table 2, in algebra and stoichiometry, the SimStudent-discovered models that have lower AICs and RMSEs ( $p<0.001$ ) than the human-generated models. This means the SimStudent models better match the data (without over-fitting). However, in fraction addition, the human-generated model performs better than the SimStudent-discovered ones.

A closer look at the models reveals that in algebra, the SimStudent-discovered model splits some of the KCs in the human-generated model into finer grain sizes. For example, SimStudent creates two KCs for division, one for problems of the form $N v=N$, and one for problems of the form
$-v=N$. This is caused by the different parse trees for $N v$ and $-v$ as shown in Figure 2. Due to this split, the SimStudentgenerated model predicts a higher error rate on problems of the form $-v=N$ than problems of the form $N v=N$. It matches with human student error rates better than the human-generated model, which does not differentiate problems of these two forms.

In stoichiometry, instead of finding splits of existing KCs, SimStudent discovers new KCs that overlap with the original KCs. There are three basic sets of skills in this domain. Within each set, the human-generated KCs are assigned based on the location of the input, while the SimStudent-discovered KCs are associated with the goals of the input. Hence, suppose in two different problems, there are two inputs at the same location in the interface. If they are associated with different goals, the human-generated model will not differentiate them, while the SimStudent-discovered model will put them into two KCs. This indicates that SimStudent not only splits existing KCs, but also discovers totally different KCs.

The fraction addition problem set consists of three types of problems in increasing difficulty: 1) addends have equal denominators; 2) the denominator of one addend is a multiple of the other; 3) addends have unrelated denominators. The human-generated model differentiates these three types of problems in calculating the common denominators and the scaled numerators, and ends up having six KCs. SimStudent, however, associates all of the numerator scaling steps with one KC and associates the common denominator calculations with two KCs. In other words, in this domain, SimStudent partially recovered three out of six KCs, but did not further split them into six KCs. SimStudent did discover the other three KCs, but eventually removed them when they were superseded by more generalized rules. This bias towards more general production rules over specific ones regardless of computational cost appears to be a limitation of SimStudent as a cognitive model. Perhaps if we had let SimStudent keep a utility function for each production rule and retrieve them based on the computational cost, last retrieval time, and correctness, SimStudent may have arrived at all six KCs in the human-generated model.

## FBI Analysis and LFA on Fraction Addition

The differences of AIC and RMSE between the models are small. This is partially because the difference between the models is small. FBI, a recently developed technique, is designed to analyze which of these differences improves the model, and by how much. We applied FBI to the SimStudent and human-generated models in each domain to determine

Table 2: CV RMSE on SimStudent-Generated models and Human-Generated Models.

|  | Human-Generated <br> Model | SimStudent-Discovered <br> Model |
| :--- | :--- | :--- |
| Algebra | 0.4024 | $\mathbf{0 . 3 9 9 9}$ |
| Stoichiometry | 0.3501 | $\mathbf{0 . 3 4 8 8}$ |
| Fraction Addition | $\mathbf{0 . 3 2 3 2}$ | 0.3343 |

why the SimStudent models are better in two of the three cases. In the analysis, we set the human-generated models as the base.

FBI shows that in algebra, splitting "divide" reduces the RMSE of those steps by $1.02 \%$. Further, splitting subtraction and addition decreases the RMSE of those steps by $3.78 \%$ and $3.10 \%$, respectively. This also indicates that SimStudent is able to discover KCs of finer grain sizes that match with human data well.

The stoichiometry results are different. SimStudent discovered new KCs that were not part of any existing KCs. Given the 40 KCs in the human-generated model, SimStudent improved 26 of them. The biggest improvement is on skill molecular weight $(4.60 \%)$, since there are sometimes more than one skill applicable to the same step. The humangenerated model misses the additional skill, while the SimStudent model successfully captures both skills.

As described previously, SimStudent did not differentiate the numerator-scaling and common-denominator steps by problem type. This hurts the RMSE of the associated KCs in the SimStudent-generated model. Nevertheless, SimStudent considers finding the common denominator to be a different KC than copying it to the second converted addend. This split decreases by $7.43 \%$ for problems with unrelated denominators, and and by $0.12 \%$ for denominator steps of problems where one addend denominator was a multiple of the other.

Given the above results, we carried out a third study on fraction addition to test that whether the new KCs created by SimStudent can be used to discover better cognitive models. We used LFA to discover cognitive models given two sets of factors. The baseline LFA model was generated based on the factors (KCs) in the human-generated model. The other LFA model was discovered using both the factors (KCs) in the human-generated model and those in the SimStudentgenerated model. Both LFA models were better than the original human-generated model in terms of AIC and RMSE. Moreover, the LFA model using both human-generated and SimStudent-generated factors had better AIC (2061.4) and RMSE ( 0.3189 ) than the baseline LFA model (AIC: 2111.96, RMSE 0.3226). In other words, with the help of SimStudent, LFA discovered better models of human students.

## Related Work

The objective of this paper is to evaluate the generality of the proposed cognitive model discovery approach. Conati and VanLehn (1999) also applied machine learning techniques to generate cognitive models that fit with human data, but
they focused on assessing self-explanation instead of student learning. Additionally, there has been considerable work on comparing the quality of alternative cognitive models. LFA automatically discovers cognitive models, but is limited to the space of the human-provided factors. Other works such as Pavlik, Cen, and Koedinger (2009); Villano (1992) are less dependent on human labeling, but the models generated may be hard to interpret. In contrast, the SimStudent approach has the benefit that the acquired production rules have a precise and usually straightforward interpretation.

Other systems (e.g., Tatsuoka, 1983; Barnes, 2005) use a Q-matrix to find knowledge structure from student response data. Baffes and Mooney (1996) apply theory refinement to the problem of modeling incorrect student behavior. In addition, some research (e.g., Langley \& Ohlsson, 1984) uses artificial intelligent techniques to construct models that explain student's behavior in math domains. Besides SimStudent, there has also been considerable research on models of high-level learning (e.g., Laird, Rosenbloom, \& Newell, 1986; Anderson, 1993; Taatgen \& Lee, 2003; Sun, 2007; Tenenbaum \& Griffiths, 2001; Schmid \& Kitzelmann, 2011). Other research on creating simulated students (e.g., Chan \& Chou, 1997) is also closely related to our work. Nevertheless, none of the above approaches focused on modeling how representation learning affects skill learning. Moreover, none of them compared the system with human learning curve data. To the best of our knowledge, our work is the first combination of the two whereby we use cognitive model evaluation techniques to assess the quality of a simulated learner, and demonstrate it across multiple domains.

## Conclusion

In this paper, we evaluated the generality of an automatic cognitive model discovery method, and carried out an in-depth analysis to better understand the proposed approach. To avoid over-generalization of KCs, we would like to further extend the skill learning component to maintain utilities associated with each production rule. Further, we plan to investigate discovery of cognitive models for individual students, to provide more personalized learning. Finally, we plan to further integrate the perceptual learning component into skill learning, so that the representation acquired by the learner is refined during the process learning.

In the study, we show that the integration of the representation learning component into skill learning is key to the success of SimStudent in discovering cognitive models. Results indicate that in two out of three domains,

SimStudent-generated models are better predictors of human students' learning performance than human-coded models. For the third domain, when given the SimStudent- and human-generated KCs, LFA finds a better model than the human-generated one. A closer analysis shows that SimStudent is able to split existing KCs into finer grain sizes, discover new KCs, and uncover expert blind spots.

#### Abstract

In learned helplessness experiments, subjects first experience a lack of control in one situation, and then show learning deficits when performing or learning another task in another situation. Generalization, thus, is at the core of the learned helplessness phenomenon. Substantial experimental and theoretical effort has been invested into establishing that a state- and task-independent belief about controllability is necessary. However, to what extent generalization is also sufficient to explain the transfer has not been examined. Here, we show qualitatively and quantitatively that Bayesian learning of action-outcome contingencies at three levels of abstraction is sufficient to account for the key features of learned helplessness, including escape deficits and impairment of appetitive learning after inescapable shocks.

## Introduction

Helplessness is a failure to avoid punishment or obtain rewards even though they are under the agent's control. The aetiology and consequences of helplessness have been studied extensively in the animal learning literature using the learned helplessness paradigm [1]. In this paradigm, helplessness is induced in healthy animals by exposure to inescapable electric shocks. Helplessness is then measured by the subsequent failure to escape escapable shocks in a novel environment. The phenomenon was first demonstrated in dogs in the context of testing the two-factor learning theory using the shuttle-box escape task [2]. In the now classical version of the task, three animals are compared. A master rat experiences electrical shocks. These come on unpredictably, but can be terminated by some action, for instance turning a wheel. A yoked rat is exposed to the exact same sequence of shocks that are delivered to the master rat, but has no action available to terminate the shocks. A third rat, the control, is not exposed to shocks. Compared to the controls, the yoked rats are impaired at acquiring new instrumental responses, but the master rats are either unimpaired or may even show an improvement $[1,3]$. Effects reminiscent of those in animal learning have been demonstrated in humans. For instance, people who have been exposed to uncontrollable loud noise or insoluble problems are more likely give up on solving anagrams in a subsequent task [4]. Hopelessness theory is a translation of the helplessness concepts to the human and attributional realm [5].

Extensive animal and human experimentation and theoretical work have clarified that the crucial compo-
nent is a perceived lack of control rather than more specific explanations. First, exposure to one type of uncontrollable reinforcer in one situation can profoundly impair the acquisition of many other types of behaviours (including escape, jumping, immobility, lever pressing, and complex sequential behaviours) in a wide range of different situations [1]. Second, the effect of inescapable shocks is not due to shock-induced analgesia, because it also impairs reward seeking in the absence of negative reinforcers [6]; and as uncontrollable rewards can also induce helplessness [7-9]. Third, it is not reducible to an interference between learned motor inactivity as it also affects the ability to acquire behavioural suppression as an escape response [10]. Furthermore, in accordance with the finding that the probability of generalization increases with the variability of the examples (see [11]), learned helplessness lasts longer when it is induced by experiencing multiple mild stressors (chronic mild stress; [12]) than when it is induced by a single severe stressor. In conclusion, there is strong evidence suggesting that helplessness is learned by generalizing from one uncontrollable situation to believing that situations are uncontrollable in general.

Maier and Seligman formalized controllability in terms of the conditional probability of the reinforcer RF (reward or punishment) given whether or not action $A$ is taken $(A$ or $\bar{A})[1]$. According to their definition, the agent has control if and only if $P(\mathrm{RF} \mid A) \neq P(\mathrm{RF} \mid \bar{A})$. Huys and Dayan formalized the essence of this definition, i.e. that helplessness exists when altering behaviour does not alter outcomes, for multiple actions, outcomes, and degrees of desirability [13]. Here we continue [13]'s argument that generalization is central to learned helplessness by investigating two crucial interactions between perceived control and generalization:

1. Learning about the controllability of one situation transfers to novel situations via generalization.
2. Abstract knowledge about control determines how strongly the observation that a particular action had a particular effect will be generalized.

Using a hierarchical Bayesian model of action-outcomecontingencies we show that these interactions are sufficient to explain various deficits observed in the learned helplessness paradigm.

Figure 1: Hierarchical Bayesian model of statetransitions and controllability. $\boldsymbol{\theta}_{s, a}$ are the transition probabilities for taking action $a$ in state $s$ (level I). The second level, abstracts away from particular actions and represents the general outcome tendency $\boldsymbol{\beta}_{s}$ of situation $s$ and its controllability $\alpha_{s}$. The third level abstracts away from any particular state and represents how controllable the world is in general $(c)$ and how much states differ with respect to controllability $\left(\sigma_{c}^{2}\right)$.

## Methods

In a novel situation $s$, a rational agent may have to learn how likely each of the available actions $a_{1}, \cdots, a_{m}$ is to lead into each of the potential successor states $s_{1}, \cdots, s_{n}$. In the absence of knowledge about the particular situation $s$, the agent can bring experience in other situations $s^{\prime}$ to bear on the problem, i.e. it can use its knowledge about one part of the transition matrix to inform its belief about others. Hierarchical Bayesian formulations provide a normative framework for such generalizations $[11,14]$. In this section, we present such a model of state-transition probabilities with three levels of hierarchy (see Figures 1 and 2). At the lowest level are the probabilities that taking action $a$ in state $s$ will lead to state $s^{\prime}$. At the second level, the model represents the typical outcome probabilities of actions in any one particular situation $s$ and how different the outcomes of different actions tend to be. The more actions are believed to have similar outcomes, the less control there is. At the third and most abstract level, the model represents knowledge about how controllable situations are in general. In this model beliefs about the world's controllability acts as an over-hypothesis that shapes how the agent learns state-transition probabilities (cf. [14]). Concretely, the agent's belief about the state $S_{t+1}$ resulting from taking action $a$ in state $s$ is a multinomial distribution (Equation 1). The agent assumes that the transition probabilities $\boldsymbol{\theta}_{a, s}$ of the actions a available in state $s$ are all drawn from the same distribution: a Dirichlet distribution with the state-specific mean vector $\boldsymbol{\beta}_{s}$ and

$$
\begin{align*}
\forall a, s: S_{t+1} \mid S_{t}=s, A_{t}=a & \sim \operatorname{Multinomial}\left(\boldsymbol{\theta}_{a, s}\right)  \tag{1}\\
\forall a, s: \theta_{\mathbf{a}, \mathbf{s}} & \sim \operatorname{Dirichlet}\left(\alpha_{s} \cdot \boldsymbol{\beta}_{s}\right)  \tag{2}\\
\forall s:-\log \left(\alpha_{s}\right) & \sim \mathcal{N}\left(c, \sigma_{c}^{2}\right)  \tag{3}\\
\forall s: \beta_{s} & \sim \operatorname{Dirichlet}(\mathbf{1})  \tag{4}\\
c & \sim \mathcal{N}\left(\mu, \sigma_{\mu}^{2}\right)  \tag{5}\\
\sigma_{c}^{2} & \sim \operatorname{InvGamma}\left(\alpha_{\sigma}, \beta_{\sigma}\right) \tag{6}
\end{align*}
$$

Figure 2: The functional dependencies of the graphical model in Figure 1.
a second parameter $\alpha_{s}$ that determines the controllability of situation $s$ (Equation 2). If $\alpha_{s}$ goes to $\infty$, then the agent becomes sure that the transition probabilities $\boldsymbol{\theta}_{a_{1}, s}, \cdots, \boldsymbol{\theta}_{a_{N}, s}$ are independent of the agent's action $a$. This means that the situation is uncontrollable (corresponding to the second notion of controllability in [13]). Values of $\alpha_{s}$ close to zero corresponds to the belief that the transition probabilities $\boldsymbol{\theta}_{a_{1}, s}, \cdots, \boldsymbol{\theta}_{a_{N}, s}$ for different actions are uninformative about each other and hence can differ. To allow for the transfer of knowledge between states, a further level is needed: in addition to its belief about the controllability $\alpha_{s}$ of individual situations $s$, the agent also has a belief about how controllable situations are in general. This belief is described by a normal distribution on $-\log \left(\alpha_{s}\right)$ (Equation 3). The parameter $c=\mathbb{E}[-\log (\alpha)]$ expresses how controllable situations are on average, and $\sigma_{c}^{2}$ expresses how much controllability varies from situation to situation.

The average controllability $c$ and the variability of control $\sigma_{c}^{2}$ are unknown properties of the world that have to be learned from experience. We describe the agent's prior beliefs about these quantities by a normal distribution on $c$ (Equation 5) and an Inverse-Gamma distribution on $\sigma_{c}^{2}$ (Equation 6). In this model helplessness results from a probabilistic belief that one's control over the world is low on average (low $c$ ) and varies very little across situations (low $\sigma_{c}^{2}$ ).

Assuming that this hierarchical Bayesian model captures the subjects' internal representation of transition probabilities and control, we can examine how they infer the controllability $c$ of the world in general from the observations $\mathbf{o}=\left\{\left(s_{1}, a_{1}, s_{2}\right), \cdots,\left(s_{t-1}, a_{t-1}, s_{t}\right)\right\}$ of the state transitions $\left(s_{1}, s_{2}\right), \cdots,\left(s_{t-1}, s_{t}\right)$ and their actions $a_{1}, \cdots, a_{t}$. In addition, we can simulate the weaker generalization on the situation-specific controllability $\alpha_{s}$ and transition-tendency $\boldsymbol{\beta}_{s}$ by computing $P\left(\alpha_{s}, \boldsymbol{\beta}_{s} \mid \mathbf{o}\right)$. Finally, we can investigate how this generalization is shaped by abstract beliefs about control $\left(P\left(c, \sigma_{c}^{2}\right)\right)$.
Simulations The effects of controllable and uncontrollable shocks were modelled by simulating the learning process taking place during the shocks as Bayesian inference on $c$ and $\sigma_{c}^{2}$. The naive subjects' belief about controllability was modelled by a probability distribution with $\mathbb{E}[\alpha]=10$ and $\operatorname{Var}[\alpha]=100$; the variance of the prior beliefs was 100 for $c$ and 0.1 for $\sigma_{c}^{2}$. To model the observations resulting from controllable $\left(\mathbf{o}_{\mathrm{c}}\right)$ versus uncontrollable shocks ( $\mathbf{o}_{\neg \subset}$ ), we assumed one observation
per second during 64 shocks lasting 60 seconds each. For controllable shocks there was one action $\left(a_{1}\right)$ that would always terminate the shock $\left(s_{1} \rightarrow s_{2}\right)$ and four actions that did not $\left(s_{1} \rightarrow s_{1}\right)$, whereas there was no such action for uncontrollable shocks.

Learning after exposure to shocks was modelled as Bayesian inference on $\boldsymbol{\alpha}, \boldsymbol{\beta}$ given $c=\mathbb{E}\left[c \mid o_{\neg c}\right]$ and $\sigma_{c}^{2}=$ $\mathbb{E}\left[\sigma_{c}^{2} \mid o_{\neg c}\right]$ for uncontrollable shocks versus $c=\mathbb{E}\left[c \mid o_{c}\right]$ and $\sigma_{c}^{2}=\mathbb{E}\left[\sigma_{c}^{2} \mid o_{c}\right]$ for controllable shocks.

Inference was performed using Markov chain Monte-Carlo (MCMC) methods. To sample from $P\left(\boldsymbol{\alpha}, \boldsymbol{\beta}, c, \sigma_{c}^{2} \mid \mathbf{o}\right)$, we used a Metropolis-Hastings algorithm with Gaussian random-walk proposals on $c$ and $-\log (\alpha)$. The proposal for $\boldsymbol{\beta}_{t+1}$ was Dirichlet $\left(10 n \cdot \boldsymbol{\beta}_{t}\right)$ where $n$ is the number of states, and the proposal for $\sigma_{c, t+1}^{2}$ was an Inverse-Gamma distribution with mean $\sigma_{c, t}^{2}$ and variance 1. 50 Markov chains were run for 51000 iterations with a burn-in period of 1000 iterations. $P\left(\boldsymbol{\alpha}, \boldsymbol{\beta} \mid c, \sigma_{c}^{2}, \mathbf{o}\right)$ was computed in the same way. The posterior expectation of $\boldsymbol{\theta}$ was computed using Monte-Carlo integration: $\mathbb{E}\left[\boldsymbol{\theta} \mid \mathbf{o}, c, \sigma_{c}^{2}\right]=\int \mathbb{E}[\boldsymbol{\theta} \mid \alpha, \beta, \mathbf{o}] \cdot p\left(\boldsymbol{\alpha}, \boldsymbol{\beta} \mid \mathbf{o}, c, \sigma_{c}^{2}\right) d \boldsymbol{\alpha} d \boldsymbol{\beta} \approx$ $\frac{1}{m} \sum_{i=1}^{m} \mathbb{E}\left[\boldsymbol{\theta} \mid \boldsymbol{\alpha}_{i}, \boldsymbol{\beta}_{i}, \mathbf{o}\right]$ with $\boldsymbol{\alpha}_{i}, \boldsymbol{\beta}_{i} \sim P\left(\boldsymbol{\alpha}, \boldsymbol{\beta} \mid \mathbf{o}, c, \sigma_{c}^{2}\right)$.

## Results

As a first step in assessing whether generalization can account for the differential effects of controllable versus uncontrollable stress, we simulated Bayesian learning from these experiences according to the model shown in Figure 1. Figure 3A shows the simulated changes in perceived controllability induced by the escapable and inescapable shocks administered in the learned helplessness paradigm [15]. After inescapable shocks, the subjects' perceived control $c$ was reduced, whereas controllable shocks increased it. Furthermore, controllable shocks increased the estimated variability of control across situations, whereas no such change was observed after inescapable shocks (Figure 3B). Thus, the two kinds of shocks have opposite effects on the subjects' high-level beliefs about controllability.

We next asked whether the beliefs induced by uncontrollable shocks were sufficient to impair escape learning in a different task, and whether the beliefs induced by controllable shocks have the opposite (mastery) effect. We modelled these beliefs by the inferred mean and variance of $c$ for escapable and inescapable shocks and simulated learning in the shuttle-box escape task. As a first step, we simulated learning from given observations with one action that did $\left(a_{1}\right)$ and four actions that did not cancel the shock $\left(a_{2}, \cdots, a_{5}\right)$. Concretely, we simulated how strongly naive subjects, subjects who had experienced inescapable shocks (yoked), and subjects who had experienced escapable shocks (masters) would believe that action $a_{1}$ cancels the shock after having taken action $a_{1}$ for $0,1,2,4,8,16$ or 32 times and each of the four other actions 8 times. Figure 4 shows that yoked subjects (red) acquired the escape response more slowly than naive subjects (blue): more evidence was required before they believed that the action was efficient in terminating the shock. Furthermore, the model

Figure 3: A: Expected controllability learned from controllable or uncontrollable electric shocks. The values on the x-axis are the change $\Delta c$ relative to the controllability expected by naive subjects and height of the bars shows how strongly the simulated agent beliefs in the corresponding value of $c$. B: Variance of controllability learned from controllable and uncontrollable electric shocks. The values on the x -axis are the change $\Delta c$ relative to the variability expected by naive subjects and height of the bars shows how strongly the simulated agent beliefs in the corresponding value of $\sigma_{c}^{2}$.

Figure 4: Simulated effects of controllable and uncontrollable shocks on the speed of learning that action 1 terminates the shock.
also captured mastery effects, whereby prior exposure to controllable shocks leads to faster learning (green; [16]).

To more quantitatively relate the learning dynamics shown in Figure 4 to empirical data, we simulated learning and decision making in the fixed-ratio operant conditioning task of [17]. In this task, rats have to learn to press a lever, but only every third lever press terminates the shock. This task was modelled as sequentialdecision making. To do so, we partitioned the 60 seconds of each trial in [17]'s experiment into 30 bins, each 2 seconds long, and simulated one decision, one observation, and one belief update for every bin. The simulated choices were to stay still $\left(a_{0}\right)$, to push the lever $\left(a_{1}\right)$, or to perform a different action $\left(a_{2}\right)$. The reward for staying still and receiving the shock was modelled as -1 $\left(r\left(s_{1}, a_{0}, s_{1}\right)=-1\right)$. Moving and receiving a shock was assumed to incur a small additional cost $\left(r\left(s_{1}, a_{2}, s_{1}\right)=\right.$ $-1.2)$. If the action stopped the shock, it was assumed to incur only the cost of movement $\left(r\left(s_{1}, a_{0}, s_{2}\right)=0\right.$ and $r\left(s_{1}, a_{i}, s_{2}\right)=-0.2$ for $\left.i \in\{1,2\}\right)$. We assumed that rats

Figure 5: The left panel shows empirical data acquired by [17] as shown in [1]. The plots on right show our simulations of the experiment.
learn the probability $P\left(S_{t+1}=s_{2} \mid S_{t}=s_{1}, A_{t}=a_{i}\right)$ that an action $a_{i}$ terminates the shock (an alternative model might consider treating different numbers of lever presses as separate actions). The subjects' internal representation of transition probabilities was modelled as the hierarchical Bayesian model shown in Figure 1. The rat's decision making was simulated by a sampling algorithm to produce behaviour akin to probability-matching [18]. Specifically, we assumed that the rat simulates five outcomes $u_{i, j}=r\left(s, a_{i}, s_{j}^{\prime}\right), s_{j}^{\prime} \sim P\left(S_{t+1} \mid S_{t}=s, A_{t}=a_{i}\right)$ of each action $a_{i}$ and chooses the action $a_{i}$ for which the average utility $\frac{1}{5} \sum_{j=1}^{5} u_{i, j}$ was largest, and ties were broken at random. Under these assumptions, the learning dynamics shown in Figure 4 capture the qualitative effects of uncontrollable shocks on the probability to escape shock and the time required to do so [17]: yoked subjects failed to escape more often than naive subjects (Figure 5, left panel), and when they succeeded to escape it took them longer (Figure 5, right panel). Furthermore, our model accounts for the mastery effect that rats who had been exposed to controllable shocks prior to the task, escaped faster than rats with no prior exposure to shock.

As outlined in the introduction, learned helplessness impairs not only the ability to learn from punishments but also from rewards. To assess whether our model captures this effect, we simulated the experiment by [6]. In the experiment's appetitive choice task, rats were rewarded with food for going into one of two chambers after they had been trained to prefer the other chamber. We modelled this task as a sequence of decisions, observations, and belief updates as described above. As Figure 6 shows our model captures that uncontrollable shocks reduced the probability that a rat would first seek out the chamber in which a reward would be delivered. Thus this apparently anhedonic behaviour can be explained purely in terms of impaired associative learning due the generalization that the world is uncontrollable.

Next, we asked whether our model can account for the finding that the effect of learned helplessness is most pronounced in tasks that are complex and require persistence. To answer this question, we simulated decision

Figure 6: Simulation of the appetitive choice distinction task by [6]. Our simulation captures that yoked rats performed worse than naive rats across all 10 blocks of the experiment.

Figure 7: Simulation of the experiment by [19]. Dashed lines are model predictions; diamonds are data points. The three columns correspond to the experimental conditions requiring 1,2 , or 3 lever presses.
making and learning in the experiment by [19]. In this experiment, yoked rats did learn to escape response when one or two, but not when three lever presses were required. In Figure 7, we show that the model can quantitatively capture the increasing penetrance of inescapable shock exposure with increasing escape response requirements.

## Discussion

Our results indicate that a normative account of generalization of action-outcome contingencies is sufficient to produce a wide range of phenomena observed in learned helplessness experiments. The account captures (i) how helplessness is induced by uncontrollable stressors and why it transfers to novel situations, (ii) why controllable stress fails to induce helplessness, (iii) that helplessness results from impaired learning that different actions have different effects, (iv) mastery effects, (v) impaired reward seeking, and (vi) the interaction between helplessness and task requirements. This suggests that the generalization of experienced control may be sufficient to account for many learned helplessness effects.

Note that our model explains helplessness as the consequence of rational learning and generalization (cf. $[11,14])$ from uncontrollable stress. Mirroring the fact that learned helplessness induces depression-like states in healthy animals and affects healthy humans, this sug-
gests one pathway by which learned helplessness may arise as a rational adaptation to an uncontrollable environment rather than from negative biases or dysfunctional information processing. In the present account, the generalization that leads to helplessness is that different actions tend to have the same effect. This generalization can occur at two levels of abstraction: (i) from the outcomes of some actions in a given situation to the outcomes of all actions available in that situation, and (ii) from the controllability of one situation to the controllability of situations in general. Our model predicts that after uncontrollable stress generalizations of the first type will be unusually strong. This may capture overgeneralization - a frequent feature of depressive thought in humans [20] - and the model explains how this learning style increases the risk for helplessness by fostering the belief that all actions are equal.

According to the classical notion [1], control requires that taking an action or not alters the probability of outcomes. Our model generalizes this notion by allowing for multiple actions, multiple outcomes, and two additional levels of abstraction, and it expands it from a binary distinction to a graded, quantitative measure of controllability. As a result, our model instantiates [13]'s second type of controllability which captured on the achievability of different outcomes. While the notion of control presented here does not take into account the outcomes' desirability (type 3 in [13]), it refines [13]'s proposal of how helplessness might be learned by generalization in two regards. First, [13] juxtaposed two extremes of generalization: the controllabilities of different environments are (i) independent (no generalization) or (ii) identical (full generalization). Arguably, both extremes correspond to pathologically inaccurate models of the world. By contrast, the hierarchical generative model proposed here formalizes the more realistic intermediate assumption that although some situations are more controllable than others, knowing about the controllability of one situation is informative about the controllability of other situations. Second, inference in this model captures an important aspect of attribution: Was the outcome due to the action I took or due to the situation I was in? In the model, a perceived lack of control induces misattributions that impair learning: the over-hypothesis that the world is uncontrollable renders implausible any interpretation according to which different actions have different effects. Therefore the perceived lack of control biases people to attribute the outcome of taking action $a$ in state $s$ to the state $s$ rather than to the action that they have taken. For extreme helplessness the situation's action-independent outcome tendency $\boldsymbol{\beta}_{s}$ will be updated just as much as the outcome probabilities $\boldsymbol{\theta}_{s, a}$ of taking action $a$ in this situation. Conversely, the actionspecific outcome probabilities $\boldsymbol{\theta}_{s, a}$ will be updated no more than $\boldsymbol{\beta}_{s}$, and the outcomes of actions $b, c, d, \cdots$ will influence the belief about $\boldsymbol{\theta}_{s, a}$ almost as much as the outcomes of action $a$ itself. This increases the amount of evidence required to discover that there is an action that achieves the goal while most other actions do not, and this is how the perceived lack of control impairs learn-
ing. Thus, according to our model, helpless behaviour in simple tasks results from slowed learning of transition probabilities. This complements a recent model of how the perceived lack of control impairs planning in complex, sequential decision problems [21].

Despite the encouraging results reported here, more research is needed to establish the validity of this modelling approach. Our simulation of the experiment reported in [19] did not fully capture the rats' learning dynamics and overestimated their performance in the simplest condition. These discrepancies could be due to the simplistic assumption that rats do not associate shock termination with the number of lever presses but only with their most recent action. As a result, the fit achieved by the reported simulation is not substantially better than the fit obtained by reducing the subjective intensity of the shock (data not shown). Therefore the results of our simulations (Figure 7) could be mimicked by analgesia [19, 22]. Furthermore, our model failed to capture the precise pattern of the data in [6]. However, the two hypotheses might be discernible using data that reveal the dynamics of learning, or by directly probing subjects' beliefs about outcome probabilities in the absence of rewards.

There are important aspects of helplessness that our model does not capture yet. It needs to assume surprisingly weak priors to explain why helplessness can be learned so rapidly -an assumption that is difficult to extend to mature animals with a lifetime of experience. Conversely, it would be challenging to explain with our model why even severe shock-induced helplessness tends to fade within 48 hours. To capture these two suggestions of temporal (in)stability of helplessness, our model could be extended by replacing the constant $c$ by a Gaussian random walk $C(t)$. This would take into account that how much control a person has, changes throughout his or her life. It could be used to explain why a very brief period of uncontrollable stress can induce helplessness despite a lifetime of experience in a controllable environment. This extension may also explain why the speed of learning about controllability increases with the environment's perceived volatility (cf. [23, 24]). Beyond these cognitive signatures of helplessness, our model has yet to engage with the affective and subjective aspects of helplessness.

Our model suggests a number of avenues for future work. As normative inference, exposure to sufficient controllability will lead to the correct inference, suggesting that experience of control should heal helplessness, and thus that the escape deficit should be temporary. Why and how the experience of shocks that an animal did not attempt to escape may nurture helpless beliefs may necessitate adaptations in the inference. Nevertheless, the model does capture that controllable stress can immunize subjects against the effects of uncontrollable stress, and suggests two computational mechanisms: first a higher expected controllability, and second a higher estimate of the variability of control across situations. If the initial expected controllability is higher, then a given reduction in perceived control may no longer be sufficient
to induce learned helplessness. Alternatively, a higher estimate of the variability of control across situations would reduce the strength of the generalization from uncontrollable stress in one situation to the controllability of the world in general. This theoretical work does, however, also echo the likely limited benefits of exposure because a subjects' helpless choices in some situations, paired with strong tendencies to generalise, can produce sufficient evidence of lack of control to drown any islands of controllability.

Our model may be able to illuminate why and how the effects of chronic-mild stress [12] differ from the effects of severe-acute stress in their scope, severity, and duration. The results suggests that the underlying mechanisms can be understood in terms of well-studied general generalization phenomena [11]. For instance, since the strength of a generalization increases with the variability of the examples, the experience of multiple stressors should render the effects of chronic mild stress more general than the equivalent amount of stress experienced in a single situation.

Learned helplessness is a behavioural paradigm with parallels in humans and animal models, and with established validity in research on depression [25]. Using methods from reinforcement and machine learning, this work has shown that abstract learning and generalization about controllability explain many of the key features of learned helplessness in animals.

# Is it Time Bayes went Fishing? Bayesian Probabilistic Reasoning in a Category Learning Task 

Marcus Lindskog (marcus.lindskog@psyk.uu.se), Anders Winman (anders.winman@psyk.uu.se), Peter Juslin (peter.juslin@psyk.uu.se)<br>Department of Psychology, Uppsala University, P. O Box 1225, Uppsala, 75142 Sweden

#### Abstract

People have generally been considered poor at probabilistic reasoning, producing subjective probability estimates that far from accord to normative rules. Features of the typical probabilistic reasoning task, however, make strong conclusions difficult. The present study, therefore, combines research on probabilistic reasoning with research on category learning where participants learn base rates and likelihoods in a category-learning task. Later they produce estimates of posterior probability based on the learnt probabilities. The results show that our participants can produce subjective probability estimates that are well calibrated against the normative Bayesian probability and are sensitive to base rates. Further, they have accurate knowledge of both base rate and means of the categories encountered during learning. This indicates that under some conditions people might be better at probabilistic reasoning than what could be expected from previous research.

Keywords: Probabilistic reasoning, category learning, Bayes’ theorem, base rate

## Introduction

Research concerned with human probability judgment has been dominated by the general conclusion that people are poor at reasoning with probabilities because they substitute hard facts about probabilities with subjective variables that are conveniently available (see e.g., Gilovich, Griffin, \& Kahneman, 2002). In fact, with respect to tasks requiring people to integrate probabilities according to Bayes’ theorem the verdict is even harder, as summarized by a quote from Kahneman and Tversky (1972, p. 450): "In his evaluation of evidence, man is apparently not a conservative Bayesian: he is not a Bayesian at all." In the present study, we present results indicating that, at least under some conditions, the claim by Kahneman and Tversky might have been somewhat premature.

To appreciate the kind of task our participants are faced with, imagine going to catch fish in a lake where the fishing authorities have farmed two kinds of bass: copper bass, and silver bass. The two kinds of bass look identical and the only feature that distinguishes them is that the copper bass weighs, on average, a little less than the silver bass. While looking identical they, however, taste very differently. If you want a delicious dinner, you should go for the silver bass while if you want to feel sick you should choose a
copper bass. To make sure that the lake is not over fished the authorities have also decided that, at all time, the ratio of copper to silver bass should be 8:2, a piece of information not made publically available.

The fish scenario illustrates a type of situation that people engage in frequently in their everyday lives. The fishermen estimate the probability of a new object belonging to a category based on previous experience. That is, each time a fish is taken out of the lake the fisherman needs to estimate the probability of a given fish being a copper or a silver bass. The estimate is informed by experience with fish previously taken up out of the lake and cooked for dinner, thus effectively categorized as copper or silver bass. More specifically, this illustrates a situation where an observer needs to learn base rates and likelihoods from experience and later integrate this information to reach an estimate of a posterior probability. In such, the fish scenario incorporates two areas of cognitive psychology: probabilistic reasoning and category learning, that have been extensively investigated separately, but seldom together (but see, Nilsson, Olsson, \& Juslin, 2005).

## Probabilistic Reasoning

Research on human probabilistic reasoning has mainly been concerned with the evaluation of subjective probability estimates against normative rules of probability. In the typical experiment, the subjective estimates are informed by a set of probabilities explicitly stated in the task. Consider, for example, the cab problem (Tversky \& Kahneman, 1980) where participants are asked to estimate the probability of a cab involved in an accident being blue rather than green based on the base rates of blue (.15) and green (.85) cabs and the hit-rate (.8) of an eyewitness with both the base rate and hit-rate being explicitly stated in the task. The normative answer (.41) can be found by integrating the information in the problem using Bayes' theorem.

When presented with the cab problem, and similar problems, people tend to give probability estimates that are much higher than what is implied by Bayes' theorem. Often the modal response is closer to the hit-rate of the eyewitness (.8). This pattern of results is commonly interpreted as a captivation in participants by the hit-rate along with neglect of the base rate (.15). The dominating explanation to this apparent neglect of base rates has been that people are prone
to use judgmental heuristics (e.g. the representativeness heuristic) that ignore base rates (e.g., Kahneman \& Tversky, 1972; but see, Koehler, 1996). More recent accounts of probabilistic reasoning, suggesting that people are prone to linear additive information integration, argue instead that the non-normative answers are the result of how probabilities are integrated rather than the use of heuristics per se (Juslin, Nilsson, \& Winman, 2009; Juslin, Nilsson, Winman, \& Lindskog, 2011).

Regardless of the underlying mechanisms explaining the results, the use of complex normative rules, such as Bayes’ theorem, to integrate probabilities seems to be beyond the ability of most people (e.g., Eddy, 1982; Gigerenzer \& Hoffrage, 1995). In fact, even explicit instructions regarding how to use Bayes' theorem to integrate the information is insufficient to improve people's judgments (Juslin et al., 2011). It should be noted, however, that the despite the somewhat discouraging picture painted by previous research, recent accounts of human cognition (e.g., Oaksford \& Chater, 2009; Tenenbaum, Kemp, Griffiths, \& Goodman, 2011) have indicated that people are rational Bayesian agents with a remarkable ability to integrate information in accordance with the laws of Bayesian probability theory.

The extent to which people's probability estimates in Bayesian reasoning tasks coincide with the normative answer has largely been tested using tasks similar to the cab problem. Three features of these types of tasks are noteworthy, features that might influence the conclusions that can be drawn about human probabilistic reasoning. First, the information to be integrated (base rates, likelihoods, etc.) is explicitly given to participants in the form of probabilities (e.g., Kahneman \& Tversky, 1972) or, sometimes, frequencies (e.g., Gigerenzer \& Hoffrage, 1995). Second, the tasks are commonly set up to give a posterior probability that is low, often .40 or smaller. Finally, the outcome for which the posterior probability is estimated is often binary (blue or green cab, disease or no disease, engineer or lawyer, etc.). All of these task features make it difficult to draw strong conclusions about the ability of people to integrate probabilistic information. In everyday life, people are unlikely to come across situations where probabilities are explicitly stated. They rather encounter situations, like the fishing example above, where probabilities are learned from experience. Many real life situations also include an outcome, for which the posterior probability is estimated, that is continuous rather than binary. Furthermore, the restriction of the range of posterior probabilities makes conclusions about the extent to which people are calibrated against the Bayesian probability difficult due to regression effects. In order to address these three issues it is necessary to find a task where participants learn probabilities from experience and where it is possible to elicit probability estimates on the entire 0 to 1 range for a
continuous outcome variable. One promising candidate is found in category learning.

## Probabilistic Reasoning and Category learning

In the typical categorization task participants are presented with a number of stimuli from two or more categories and are asked to assign an appropriate category to each based on a set of features. During learning, the categorization is often followed by feedback regarding the correct category.

The literature contains several different models of how categorization is made, including prototype, exemplar, and decision-bound models (Ashby \& Maddox, 2005). The purpose of this study is not to distinguish between the different kinds of models. Rather, we draw upon the notion that most models of human categorization make assumptions about: a) how and what information is accessed from the categories and what computations are performed on this information and, b) how a response is selected after computations are made (Ashby \& Alfonso-Reese, 1995). For most models that assume a probabilistic, in contrast to a deterministic, response selection process, the decision rule subjects are assumed to use could be described as; respond category A to stimulus $x$ with probability $M(\mathrm{x})$ where:

$$
\begin{equation*}
M(x)=\frac{\beta_{A} S_{x A}}{\beta_{A} S_{x A}+\beta_{B} S_{x B}} \tag{1}
\end{equation*}
$$

In this expression $\beta_{i}$ is the response bias towards category $i$ and $S_{x i}$ is a measure of the similarity between stimulus $x$ and category $j$. At least under some conditions Eq. 1 can be reduced to

$$
\begin{equation*}
M(x)=\frac{\hat{P}(A) \hat{f}_{A}(x)}{\hat{P}(A) \hat{f}_{A}(x)+\hat{P}(B) \hat{f}_{B}(x)} \tag{2}
\end{equation*}
$$

where $\hat{P}(i)$ and $\hat{f}_{i}$ are estimators of the base rate and probability density function of category $i$ respectively (Anderson, 1991; Ashby \& Alfonso-Reese, 1995). Ashby and Alfonso-Reese (1995) argued that these properties of the categorization task transform it into a density estimation task where participants are faced with estimating base rates and probability density functions of each category. Indeed, several investigations of models of categorization have shown that they are mathematically equivalent to density estimation (e.g., Anderson, 1991; Ashby \& Alfonso-Reese, 1995; Griffiths, Sanborn, Canini, \& Navarro, 2008)
The similarities between Bayes' theorem and Eq. 2 suggest that categorization tasks are similar to probabilistic reasoning tasks with the difference that while probabilities are explicitly stated in the reasoning task they need to be learned from trial-by-trial feedback in the categorization task. Further, while the literature on probabilistic reasoning is somewhat pessimistic about people's ability to integrate
probabilities the categorization literature suggests that people are quite apt at categorization (Ashby \& Maddox, 2005). However, while research on categorization has been extensively concerned with how categories are represented and the processes leading up to a categorization (Ashby \& Maddox, 2005) it has put much less focus on the extent to which base rates and likelihoods are learned. Further, the typical categorization task requires participants to assign a stimulus to a category leaving the question of whether $M(\mathrm{x})$ in Eq. 2 is close to the normative posterior probability unanswered.

It should be noted that categorization research indicates that people are able to learn base rate information from experience (Medin \& Edelson, 1988), at least under some conditions, and that models of categorization can be seen as the cognitive substrate of subjective probability estimates (Nilsson et al., 2005).

## The Present Study

The present study investigates the accuracy of subjective probability estimates in a Bayesian probability reasoning task. Instead of being presented with base rates and likelihoods explicitly, however, participants learn them through experience in a categorization task.

Further, we elicit probabilities from the entire range of possible posterior probabilities for a continuous outcome variable in order to have a task that is as ecologically valid as possible.

To investigate factors that might influence the learning of base rates and likelihoods as well as the process used to elicit probability estimates, we manipulate both base rate and the distance between categories (i.e., the likelihood ratio).

## Method

## Participants

Participants were 40 ( 24 female and 16 male) undergraduate students from Uppsala University with a mean age of 25.1 years ( $S D=4.3$ years). They received a movie ticket or course credits for their participation.

## Design

The experiment used a $2 x 2$ between-subjects design with base-rate-ratios (8:2/6:4) and category-distance (short / far) as independent variables.

## Materials and Procedure

The computerized task was carried out on a PC and consisted of a learning phase and a test phase. On each of the 200 trials in the learning phase, participants categorized an exemplar to one of two categories ( A and B ) along a single dimension. The number of exemplars from each category was determined by the base-rate-ratio. In the 8:2condition the ratio of the number of exemplars in the two
categories was 8:2 (i.e., 160 A-exemplars and 40 Bexemplars) and in the other condition it was $6: 4$. The 200 items were presented in an individually randomized order.

A unique training set was created for each participant by randomly sampling stimuli from two Gaussian distributions with equal standard deviation $(\sigma=6)$. In the short categorydistance condition, the mean of the two Gaussians were 40 and 49 respectively while in the far condition they were 40 and 52. Whether category A or B had the highest mean was counterbalanced over participants.

The experiment used two cover stories. Either the categories where two types of projectors (Braun / Kodak) categorized on their brightness (lumens) or two types of disease (Buragamo / Terrigitis) categorized on the fictitious PKS-value. Participants were told that the values they would experiences were created specifically for this study and that they could not use any prior knowledge to solve the categorization task. The two cover stories, and which category was A or B, was counterbalanced over participants.

On each of the 52 trials in the test phase participants were presented with a value (lumens or PKS) not seen in training and were asked to state the probability (in percent) that the item belonged to category A (i.e., the category with the highest base rate). To create the 52 items for the test phase the range of the training set was divided into eleven intervals based on the posterior probability $p_{A x}$ that a test item $x$ belonged to category $A\left(p_{A x}=0,0<p_{A x}<.1, .1 \leq\right.$ $p_{A x}<.2, \ldots, .9 \leq p_{A x}<1.0, p_{A x}=1.0$ ). For each of the nine middle intervals ( $0<p_{A X}<.1, \ldots 9 \leq p_{A x}<1.0$ ) four items were randomly drawn uniformly from that interval. Six items each were randomly drawn from the two extreme intervals, where the posterior probability is 0 and 1 . Finally, four critical items with an equal distance to the category means were included in the test set. After completing the test phase participants gave explicit estimates of the base rates and means of the two categories.

## Results

## Learning Performance

To investigate learning performance, the learning phase was divided into 10 blocks of 20 trials each. For each block, we calculated the proportion of correct categorizations. Figure 1 illustrates that participants quickly learn to categorize the training stimuli to the appropriate category with proportion correct reaching .8 at the end of the training phase.

We investigated the extent to which the base-rate-ratio and category-distance manipulations influenced the rate of learning by entering proportion correct as dependent variable into a $2 \times 2 \times 10$ split plot ANOVA with base-rateratio ( $8: 2$ / 6:4) and category-distance (short / far) as between-subjects independent variable and training block as within-subjects independent variable. The analysis revealed a significant main effect of training block $(F(9,324)=4.95$, $M S E=0.012, p<.001$ ) with a significant difference between the first and last block. Further, there was a significant main effect of category-distance $(F(1,36)=$
5.09, $M S E=0.068, p=.03$ ) where participants in the far condition performed better ( $M=.78, S E M=.018$ ) than participants in the short condition ( $M=.72$, $S E M=.018$ ). Notably this difference was significant also in the last training block $(t(38)=2.6, p=.01)$.

Figure 1: Proportion correct as a function of training block. Vertical bars denote 95 \% - confidence intervals.

Neither the main effect of base-rate-ratio $(F(1,36)=2.83$, $M S E=0.068, p=.10$ ) nor any of the interactions (all $p: s>$ .13) reached significance. Notice that while the main effect of category-condition indicates that it was easier for participants to learn the categories with means far apart as opposed to close together, the lack of interactions suggest an equal learning rate in all conditions.

## Subjective Probability Estimates

In the test phase participant gave explicit estimates of the posterior probability that an item $x$ belongs to category A (i.e., the category with the highest base rate). Figure 2 shows the mean estimated probability plotted against the normative Bayesian probability. In the figure, estimates are grouped into the eleven intervals described above.

As is evident from the figure participants are on average fairly well calibrated in their subjective probability estimates. To investigate the effect of base-rate-ratio and category-distance on the subjective estimates of posterior probability we calculated the mean absolute difference between the estimated and normative probability. The difference was entered as dependent variable into a 2 x 2 factorial ANOVA with base-rate-ratio (8:2 / 6:4) and category-distance (short / far) as between-subjects independent variables. There were no significant effects (all $p: s>.18$ ). Thus, probability estimates were on average not influenced by base-rate-ratio or category-distance.

To investigate a possible bias in the probability estimates the signed difference (rather than absolute difference) was entered into the corresponding ANOVA. Once again there were no significant effects (all $p:$ s > .26) and a single
sample t-test on the signed difference revealed that it did not differ significantly from $0(t(39)=.96, p=.35)$.

Figure 2: Subjective probability plotted against the normative Bayesian probability. Dotted line indicates perfect calibration.

The results illustrated in Figure 2 indicate that the accuracy of subjective probability estimates might vary as a function of the Bayesian posterior probability. To investigate this probability we conducted a more fine grained analysis where Bayesian probability interval was added as a within-subjects factor in the analysis of absolute error. This $2 \times 2 \times 11$ split-plot ANOVA revealed two significant effects. First, the main effect of Bayesian probability interval was significant $(F(10,360)=3.07$, MSE $=0.018, p<.001$ ). The effect is due to absolute errors for the larger probability intervals being smaller than those for the lower intervals. Second, the significant probability interval by base-rate-ratio $(F(10,360)=2.79, M S E=0.018$, $p<.001$ ) is illustrated in Figure 3 by means of a calibration curve. As can be seen in the figure, the interaction is due to estimates in the low probability intervals being slightly better for participants in the 6:4-condition than for participants in the 8:4-condition while it is the opposite in the high probability intervals.

The analysis above suggests that the base-rate-ratio manipulation might influence the extent to which participants use base rates to inform their subjective probability estimates. To investigate this possibility we analyzed participants’ probability estimates of the critical items included in the test set. Remember that the critical items are positioned with the same distance to both category means. If participants disregard the base rate information and instead use the ratio of the distance from a test item to each of the two means as a proxy for the posterior probability, or some similar strategy, they should estimate the posterior probability of all critical items to be .5.

Figure 3: Subjective probability plotted against the normative Bayesian probability for the two base-rate-ratio conditions separately. Dotted line indicates perfect calibration.

Figure 4 displays the distribution of responses to the critical items. As is evident from the figure a majority of responses are larger than .5 , indicating that participants take the base rate of the two categories into account when giving subjective probability estimates. To further investigate the use of base rates the subjective probability estimates of critical items were entered as dependent variable into a 2 x 2 factorial ANOVA with base-rate-ratio and category distance as between-subjects factors. One participant, considered an outlier ( $|z|>2.5$ ), was excluded from the analysis. The ANOVA revealed a significant main effect of base-rate-ratio $(F(1,35)=4.63, M S E=0.037, p=.038)$ with higher probability estimates in the $8: 2$-condition $(M=.76, S D=$ .14 ) then in the $6: 4$-condition ( $M=.62, S D=.24$ ). None of the other effects reached significance (both $p: s>.20$ ). More importantly in all conditions, participants gave estimates larger than .5 , even though not significantly larger in the short-6:4-condition, indicating sensitivity to base rates.

Figure 4: Distribution of subjective probability estimates of critical items in the test phase.

A further indication of sensitivity to base rates is given by the explicit estimates of base rates illustrated in Figure 5.

Figure 5: Means of explicit estimates of base rate for the four different true base rates separately. Vertical bars denote $95 \%$ - confidence intervals.

As can be seen in the figure the explicit estimates are sensitive to the experienced base rates. In addition there is little difference in the accuracy of estimates in the different conditions indicating that the differences in use of base rates seen above is not an effect of differences in learning.

## Discussion

Research on probabilistic reasoning has long been dominated by the general conclusion that people are very poor at integrating information according to the laws of probability (e.g., Bayes’ theorem). At the same time research concerned with category learning, indicates that people are quite apt at solving categorization tasks that, at least mathematically, are similar to probabilistic reasoning tasks. In the present study, we therefore combined these two research traditions by eliciting subjective posterior probabilities from base rates and likelihoods learned in a categorization tasks.

Performance in the learning phase indicated that our participants quickly learned to categorize the stimuli correctly. Performance was somewhat better when category means were far apart as opposed to close together. This was expected because the closer the two category means get the more two their probability density functions overlap, which in turn makes it more difficult to distinguish the two categories.

The subjective probability estimates given by participants in the test phase were, as is illustrated in Figure 2, well calibrated against the normative Bayesian probability. There was no systematic bias in the estimates and the pattern of results seen in Figure 2 suggests that the deviations from the normative Bayesian probability could be attributed to
regression effects. Notably, even though there was a difference in learning between the two category-distance conditions, this did not affect the correspondence of the subjective estimates.

The explicit estimates of base rates and category means indicated that participants learned these category properties. Arguably, however, they might not have used them to reach a subjective probability estimate. However, the analysis of the critical items included in the test phase showed that participants in all conditions were sensitive to the base rate and, at least to some extent, integrated this knowledge in their probability estimates.

Similar to previous research demonstrating that people can be good at reasoning under some conditions (e.g., Baron, 2000), the results of the present study show that when people are allowed to learn base rates and likelihoods in a category learning task they are at least under some conditions able to produce subjective probability estimates that are well calibrated and sensitive to base rates. This suggests that the conclusion by Kahneman and Tversky (1972, p. 450) may have been somewhat premature. An interesting question for future research is to investigate the processes leading up to what is apparently a normative answer.

# Extreme Expertise: Exploring Expert Behavior in Tetris 

John K. Lindstedt (lindsj3@rpi.edu) \& Wayne D. Gray (grayw@rpi.edu)<br>Cognitive Science Department<br>Rensselaer Polytechnic Institute

#### Abstract

Expertise is easy to identify in retrospect. It is the most expert player who wins the meet and the most proficient team that wins the playoffs. However, sometimes during play we see a masterful move that clearly separates one player from the competition. Our goal, in this work, is to identify the masterful moves or elements of expertise that predict the continuum of performance in the game of Tetris. As a first step we have collected data from a wide variety of Tetris Tournament players and used it to derive metrics of global, local, and immediate interactions. Here we present statistical models of these data and report the initial success of these models at predicting level of expertise.

Keywords: expertise, skill acquisition, exploratory analysis, videogames, regression modeling, thin-slicing

## Introduction

It seems easy to identify which baseball players are experts. We can look at their outputs: batting average, fouls, or total runs scored. The trouble is, we can only really make assessments on these outputs after the fact, once all the numbers are in, and the point is somewhat moot. But there must be something different about these experts at a more fundamental level, something identifiable in the way they are playing the game that forms the basis for their continued excellent performance.

What are the hallmarks of the exceptional player's expertise? Is it something about the way they grip the bat, or their stance? Is it in their ability to hit a certain kind of pitch over others? Are they slightly faster to respond, or more deliberate with their actions? Is it because they know when to bunt? Moreover, how much of the player's performance do we need to see in order to make an informed assessment of his or her expertise?

These questions lay the groundwork for asking the question: can we identify elements of expertise, behaviors made from instant to instant during performance which will allow us to rank a person on a scale ranging from novice to expert by observing just a thin slice of their behavior? We investigate this question using the video game Tetris.

## Background

The history of the scientific study of human expertise is nearly as long as the history of scientific psychology, with publications dating back to the discovery of the plateau in skill gain in telegraph operators in 1897 (Bryan and Harter), to an overthrowing of that notion in favor of continuous,
if subtle, skill gains throughout the acquisition of expertise (Keller, 1958), and ultimately to a reconciliation of the two findings as valid depending on the measurement device (e.g., Robertson \& Glines, 1985).

Our reading of the historical literature is that the discrepancy of major claims about the nature of expertise highlights the importance of metrics and of the available theoretical constructs. Although Bryan and Harter collected some data with millisecond accuracy, their general methodology lacked a few important controls and their main theoretical construct was stated in intuitive terms. Fifty years later, Keller (one of the foremost behaviorists of his day) had much higher standards for experimental design as well as a theoretical framework, behaviorism, that had no room for unobservable hierarchical structures. Just 30 years after Keller, Robertson and Glines had available to them the hierarchical theories of the information processing theorists as well as an understanding of the ways in which adopting different strategies could lead to differences in performance. As a consequence, unlike Keller when they looked, they found abundant evidence for individual differences in plateaus that seemed to reflect differences in strategies available or discoverable by students with different intellectual backgrounds (i.e., primarily engineers versus humanities students).

Our longterm goal is to provide a theoretical account of extreme expertise in dynamic tasks; that is, those which require an integration of real-time decision-making with a (figurative) tight loop among cognition, perception, and action. Examples of such skills include laproscopic surgery (Keehner et al., 2004), piloting jet aircraft and helicopters (Proctor, Bauer, \& Lucario, 2007; Hays, Jacobs, Prince, \& Salas, 1992), and detection of enemy submarines hiding in deep waters (Ehret, Gray, \& Kirschenbaum, 2000). Of course, we lack access to surgeons, helicopter pilots, and submarine commanders. However, we do have people who have spent thousands of hours acquiring extreme expertise in videogames. These people are the subject of our study and our first attempt at thinslicing the expertise in Tetris is the subject of this paper.

## Why Tetris?

Tetris is a videogame that is both easy to comprehend and difficult to achieve mastery over. The game is simple in that it has relatively simple rules (introduced in the next section) and players make decisions based on a limited set of potential actions (arranging and placing game pieces). However, there is much for a novice player to learn. The game space changes as a result of decisions made by the player. Errors accumulate
and one error tends to lead to another error until catastrophic failure (i.e. the end of the game) occurs. As the player succeeds, time pressure increases so that decisions have to be made within decreasing time windows. Furthermore, achieving the highest rewards requires performing maneuvers that risk error and reaching levels of the game where time pressure is highest.

To become highly proficient in the task, players must learn to effectively negotiate the error cost and the increasing time pressure by employing cognitive abilities such as: use of working memory, mental rotations, perceptual comparisons, strategic planning, and prediction, as well as the dexterous and rapid execution of chains of motor commands. Mastering Tetris requires the novice to coordinate the effective and efficient use all of these cognitive resources, abilities, and strategies. For these reasons, we see Tetris as an excellent platform for investigating the acquisition of expertise in a dynamic, real-time task.

In addition, Tetris has been used to document a variety of cognitive phenomena. A short list includes: epistemic versus pragmatic action (Destefano, Lindstedt, \& Gray, 2011; Kirsh \& Maglio, 1994), gains in cortical mass and BOLD response (Haier, Karama, Leyba, \& Jung, 2009), and near and far transfer (Sims \& Mayer, 2002).

## The Game of Tetris

(For readers already familiar with the game of Tetris, this section is optional review.)

Tetris is a game of increasingly fast-paced, generative puzzle-solving. When playing Tetris, a player manipulates a series of falling shapes, zoids, into an arrangement called the accumulation at the bottom of the game space. To score points, the player must clear rows. This is accomplished by filling at least one row in the accumulation. The immediate result is that points are scored and the row vanishes from the screen (thereby lowing the height of the accumulation). Since not all zoids fit perfectly together, the accumulation gradually rises as rows begin to go unfilled. When the accumulation reaches the top of the game space, the game ends. As the player clears lines, the game-level increases, speeding up the drop-rate of the zoid, and thus the difficulty, but also offering increased score payoffs for successfully cleared lines. Figure 1 illustrates the game screen as a player would see it.

Each zoid is one of seven unique shapes, all consisting of four contiguous block segments. Once a zoid is released into the game board, it begins automatically dropping, traversing the game space top to bottom in 12 seconds initially, down to 2 seconds at the highest difficulty level.

Scoring is nonlinear with respect to the number of lines cleared simultaneously. Initially, clearing 1 line awards 40 points, 2 lines awards 100 points, 3 lines awards 400 points, and clearing 4 lines simultaneously awards an extreme 1200 points. Clearing four lines simultaneously scores a Tetris, and
is notable because of both its high payoff and difficulty. Points awarded for $a$ Tetris are also modified multiplicatively by the current difficulty level.

Our version of Tetris, written in Flash, incorporates a robust logging system which captures all game events and states as they occur in real time. These events are detailed in the next section.

Figure 1. Example of the game environment.

## Events and Metrics

## Events in Tetris

Our basic unit of measurement is the episode, the time from when a zoid is released until it collides with and locks into the accumulation. It is in this time frame that all measurements of behavior and game state occur.

The player has available three kinds of actions: rotating clockwise and counterclockwise, moving a zoid to the left or right (i.e., translating between columns), and dropping the zoid (increasing the gravity intentionally). System events are any actions performed by the game environment, these include: automatically dropping the zoid due to gravity, clearing filled rows and awarding points, and releasing new zoids. Many of these actions occur within milliseconds of one another, a fact which is captured by time stamping in our continuous logging system.

Though the accumulation changes over time as zoids are placed and lines are cleared, during an episode the player interacts with one unique accumulation. Features of the accumulation are critical for understanding the player's current task status: its height determines how close the player is to failure, it may contain unreachable holes or pits which, for the game's continued success, must be uncovered (by clearing the rows which cover the pits) and filled, or overhangs (which can be thought of as a little cave that must somehow be filled by moving a zoid into it from its left or right side $a$ very difficult maneuver, especially for novices).

## Measure of Expertise

To assess the behavioral differences of expertise, we must define it quantitatively. Due to the difficulty of achieving high scores in Tetris, and the unlikelihood that a player will score highly simply "by accident," we consider a player's long-term ability to achieve high scores a basic measure of their expertise; that is, a player's expertise is equated to the maximum score the player was able to achieve during any of their games played during data collection. Because scores tend to increase nonlinearly (later levels award disproportionately more points) and seem to follow a somewhat exponential pattern, our metric of a player's expertise is the base-10 logarithm of their maximum game score.

## Predictive Measures

Because the task environment in Tetris is sufficiently simple, we are able to extract many details of task performance which may reflect differences in novice and expert behavior. It is important to point out that we are not searching only for those metrics which are the root cause of more expert performance, but also any metrics which reliably co-occur with expert ability. This investigation remains agnostic to this distinction between components and markers of expertise.

Our various metrics can be categorized at three successive time scales of human action (Newell, 1990, p. 122): global $\left(10^{2}\right)$, local $\left(10^{1}\right)$, or immediate $\left(10^{0}\right)$.
Global metrics. These assess the player's overall game status as reflected in the built accumulation. These metrics are associated most closely with survivability in the game, such as the overall height of the accumulation, or the number of unworkable holes, or pits, which the player has accrued during play. These metrics, averaged across sections of gameplay, indicate broad patterns of performance which may differentiate between novices and experts, particularly in terms of long-term strategies.
Average height: The average of all column heights in the accumulation.
Pits: The total number of unworkable pits (covered empty spaces) present in the accumulation.
Overhangs: The number of covered spaces into which a player may still dextrously maneuver a zoid.
Roughness: A measure of the "randomness" of the accumulation.
Levelness: Measures the relative flatness of the top of the board.
Spire: The difference between the highest point in the accumulation and the average height.
Tetris progress: The number of nearly-filled rows presently lined up in the accumulation, ready to produce highscoring line-clears.
Zoid-positions: The amount of "good" positions available for any kind of zoid. This is a rough measure of the
functional "goodness" of the accumulation the player has built.

Local metrics. These assess the kinds of zoid-placements the player selects in relation to possible positions on the accumulation. This includes features such as the number of perimeter segments matched during a placement (i.e., does that zoid fit flush with its surroundings, or does it stick out precariously?), or whether the placement creates pits or overhanging segments in the accumulation which complicate later gameplay decisions. Zoid placements are also compared across all potential placement locations and orientations for the current zoid, giving a ratio of assumed "goodness" for a placement. These local metrics account for the kinds of decisions made at each step of the game.

Matched edges: The number of segments of the placed zoid which are touching the surrounding accumulation.
Match ratio: Ratio of the number of matched edges to the maximum possible for all positions the zoid could have been placed this episode.
New pits: The number of new pits created by this move.
Uncovered pits: The number of pits uncovered by this move.
Filled overhangs: The number of overhang cavities filled by the current move.
Current zoid-positions: The number of "good" positions available for the current zoid, which may indicate a player's planning for the next zoid in the previous episode.

Immediate interaction metrics. These account for how a zoid placement is executed, what can be thought of as the sensory-motor aspects of the gameplay. These include measurements of reaction times for various actions, such as the first keypress in an episode, and the first commission of a zoid drop to indicate that a decision has been made. These measures account for the rapid interactive skills a player employs to perform the basic decisions in the local metrics.

Total translations: The number of times a zoid was moved left or right in the episode.
Total rotations: The number of rotation actions performed on the zoid this episode.
Grouped actions: The number of clusters of similar actions performed in sequence (i.e., 3-translations, 2-rotations, 16 -drops). This measure reduces the sequences of actions to more conceptually coherent segments, with lower numbers implying less scattered executions.
Drop ratio: The proportion of the zoid's downward movements (in this episode) that can be attributed to the player's intentional dropping versus the system's automatic dropping.
Initial latency: The time (in milliseconds) between the start of the episode and the first action taken by the player.

Average latency: The average time between actions taken by the player.
Drop latency: The time from the start of the episode until the player decides to drop the zoid.

Each of these metrics is tallied and recorded once per episode. By examining elements from these three categories of performance, we hope to capture a broad, detailed picture of each player's gameplay as it occurs in real time.

## Methods

## Data collection

To acquire data from a cross section of players with different levels of expertise, we sponsored a Tetris tournament at Rensselaer Polytechnic Institute's Genericon - a convention for gaming, comics, Japanese anime, and all things "nerd culture." Participants in the tournament were volunteers from the pool of all those attending the convention, comprised primarily of RPI undergraduates.

Before the tournament, participants played two rounds of Tetris to determine their eligibility for competing. Once entered, participants competed in pairwise elimination matches wherein the highest score wins. The top three players of each tournament were offered a cash prize, provided they came to the laboratory and played an additional hour of Tetris.

We collected data using this procedure at two successive Genericons in 2006 and 2007. At the end of data collection, we had data from 57 unique players, with game scores spanning six orders of magnitude (less than 100 points to over $1,000,000$ ).

## Data filtering

Games wherein a player did not clear any lines were omitted from analysis, as these represent sessions which were either aborted or wherein the player clearly did not understand the game rules. Additionally, we sometimes observed players self-aborting games by rapidly dropping zoids until a gameover was achieved. These episodes were omitted from analysis, as they reflected gameplay behavior with maligned goals.

## Observation window

An important consideration for our data set is that it is naturalistic: no experimental controls were put in place, and no manipulations were made to the basic game. As such, there is a great deal of unevenness in the data set. The task environment is influenced greatly by the randomness of the zoid selection and player strategy, as is the number of episodes it takes a player to advance to the next difficulty level (where game speed is increased), or even the number of episodes played before the game ends. To control these elements would be to interfere with the basic structure of the game and deviate from the way players would naturally approach the
game, hindering our ability to find natural expert players in the wild as such. Thus, we leave these vital game elements uncontrolled, and instead institute a moving window through which to examine the gameplay data.

A key element of this exploration is whether we can thinslice by predicting expertise from a relatively small amount of data. Across all subjects and games, the mean number of episodes per game was 264.74 [Min. $=41$, Max. $=1388$, S.D. $=210.97]$. For our thin-slicing, in all cases the observation window begins with the $1^{\text {st }}$ episode of each game, wherein all players have a completely empty accumulation with which to work. For each player, we then averaged the data for all games for episodes 1-2 (an extremely thin slice of behavior), $1-10,1-100$, and all (using all available data for the analysis). Averaging behavioral measures across this window results in aggregate measures of performance which are representative of a player's behavior for the chosen observation window. Our question is whether measures made on these different slices of performance are predictive of overall performance.

## Results

## Multiple linear regression models

Prior to modeling, the dataset was sampled using a simple random assignment, using $80 \%$ of the data for training and leaving $20 \%$ for testing model predictions. The samples were verified as having similar distributions for the dependent measure of expertise [Training set: Mean = 4.43, S.D. $=0.61$; Test set: Mean $=4.51$, S.D. $=0.73$ ].

For each of the four selected observation window sizes (2, 10,100 , and all episodes), we conducted a multiple regression on each training data set using all predictors detailed in the Predictive Measures section. To account for any suppressor effects, a backward step-wise selection process was used in the regression. Table 1 shows the results of these models, and Table 2 illuminates the significance of each model's predictors. Note that the number of predictors ultimately used in each model varies due to the stepwise selection process. Figure 2 shows the fit of each model to the training data.

## Prediction

To assess each model's ability to predict unseen data, we performed predictions on the test data set ( 20 percent of observations). The Predictions section of Table 1 shows the relative success of each model as determined by the fit of a Pearson's product-moment correlation. Figure 3 shows the fit of the test set data to the model predictions.

## Discussion

From these results, we see significant fits for models created using all sizes of observation windows, from data spanning just two episodes to the use of the entire data set. The two models sampling from just 2 and 10 episodes each are

Table 1
Results of linear regression model for all window sizes.

|  | Observation window size |  |  |  |
| :--- | ---: | ---: | ---: | ---: |
|  | eps | 10 eps | 100 eps | all eps |
| Multiple $\mathrm{R}^{2}$ | .4607 | .3913 | .5882 | .8185 |

notable for their good fits, but both ultimately fail to predict unseen data. Nonetheless, their fits are encouraging in that they achieve a measure of success even when based on such a small proportion of the player's observable performance data.

Figure 2. Fit of multiple regression model to training data. Different plots for models sampling from A) 2 episodes, B) 10 episodes, C) 100 episodes, and D) all observed episodes per game.

Models sampling from more data are naturally able to account for more of the variance in the data, as seen by the increasing adjusted $\mathrm{R}^{2}$ values for those models with larger windows, with the model sampling all data presumably demonstrating a maximum of success. Interestingly, we see that the model sampling only the first 100 episodes (less than a quarter of all observed data), maintains a fit to the training data and ability to predict the test data comparable to that of the model sampling all data. This, too, is encouraging in our pursuit of using small proportions of data to predict long-term performance.

It is tempting to draw conclusions from the lists of significant predictors presented in Table 2, but there is, regrettably, a non-trivial sampling effect; depending on how the data set is partitioned into training and test sets, these significant variables tend to shift, vanish, and reappear on subsequent samplings. This is likely due to two underlying effects: a strong effect of individual differences, as suggested by Robertson and Glines (1985); and a high level of correlation between these variables, because many of them necessarily depend on one another (e.g., average height being necessary for Tetris progress). We cannot yet account for these covert effects and are not prepared to draw strong conclusions about the individual predictors' viability in predicting longterm Tetris performance. We can, however, offer two points of speculative commentary based on observation of these effects: first, some predictors seem to emerge as significant more frequently than others, and second, predictors representing all three categories (global, local, and immediate) tend to emerge as significant across samplings, indicating that there

Figure 3. Fit of predictions from models to the test data set. Different plots for models sampling from (A) 2 episodes, (B) 10 episodes, (C) 100 episodes, and (D) all observed episodes per game.
may exist latent factors within each of these categories which contribute independently to skilled performance.

## Conclusions

Our goal is to identify the elements of expertise that predict the continuum of performance in the game of Tetris. As a first step, we collected data from a wide variety of Tetris Tournament players and used it to derive metrics of global, local, and immediate interactions. Here we reported our first statistical models of these data and our initial success at predicting level of expertise from thin-slices of behavior.

Although our results are tentative, we are pleased with our initial success in applying a general cognitive task approach to extreme expertise. Our categories of global, local, and immediate interaction are based on three successive levels of the time scale of human action (Newell, 1990). At least some of our initial items for each scale shows some success as a predictor of expertise. Thin-slicing seems to produce valid predictions as, to our surprise, even the regression model based on the first two episodes of each game had some predictive validity. We are embolden by these initial successes and have made plans to collect an order of magnitude more data from an order of magnitude more players at all levels of expertise.

Our predictive modeling has thus far been limited to the statistical technique of multiple regression. Other techniques have been suggested and we are openly soliciting suggestions from the cognitive community. Further work will also seek to address the individual differences across players at the same skill level and will attempt to extract a more refined set of metrics of behavior with fewer co-dependencies.

## Acknowledgements

We thank Michael Kalsher for his advice on some of the statistical models presented in this paper. The work was supported, in part, by grants N000140910402 and N000141310252 to Wayne Gray from the Office of Naval Research, Dr. Ray Perez, Project Officer.

#### Abstract

Recent evidence has suggested that the relationship between a test of fluid intelligence, Raven's Progressive Matrices, and working memory capacity (WMC) may be invariant across difficulty levels of the Raven's items. We show that this invariance can only be observed if the overall correlation between Raven's and WMC is low. We demonstrate that by using a composite measure of WMC, which yields a higher correlation between WMC and Raven's than reported in previous studies, that there was a significant positive relationship between Raven's item difficulty and the extent of the itemwise correlation with WMC. This result puts strong constraints on theories of reasoning and challenges some existing views. Keywords: Raven's Progressive Matrices; Working Memory Capacity.

## Introduction

Working memory (WM), the architecture responsible for the retention and manipulation of information over short periods of time, is a core component of human cognition. People's working-memory capacity (WMC) shares around $50 \%$ of the variance with general fluid intelligence (Kane, Hambrick, \& Conway, 2005) and is predictive of performance in a number of reasoning tasks and other measures of higher cognitive ability. However, there is some dispute about the exact nature of the relationship between WMC and one important assay of fluid intelligence, Raven's Progressive Matrices (e.g., Raven, Raven, \& Court, 1998).

Raven's test is designed such that items differ considerably in difficulty, with easy items-presented early in the test-solvable by more than $90 \%$ of participants and the hardest items-presented last-being solvable by fewer than $10 \%$ of participants. Carpenter, Just, and Shell (1990) presented a taxonomy of rule types that were used to create each of the Raven's items. To illustrate, Figure 1 presents two sample Raven's-like problems created using different rules. The matrix in panel A contains an incremental rule (i.e., the dots increase across items) and a distribution of 3 , permutation

Figure 1: Two examples of matrices like those in the Raven's test. A: Example of an item containing a pairwise incremental rule and a distribution of 3 permutation rule. B: Example of an item containing a constant rule and a distribution of $2(\mathrm{XOR})$ rule.
rule (i.e,. objects with 1,2 and 3 triangles are permuted across rows and columns). The matrix in panel B contains a constant rule (i.e., the center dot appears in all items) and a distribution of 2 (or logical XOR) rule (i.e., features which appear in the first two objects do not appear in the third object and features which appear only in one of the first two objects also appear in the third object). Carpenter et al.'s rule taxonomy also included feature decrements between objects, logical disjunction rules (OR) and logical conjunction rules (AND). Participants must infer these rules from the objects in the matrix and then predict and select the missing lower right object in the matrix from the set of possible response options.

Carpenter et al. (1990) compared two production system models that demonstrated the importance of the number and type of rules and WMC. Both of the models operated by finding correspondences between the

Figure 2: Left Panel: Observed accuracy from Unsworth \& Engle (2005). Right Panel: Observed itemwise point bi-serial correlations in Unsworth \& Engle (2005).
symbolically-coded features of the items, transferring these correspondences to a working memory buffer where any rule satisfied by the extracted correspondences was invoked, using the instantiated rules to generate the missing item, and finally, searching through the response options to find the best match. One model (called FAIRAVEN) had no strategic memory organization and did not have access to distribution of 2 (XOR) rules; the other model (called BETTERAVEN) was endowed with better control processes and contained access to all of the rules types. The assumptions of the models were consonant with observed accuracy, response time, and eye fixation data and the models were able to explain the performance of median Raven's performers and the very best Raven's performers, respectively.

If we assume that increased WMC allows for an improved ability to maintain goals and retain intermediate results and rules necessary to successfully solve the most difficult Raven's items, the implication of the modeling is that performance on more difficult items should be more highly correlated with WMC. In subsequent tests of that idea, Unsworth and Engle (2005) and Wiley, Jarosz, Cushen, and Colflesh (2011) examined the correlation between WMC and Raven's performance across ordinal item position, which is a proxy for item difficulty. Contrary to expectation, those studies found that the role of WMC remained invariant across item position. The left and right panels of Figure 2 show the accuracy and itemwise correlations observed by Unsworth and Engle (2005). Although the itemwise pattern is quite noisy, there appears to be no systematic relationship between ordinal item difficulty (on the abscissa) and the correlation between performance on those items and WMC (as measured by OSPAN). This impression of an invariant relationship was statistically supported by the failure to find an increasing correlation between OSPAN and the proportion correct within each quartile of the Raven's test.

Those reports of invariant itemwise correlations have been used to reject the model of Carpenter et al. (1990), or indeed any other proposal that cites the ability to hold
rules and goals in working memory as underlying Raven's performance. The failure to find a selective involvement of WMC has motivated alternative theorizing about the relationship between the Raven's test and WMC. For example, Unsworth and Engle (2005) concluded that the variance shared by WMC and Raven's reflected attentional control mechanisms, presumed to be implicated in both tasks, which were thought to be uniformly important across all of the Raven's items. Thus, irrespective of item difficulty, a person with larger WMC benefits from an enhanced ability to selectively focus on those features of an item that are relevant to the item-appropriate rule and to filter out distracting non-relevant goals and features. Although this account has not been quantitatively formalized, there is empirical support from other domains that working memory underwrites an ability to filter out distracting information (Conway, Cowan, \& Bunting, 2001).

The current state of affairs thus presents a conceptual puzzle: On the one hand, intuition and at least one theory (Carpenter et al., 1990) suggest that the importance of WMC should be accentuated for the more difficult Raven's items, for the simple reason that the easiest items are - by design - solvable by most participants and hence ought not to correlate much with WMC. On the other hand, there are now several reports that the role of WMC is invariant across item difficulty (Unsworth \& Engle, 2005; Wiley et al., 2011). Those results appear consonant with an attentional view of working memory but run counter to the model of Carpenter et al. (1990). However, there are several reasons to examine those reports further: First, the counter-intuitive nature of those results deserves to be underscored - after all, how can the correlation between WMC and performance be identical for items that are solved by $90 \%$ and $10 \%$, respectively, of participants?

There are other reasons to expect that the acceptance of an invariant relationship between Raven's performance and WMC may have been premature. By definition, those results rely on a failure to reject the null hypothesis, and the "noisiness" of the data is considerable (see Figure 2, right panel). Moreover, studies showing an invariant itemwise correlation were marred by the fact that only a single task (OSPAN) was used to measure WMC-consequently, measurement error or "method variance" from that single task might have masked a relationship between WMC and the more difficult Raven's items in the studies of Unsworth and Engle (2005) and of Wiley et al. (2011). In support of this claim, the correlations reported in those papers $(r=.335$ and $r=.33$, respectively) fall on the lower end of the range of correlations between WMC and Raven's identified in a recent meta-analysis (i.e., . 312 to .641; Ackerman, Beier, \& Boyle, 2005). Further, Unsworth and Engle (2005), participants were allocated 30 minutes to complete the

Raven's test rather than the standard 40 minutes, which likely resulted in decreased overall accuracy, that may have further obscured an increasing effect of WMC.

We suggest that there are strong and well-supported reasons to expect the involvement of WMC in performance to increase across item difficulty in the Raven's test. Reports to the contrary have relied on acceptance of the null hypothesis and have involved limited measures of WMC. The issue of how working memory relates to Raven's performance may therefore be worthy of further exploration. We revisit this issue and resolve it by presenting a behavioral study using a composite measure of WMC that correlates more strongly with Raven's and results in an increasing itemwise correlation-as predicted by Carpenter et al. (1990) and contrary to the null results reported to date.

## Behavioral Study

In this study, we sought to maximize the likelihood of finding an increasing itemwise corrrelation function by using multiple tasks and deriving a composite latent measure of WMC, thus reducing the task-specific variance and measurement error that beset a single-task measure such as OSPAN. We therefore expected the correlation between WMC and RAPM performance to be greater than in relevant previous studies. Why should we expect the overall correlation between WMC and Raven's to affect the itemwise correlation? The answer lies in the constraints imposed by the decreasing accuracy function across Raven's items: Because nearly everyone gets the early items correct, the corresponding point-biserial correlations for those items must be near zero. It follows that the overall correlation between WMC and Raven's can only express itself in the pointbiserial correlations for the later items where performance is more variable across individuals. Consequently, a greater overall correlation is preferentially observed in the later items, which necessarily translates into an increasing itemwise slope across the entire test.

This increasing slope fails to be observed only if performance on the final test items falls sufficiently close to the floor to constrain their variance, thereby curtailing the itemwise correlations for the last items. The shorter test duration used by Unsworth and Engle (2005) led to near-floor performance on the later test items, thereby preventing the detection of an increasing itemwise slope. This is likely to have been the case even if the overall correlation had been greater. For the increasing slope to be observed, performance on the later items ought to be off the floor and the overall correlation must be large. The standard 40 minute allocation in our study should act to increase accuracy for the later items, and the use of a battery of WM tests should serve to increase the overall correlation between WMC and Raven's performance.

## Method

Participants The participants were 130 volunteers (95 female; mean age 21.12) from the University of Western Australia campus community. Participants received either partial course credit for an undergraduate psychology course or $\$ 20$ for two 1-hour sessions.

Procedure In the first session of the study, participants completed a battery of four WMC tasks (see Lewandowsky, Oberauer, Yang, \& Ecker, 2010).

Memory updating (MU). The MU task required participants to (a) store a series of numbers in memory, (b) mentally update these numbers based on a series of arithmetic operations, and (c) recall the updated numbers. On each trial, three to five frames containing random digits were presented on the screen. Following memorization, successive arithmetic operations, (e.g., ' +4 ' or '-3') were presented in the frames, one at a time for a random number of steps before final recall was cued. The key dependent variable is the proportion of updated digits recalled correctly.

Operation span (OSPAN) and Sentence span (SS). On each OSPAN trial, a series of arithmetic equations were presented (e.g., $4+3=7$ ), each of which was followed by a consonant for memorization. Participants judged the equation for correctness and recalled the consonants immediately after list presentation in the original order. The SS task was identical to the OSPAN, except that instead of judging correctness of an equation, participants judged the meaningfulness of sentences (cf. Daneman \& Carpenter, 1980). For OSPAN and SS, the key dependent variable is the proportion of consonants recalled correctly.

Spatial short-term memory (SSTM). The SSTM task was adapted from Oberauer (1993) and involved memorization of the spatial location of circles presented, one-by-one, in various locations in a $10 \times 10$ grid. Participants used the mouse to indicate the memorized location of the dots in any order by clicking in the corresponding grid cells. For this task, participants are given a score based on how similar their recalled pattern was to the to-be-memorized pattern (see Lewandowsky et al., 2010).

Fluid intelligence tests (RAPM) In the second session, participants completed Sets I and II of the 1962 Raven's Advanced Progressive Matrices. As recommended by Raven et al. (1998), RAPM Set I was included to familiarize participants with the matrices. Participants had 5 minutes to complete the 12 items in Set I before being given the standard 40 minutes to complete the 36 items in Set II. We only report the results for the last 36 items (Set II).

## Results

Data from two participants who failed to complete all tasks were removed from analysis, and data from two

Table 1: Means $M$, standard deviations $S D$, skewness, and kurtosis for the operation span task (OSPAN), sentence span task (SS), spatial short-term memory task (SSTM), memory updating task (MU), and Raven's Advanced Progressive Matrices (RAPM).

| Measure | $M$ | $S D$ | Skewness | Kurtosis |
| :--- | :---: | :---: | :---: | :---: |
| OSPAN | 0.71 | 0.14 | -0.99 | 4.07 |

| MU | 0.66 | 0.18 | -0.34 | 2.48 |
| RAPM | 24.47 | 5.37 | -0.34 | 2.90 |

further participants were discarded for having WMC and Raven's scores less than three standards deviations below the mean, respectively. The final analyses thus used a sample size of $N=126$. Descriptive statistics for the four WMC tasks and RAPM are shown in Table 1. The top left panel of Figure 3 shows average performance on the RAPM items from Set II. The pattern conformed to expectation in that accuracy decreased with ordinal item position.
WMC and item difficulty For the correlational analyses, we computed a composite measure of WMC by first converting each participant's score on each WM task into a $z$-score, and then computing that person's average $z$-score across the four tasks ( $z \mathrm{WMC}$ ). As anticipated, the overall correlation between $z \mathrm{WMC}$ and the total RAPM score was moderately large, $r=.56, p<.001$, and larger than was found in previous studies using only a single measure of WMC.

The top right panel of Figure 3 shows the pointbiserial correlations between WMC and performance broken down across Raven's items, together with the best-fitting regression line. In contrast to Unsworth and Engle (2005), accuracy was high enough to permit inclusion of all of the Raven's items. The slope of the regression line (.004) was significantly greater than zero, $t(34)=2.87, p<.01, r^{2}=.20 .{ }^{1}$ The data confirm that when there is at least a moderate correlation between WMC and Raven's performance, the itemwise correlations increase with item difficulty.

Further, to analyse the relationship between $z \mathrm{WMC}$, item difficulty, and performance on Raven's, we conducted a multilevel logistic regression, which circumvents problems due to items with very high or very low accuracy by relying on the logistic (or inverse-logit) function to model the accuracy proportions for each item. We examined a model which includes WMC, ordinal item position (as a proxy for difficulty), and the inter-

[^139]

Figure 3: Left: Performance on Raven's Advanced Progressive Matrices items. Right: Observed correlations between working memory capacity ( $z \mathrm{WMC}$; based on a battery of four tasks) and performance on each Raven's item. The solid line represents the best-fitting regression line (intercept .13 , slope .004). Bottom panels: Results from a bootstrapping analysis resulting in correlations of $.52, .23$, and .09 , respectively, between WMC and overall Raven's performance. The framed bottom-left panel matches the overall correlation and itemwise results in the top right panel.
action between these variables. ${ }^{2}$ We also systematically tested alternative random-effect models (i.e., letting one or more of intercept or ordinal item position vary randomly across participants. ${ }^{3}$ ) and determined the preferred model using BIC.

The logistic regression assumes that the predictors are linearly related to the logit transformation of the dependent variable; consequently, we examined the relationship between each variable and accuracy using a White test for nonlinearity (Lee, White, \& Granger, 1993). Ordinal item position showed a demonstrable nonlinear relationship with accuracy $\chi^{2}(2)=61.12, p<.001$. A Box-Tidwell analysis indicated that the nonlinearity could be removed by raising ordinal item position to a power of $1.704, \chi^{2}(2)=4.29, p=.12$ (see Box \& Tidwell, 1962). Because item position is only a proxy for difficulty, the transformation of that variable is acceptable because it retains the ordinal association with the unknown scale of actual difficulty. None of the other variables showed any nonlinear relationship with the largest

[^140]Table 2: Estimated parameters (and standard errors) of mixed effects modeling of the RAPM behavioral study. All significant coefficients are bolded.

$\chi^{2}$ being for $z \mathrm{WMC}\left(\chi^{2}(2)=2.86, p=.24\right)$.
Exponentiating ordinal item position to correct for nonlinearity, our first model is given by the following equation:

$$
\begin{equation*}
y_{i j}=\beta_{0}+\beta_{z} z_{i}+\beta_{\psi} \psi_{j}^{\lambda}+\beta_{(z \times \psi)} z_{i} \times \psi_{j}^{\lambda}+\left(S_{i}+e_{i j}\right) \tag{1}
\end{equation*}
$$

where $y_{i j}$ is a binary response variable indicating whether participant $i$ made a correct (1) or incorrect (0) response on item $j, z_{i}$ is the $z \mathrm{WMC}$ score for participant $i, \psi_{j}$ is the ordinal item position of item $j, \lambda$ equals 1.704 (as indicated by the above Box-Tidwell analysis), $S_{i}$ is the set of subject random effects and $e_{i j}$ is an error term.

We tested this model using only the intercept as a random effect (e.g., Model 1, see Table 2) or the intercept plus $\psi^{\lambda}$ as random (Model 2). Comparison of the BICs pointed to the model in which only the intercept varied randomly as being preferable (i.e., Model 1). This model revealed significant effects of $z \mathrm{WMC}(p<.001)$, ordinal item position $\left(\psi^{\lambda}, p<.001\right)$, and the critical $z \mathrm{WMC} \times$ ordinal item position interaction $(p<.01)$. The latter interaction confirms that WMC played an increasingly important role as item difficulty increased, precisely paralleling our initial correlation-slope analysis.

Bootstrapping analysis We next conducted a bootstrapping analysis in which we simulate the effect of decreasing the overall correlation. In other words, to confirm that the magnitude of the overall correlation was responsible for the emergence of an item-difficulty effect in our study, we conducted bootstrapping analyses based on the observed subject $\times$ item $(126 \times 36)$ response matrix, with rows ordered according to the observed $z \mathrm{WMC}$. The overall correlation between $z \mathrm{WMC}$ and Raven's was manipulated by generating new $z \mathrm{WMC}$ scores for each participant and examining the effect of that manipulation on the itemwise correlations.

We created three conditions, each involving 10,000 bootstrapping runs. For each run, $n$, a new vector of $z \mathrm{WMC}$ scores was randomly derived from the observed values according to: $z \mathrm{WMC}^{(n)}=\nu \times z \mathrm{WMC}+\epsilon$ where $\epsilon \sim N\left(0, \sqrt{\left(1-\nu^{2}\right)}\right)$ and $\nu$ varied across conditions. This new vector contained $z \mathrm{WMC}$ scores which were derived from the observed $z \mathrm{WMC}$ scores but had a reduced correlation with the observed Raven's scores. The rows of the observed binary response matrix were then resorted according to the new vector $z \mathrm{WMC}^{(n)}$ yielding another bootstrapped replication with a specified correlation between $z \mathrm{WMC}$ and RAPM that maintained the overall itemwise error rate and overall Raven's correct for each participant observed in the study. Item-wise correlations were then computed between the bootstrapped replication and the $z \mathrm{WMC}$ scores.

The three bootstrapping analyses used $\nu=.95, .50$, and .20 , respectively, which yielded actual correlations $z \mathrm{WMC} \times \mathrm{RAPM}$ of $.53, .23$ and .09 (left, center, and right panel in bottom row of Figure 3, respectively). These actual correlations span a large range of possible overall correlations between WMC and Raven's. The bottom left panel provides an idea of the variability expected when the population correlation is approximately equal to that observed in our study. The remaining two panels show that as the population correlation decreases, so does the slope of the itemwise correlations. The center panel roughly corresponds to the correlation observed by Unsworth and Engle (2005) and confirms that the effect of item-difficulty is sufficiently small under those circumstances to escape detection when statistical power is insufficient.

Operation span and RAPM To provide further empirical confirmation that a reduction in the overall correlation between WMC and RAPM attenuates the itemwise effect, we examined the correlation between the OSPAN subtask and RAPM. For this task, the overall correlation with Raven's was much lower, $r=.36, p<.001$. The slope of the regression line for the point-biserial itemwise correlations was not significantly greater than zero, $t(34)=1.39, p=.17, r^{2}=.05$. Likewise, a multilevel logistic regression (see Equation 1) in which $z \mathrm{WMC}$ was replaced by OSPAN failed to find a significant interaction between OSPAN and exponentiated ordinal item position $(p=.09)$. This result replicated the invariant relationship found by Unsworth and Engle (2005), supporting our claim the previously published results were obscured by method-specific variance; that is, with a single task, the correlation includes taskspecific variance that hides the true magnitude of the underlying correlation between constructs.

## Discussion

There were two principal differences between our methodology and previous research. First, we used a
composite measure of WMC which resulted in a higher overall correlation between WMC and Raven's performance. Second, we extended the test time for RAPM to the recommended duration, which resulted in increased overall accuracy. Our results converge on the conclusion that when there is a moderate to strong overall correlation between WMC and performance on the Raven's test of fluid abilities, then the role of WMC becomes increasingly more important as item difficulty increases. Our results suggest that other studies failed to find an effect of item difficulty because in their cases the overall correlation involving WMC was small in magnitude (e.g., Unsworth \& Engle, 2005; Wiley et al., 2011). Moreover, the study by Unsworth and Engle (2005) was subtly biased against finding an itemwise effect because of their use of a shorter, non-standard time period for completion of the RAPM test ( 30 instead of 40 minutes). This nonstandard timing made it more likely that performance on the most difficult items would be near the floor (because most people ran out of time before solving those items), thereby necessitating their removal for lack of variance with an ensuant reduction in the power of the analysis.

On the surface, the present work may appear to be merely a statistical issue, but given the intense theoretical attention and interpretation this issue has received, its resolution has considerable psychological implications. In particular, our research cautions against reliance on a null result which has been a substantial barrier to theorizing in this domain. Previously, any model hoping to account for the relationship between WMC and Raven's also had to explain the invariant relationship across item difficulty. The present result shows that this invariance is of questionable generality. By contrast, although not presented here due to space limitations, we have replicated our result using the Raven's Standard Progressive Matrices in another study. Our results therefore open the door for quantitative models of WMC and Raven's that do not predict this invariance. We now know that any model attempting to explain the relationship between the two tasks has to predict that high WMC will allow you to do particularly well on hard items.

Our results are compatible with theoretical analyses of Raven's performance that appeal to working memory as a repository for rules and intermediate results (e.g., Carpenter et al., 1990). Although those theoretical views have fallen out of favor, largely due to the apparent absence of a modulating effect of item difficulty on the relation between WMC and Raven's performance, our results suggest that abandoning those approaches may have been premature.

#### Abstract

Time concepts are named differently across the world's languages. In English, the names for days of the week and months of the year are opaque - to people learning and using English, there's no obvious reason why Friday or September have the names they do. But in other languages, like Chinese, time concepts have numerically transparent names-the days of the week and months of the year are named using sequential numbers. We investigated whether having opaque versus mathematically transparent time concepts affects how people reason about time. Results show that Chinese speakers are more likely to spontaneously employ arithmetic when doing temporal calculations, which in turn improves the speed and accuracy of some time calculations. English speakers appear to use other strategies, such as sequential recitation.

Keywords: time concepts; temporal reasoning, mathematical ability; linguistic relativity.

## Introduction

The world's languages encode time terms in different ways. In English, names of days of the week (DOW) or months of the year (MOY) are derived from planetary or mythical terms (Zerubavel, 1985), and as a result are largely opaque to contemporary users of the language-why for instance do Wednesday or April have the names they have? By contrast, many other languages exhibit more numerically transparent naming systems. Chinese Mandarin is exemplary of this pattern. It uses numbers in the names of months and days. For DOW, this system begins with Monday as the first day of the week. Thus, xingqi yi, "weekday one", is Monday, xingqi er, "weekday two", is Tuesday, etc. The only exception is Sunday, the last day of the week, xingqi ri, which translates to "weekday of sun". Similarly, months in Chinese are numbered from one to 12 , with "month one" denoting January, "month two" February, and so on.

Do differences in how languages name time concepts cause differences in how speakers of those languages reason about time? For instance, does the numerical transparency of DOW and MOY terms affect the kinds of cognitive mechanisms people use to make temporal calculations? There has been little work on this issue. The most relevant line of work has focused on cross-linguistic effects of transparency of number systems themselves, showing that differences in number naming systems can affect cognitive development and non-linguistic performance. Most
relevantly, acquisition studies (Miura et al., 1993, 1994; Miller et al., 1995; Paik \& Mix, 2003) have found that preschool-aged children whose native languages employ more systematic naming systems for their numbers outperform their counterparts who speak languages that use less transparent number naming systems, on both number matching and number identification tasks. When asked to demonstrate numbers using combinations of individual unit cubes representing the quantity one and long blocks representing ten, Asian children whose languages use numerical names that are congruent with base 10 numeration systems (Fuson, 1990) were much more likely to use the blocks of ten in constructing multi-digit numbers than their counterparts, whose native naming systems were not similarly transparent. This led the authors of that study to argue that "numerical language characteristics may have a significant effect on cognitive representation of numbers" (Miura et al., 1994, p. 410), which in turn may enhance the performance of Asian-language-speaking children on tasks involving the concept of place value.

The types of names given to various symbolic systems, such as numbers, have also been shown to affect the problem solving abilities of competent symbol users. Seron and Fayol (1994) noticed that the number naming system in French-speaking Belgium is simpler than the one used in France (in Belgium, 98 is roughly "ninety-eight" but in France, it's "four-twenty-eighteen"). They reported that second-graders in France made more errors in number production than their Belgian counterparts. The effects of naming system also extend into adulthood and mathematical performance. For instance, adult English speakers have more difficulty reversing two-digit numbers ending in 1 (e.g., saying " 14 " when shown " 41 ") than Chinese speakers do, presumably a result of English's idiosyncratic rules for naming numbers between 11 and 19 (Miller \& Zhu, 1991).

In sum, differences in number naming systems affect the acquisition and use of number concepts. The current study investigated whether the same is true for the naming of time concepts (in this case, DOW and MOY). In particular, we asked whether the mathematically transparent naming of time concepts confers advantages on acquisition of time concepts and reasoning about time. There has been limited work on this question. Kelly et al. (1999) is the only systematic experimental investigation. They asked college
students in China and the United States to name the day or month that occurs a specified length of time before or after another given day or month. Chinese college students performed these calculations faster than American college students. Kelly and colleagues argued that the difference resulted from the use of different strategies as a consequence of the naming systems used in Chinese and English. However, this argument about the mechanisms used was based on participants' self-reports. Moreover, the calculation distance in Kelly et al.'s (1999) experiment was held constant-4 for the DOW task and 7 for the MOY task. The use of the constant distance caused some participants to predict the answers; one of the strategies participants reported was memorizing specific pairs of items. The experiment described below, in which distances vary, indirectly assesses the mechanisms adults use to perform temporal reasoning tasks, and whether these mechanisms vary with native language.

## Testing mechanisms indirectly

Kelly et al., (1999) reported that adult Chinese speakers outperform their English-speaking counterparts in time calculation tasks. This could be due to the differences in the numerical transparency of time words in the languages they speak. That is, the transparent numerical structure of Chinese time words might facilitate time calculation, by allowing Chinese speakers to employ arithmetic strategies made possible by the use of numerical names. For example, "Four days after Monday is what day?" translates to "Four days after Weekday one is what day?" To the Chinese speaker, this directly evokes arithmetic, $4+1$, and as a result, they might be able to use arithmetic quickly to produce the answer: "Weekday five" (Friday). The same should be true of making calculations about months. By contrast, English speakers do not have the arithmetic laid out for them in tasks like this, so they might rely on alternate strategies, like reciting a sequence of days or months.

But Kelly et al.'s (1999) results could alternatively be the result of other cultural differences, for instance, in the depth, length, and nature of the math education each group receives. It might be that the Chinese population that was sampled simply was better at performing mental calculations than their English-speaking counterparts.

Our experiment teases apart these two possibilities with a nuanced design, based on three predictions. First, if the use of different arithmetic strategies by Chinese and English speakers is responsible for the performance difference, then the Chinese advantage should disappear in cross-week or cross-year calculations. Chinese speakers may encounter difficulties in calculating distances across boundaries since they have to convert the answers into modulo-7 or modulo12 systems; 3 days after "weekday 5 " is not "weekday 8 ", but rather 8 modulo 7 , thus "weekday 1 "; 3 months after "month 11 " is not "month 14 ", but 14 modulo 12 , thus "month 2". If English speakers use a non-arithmetic strategy by default, then they should exhibit less increase in difficulty when calculating across boundaries.

A second prediction of the hypothesis that Chinese speakers use arithmetic more than English speakers is that the calculation of distances from Sunday (which is called "weekday sun" in Chinese) should be more difficult for Chinese speakers than from any other day in a week, since number is not used in naming this day. This irregularity may cause trouble in applying the arithmetic strategy, thus slowing down Chinese speakers' calculations, compared to calculation involving other days of the week. Again, by contrast, English speakers should show no increased difficulty when making calculations relative to Sunday.

A third prediction is that the Chinese speakers' speed of calendar calculating should not vary much with longer temporal distance if they primarily use an arithmetic method in the calculation, while the English speakers' performance may be negatively affected by increases in temporal distance to be calculated if they are reciting sequences.

## Method

## Participants

Thirty-two (22 female and 10 male) native Chinese speakers, college students from Beijing United College, ranging in age from 18 to $31(M=21, S D=4.9)$, and 40 native English speakers (19 female and 21 male), undergraduate students at the University of Hawai'i, aged 18 to $29(M=21, S D=2.5)$, participated in the experiment either for extra credit in an introductory linguistics class or for five dollars or the equivalent.

## Materials and design

Each participant completed two temporal reasoning tasks, pertaining to DOW and MOY respectively. For each, we manipulated two factors-Boundary Type (Within/Across boundary) and Direction (Forward/Backward), which produced four question types, as below (showing only DOW). Both factors were manipulated within participants. Language was a between-participants factor. An additional factor, Sunday, applied only to the DOW blocks. Half of the DOW questions involved Sunday, to reveal eventual effects of this non-numerically-named day in Chinese.
(1a) If today is Monday, three days from now is what day?
(Within/Forward)
(1b) If today is Thursday, two days ago was what day?
(Within/Backward)
(2a) If today is Saturday, three days from now is what day?
(Across/Forward)
(2b) If today is Tuesday, five days ago was what day?
(Across/Backward)
Calculation distance differed across conditions; distance ranged from 1 to 7 for DOW questions (1-4 for Within and 2-7 for Across) and 2 to 12 for MOY questions (2-10 for Within and $2-12$ for Across) in order to match the cyclical nature of the weeks and months. There were 32 questions in the DOW block and 48 in the MOY block.

## Procedure

Participants were seated in front of a computer. Each trial began with a fixation cross in the center of the screen. Participants initiated the trial by pressing the SPACE bar when they were ready. They heard a recorded voice read a question to them over headphones. They were instructed to speak the answer as quickly and accurately as possible after hearing the question into a microphone, which was used as a voice key, connected to an E-Prime SR-BOX. A digital recorder was also used to record the answers.

Four practice items preceded the experiment, which was divided into two blocks, one for DOW and one for MOY. Block order was counterbalanced across participants. The questions were randomized within each block. There was a short break between blocks.

## Measures

Reaction times in milliseconds were measured from the offset of the question to the onset of the participant's answer. Accuracy (individual proportions of correct answers were arcsine transformed to comply with the normal distribution premise) were calculated as another dependent measure.

## Results

All filler syllables, tongue clicks, partial responses, and repeated responses (due to failure to trigger the voice key) were manually excluded. No participants were excluded because of outlying RTs or low accuracy.

## Error analysis

Figure 1 shows mean accuracy for each Boundary Type and Direction by language in the MOY and DOW tasks. We performed separate repeated-measures ANOVAs with participants $\left(\mathrm{F}_{1}\right)$ and items $\left(\mathrm{F}_{2}\right)$ as random factors. In the participants analysis, Language (Chinese/English) was between participants but Direction (Forward/Backward), and Boundary Type (Within/Across) were within subjects. For items, Language was a within-items factor and the other factors (Boundary Type and Direction) were between-items.

As predicted, Chinese speakers made fewer errors than English speakers on the MOY task-a main effect of Language: $F_{1}(1,68)=26.846, p<0.001, F_{2}(1,44)=54.265$, $p<0.001$. However, as Figure 1 shows, this advantage was carried by the Within Boundary questions, confirmed by an interaction between Language and Boundary Type, $F_{1}$ (1, $68)=34.842, p<0.001 ; F_{2}(1,44)=44.876, p<0.001$.

As the second part of Figure 1 shows, Language was a less robust factor in the DOW task. The main effect of Language did not reach significance by participants analysis, but it did by items, $F_{2}(1,28)=5.177, p=0.031$. This indicates that Chinese speakers did not have a global accuracy advantage over English speakers. The lack of Language effect was probably driven by the Chinese speakers' relatively poor performance in the AcrossBoundary condition. As with MOY, an interaction effect
was found between Language and Boundary Type, $F_{1}(1,68)$ $=18.537, p<0.001 ; F_{2}(1,28)=24.596, p<0.001$. Once again, Chinese speakers produced more errors in cross-week calculations compared to their English-speaking counterparts.

Figure 1: Accuracy rate on the MOY (upper) and DOW (lower) task for Chinese and English speakers.

Questions involving Sunday As discussed in the Method section, half of the DOW questions were Sunday-related questions. These questions could have been the cause of the Chinese speakers' low DOW accuracy if the irregular Sunday term ("weekday sun" instead of "weekday seven") affected the use of an calculation strategy. Statistical analysis confirms this. Chinese speakers were significantly less accurate on Sunday questions than non-Sunday questions, $F_{1}(1,29)=2.38, p=0.024 ; F_{2}(1,30)=2.83, p=$ 0.031 , while English speakers were not sensitive to Sunday and showed no difference in accuracy on Sunday questions (see Figure 2).

Figure 2: Chinese- and English-speaking participants' accuracy in different Sunday conditions.

## Reaction time analysis

All trials with incorrect responses were removed (16.7\% of the data). We also removed all responses that were greater
than 2.5 standard deviations from the mean of all responses in each of the four conditions (Boundary Type x Direction) for each language group. This excluded another $2.72 \%$ of the data. No participants or items were removed for reasons of accuracy or outlying $S D$. The reaction time data approximate normal distribution after this cleaning. Reaction times for correct responses were analyzed using a repeated-measures ANOVA with Boundary Type (Across/Within) and Direction (Forward/Backward) as within-subject factors and Language (Chinese/English) as a between-subject factor. An Item analysis took Language as a within-items factor and Boundary Type and Direction as between-items factors. The results in the MOY and DOW tasks, seen in Figure 3, show mean reaction time for each Boundary Type and Direction by language.

The results from MOY block mirrored the error analysis. A large main effect of Language, $F_{1}(1,68)=36.155, p<$ $0.001, F_{2}(1,44)=134.986, p<0.001$, confirmed that Chinese speakers were faster than English speakers. There were also significant interactions between Language and Boundary Type, $F_{1}(1,68)=35.809, p<0.001, F_{2}(1,44)=$ 9.613, $p<0.001$, and between Language and Direction, $F_{1}(1,68)=13.423, p<0.001, F_{2}(1,44)=8.407, p=0.006$. These effects showed that Chinese speakers gained more of a speed advantage from Within month questions than English speakers did, but that English speakers gained more of an advantage from Forward calculations.

Figure 3: Reaction times on the MOY (upper) and DOW (lower) task for Chinese and English speakers.

Reaction time results from the DOW task are more complicated because of the presence of Sunday. The Chinese speakers were consistently faster than their Englishspeaking counterparts, as shown by a main effect of language, $F_{1}(1,68)=20.617, p<0.001, F_{2}(1,28)=63.776, p$ $<0.001$. Both language groups answered Within questions faster than the Across ones, $F_{1}(1,68)=161.850, p<0.001$,
$F_{2}(1,28)=27.446, p<0.001$, and the Forward questions faster than the Backward ones, $F_{1}(1,68)=42.243, p<0.001$, $F_{2}(1,28)=11.496, p=0.002$. There was also an interaction between Language and Direction, $F_{1}(1,68)=15.407, p<$ $0.001, F_{2}(1,28)=9.244, p=0.005$. English speakers were much faster with Forward questions, $F_{1}(1,39)=86.977, p<$ $0.001, F_{2}(1,28)=13.090, p=0.001$. Chinese speakers were also faster in answering Forward questions than Backward questions, but the difference was much smaller, $F_{1}(1,29)=$ $13.460, p=0.001, F_{2}(1,28)=4.933, p=0.035$.

Questions involving Sunday The analysis of the accuracy data above showed that Chinese speakers made more errors on questions involving Sunday. But their reaction times were unaffected, as Figure 4 shows. A two-way ANOVA showed a main effect of Language, $F_{1}(1,68)=15.681, p<$ $0.001, F_{2}(1,30)=34.942, p<0.001$; Chinese speakers were faster than English speakers. But there was no interaction.

Figure 4: Reaction times in Sunday and Non-Sunday conditions for Chinese and English speakers.

## Calculation Distance analysis

Because the mean distance varied across conditions, we also did exploratory analyses by calculation distance, to see if different calculation difficulty revealed strategy differences. Reaction times by distance are presented in Figure 5.

As shown in Figure 5, the two language groups showed different level of sensitivity to the distance calculated. The Chinese speakers' reaction times were far less sensitive to either distance or direction, especially in the within-week condition. This is consistent with the hypothesis that they were using addition and subtraction of small numbers. The across-week condition is more complicated, as an extra step of modulo calculation could have been involved for the Chinese speakers.

The English speakers' reaction times were more strongly affected by the length of temporal distances. As can be seen on the right side of Figure 5, questions that required backwards calculations took much longer than Forward questions, presumably because counting backwards is less familiar. Moreover, reaction times increase steadily as the distances increase. The rise and drop of reaction times with longer distances suggests that the English speakers were applying different approaches when encountering calendar questions with different distances. When the distances grew longer, which makes verbal list counting a less efficient strategy, they may have flexibly and strategically switched to methods such as using numerical equivalents as a shortcut to reciting the list, such as "counting forward by the

12's or 7's complement to solve backward problems" (Kelly et al., 1999). The partial use of an arithmetic strategy was self-reported by some of the English participants in Kelly et al.'s work, and is consistent with the reaction time evidence we find here.

Figure 5: Reaction times of Chinese (left) and English (right) in Within (upper) and Across (lower) Week calculations (The $x$-axis shows calculation distances.)

Figure 6: Reaction times by Chinese (left) and English (right) speakers in Within (upper) and Across (lower) Year calculations (The $x$-axis shows calculation distances.)

The year cycle has longer distances and so can provide more information about strategies used in response to possible calculation difficulties. The two language groups' reaction time data were categorized by distance for the Within task and for the Across task, as shown in Figure 6.

Again, the Chinese speakers' reaction times were not affected nearly as much as the English speakers' were by calculation distance or direction, especially in the Within Year tasks, again consistent with the possibility that they are calculating arithmetically. On the other hand, the English speakers present a more complicated picture of responding to different distances. They were generally faster with Forward than Backward questions, and they spent more time when the distances got longer, except for the longest distances (10 through 12), with which they might be using strategies other than reciting due to the difficulty of counting all the way through the month list.

## Discussion

Languages differ in how numerically transparent their time words are, and we hypothesized that these differences would affect the temporal cognition of adult speakers of languages with distinct systems. Our results provide several types of experimental evidence that Chinese and English speakers use different strategies in temporal calculation tasks. As a result, Chinese speakers determine temporal distance calculations faster and more accurately. These findings are not consistent with the hypothesis that other factors, such as general mathematics ability, cause differences in overall accuracy or speed.

There are three pieces of relevant evidence. First, Chinese speakers were consistently more accurate in the Within Week and Within Year tasks, but their accuracy dropped significantly and their advantage disappeared with calculations across week or year boundaries. In contrast, the English speakers' answers were not particularly sensitive to boundary crossings. For the reaction time results, although the Chinese speakers were still faster than the English speakers in the Across Boundary calculations, they were slower compared to their own Within Week calculations. So although arithmetic strategies for time may be advantageous for some local calculations, the Chinese speakers' advantage in accuracy and speed diminishes when answering questions that involve temporal boundary crossings.

Second, the results confirmed that the irregularity of Sunday's Chinese name causes trouble in applying the arithmetic strategy, resulting in more mistakes by Chinese speakers in answering questions involving Sunday compared to calculations involving other days of the week. By contrast, English speakers showed no increased difficulty when making calculations relative to Sunday, and their accuracy rates were not affected by questions involving Sunday.

Finally, Chinese speakers' reactions seem not to systematically relate to distance or directions of calculation, whereas the English speakers' reaction times for Forward calculations increase steadily and substantially, implying an
increase in time spent reciting day or month lists, and their pattern on Backward questions were more complicated. We hypothesized that versatile/mixed strategies might be used due to the difficulty of reciting lists backwards.

In sum, these results suggest that differences in calendar terms between the two languages lead to dominant arithmetic or list-reciting strategies for speakers of those languages. The verbal list strategy is substantially slower than the number-transferring one, yet the latter results in more possible errors across boundaries because of required modulo 7 and modulo 12 calculations.

Previous cross-linguistic studies have shown that there is at least some causal influence from language to non-verbal cognition and unconscious habitual thought (Kay \& Kempton, 1984; Lucy, 1992; Gumperz \& Levinson, 1996, etc.). More specifically, the way time is described in a language can affect its speakers' conceptualization of time (Boroditsky, 2001) and can even shape low-level mental processes in psychophysical tasks (Casasanto et al., in revision). The current study adds to this line of study by showing that transparent numerical structure of the calendar might facilitate calendar calculation, causing Chinesespeaking adults to outperform their English-speaking counterparts in time calculation tasks, by exhibiting shorter reaction times and making fewer errors. We conclude that adults' temporal reasoning abilities differ, depending on the transparency of the naming systems that their languages employ for time sequences. In general, such a finding supports the hypothesis that linguistic differences can produce non-linguistic consequences, in this case in affecting people's reasoning about time (Boroditsky, 2000, 2003; Boroditsky \& Ramscar, 2002, Matlock et al., 2005; Núñez and Sweetser, 2006; Casasanto \& Boroditsky, 2008).

# Modeling Spatial Ability in Mental Rotation and Paper-Folding 

Andrew Lovett (Andrew@cs.northwestern.edu)<br>Kenneth Forbus (Forbus@northwestern.edu)<br>Qualitative Reasoning Group, Northwestern University, 2133 Sheridan Road<br>Evanston, IL 60208 USA

#### Abstract

Spatial ability tests like mental rotation and paper-folding provide strong predictions of an individual's achievement in science and engineering. What cognitive skills are involved in them? We use a computational model to analyze these tasks, asking how much information must be processed to perform them. The models demonstrate that in some cases stimuli can be vastly simplified, resulting in consistent performance regardless of stimulus complexity. The ability to produce a scaled-down representation of a complex stimulus may be a key skill underlying high spatial ability.

Keywords: spatial ability; mental rotation; paper-folding; cognitive modeling.

## Introduction

There is strong evidence linking spatial ability to academic achievement. Children who perform well on spatial ability tests are more likely to study STEM disciplines (Science, Technology, Engineering, and Mathematics) and to go into a STEM profession (Shea, Lubinski, \& Benbow, 2001; Wai, Lubinski, \& Benbow, 2009). This effect holds even when controlling for verbal and mathematical ability, suggesting that spatial ability is an independent component of intelligence. If we are to improve STEM achievement, it is critical that we better understand the skills that compose spatial ability and how they can be taught.

Traditionally, spatial ability has been evaluated using tasks such as mental rotation and paper-folding. In mental rotation (Figure 1A, 1B), individuals are shown two shapes and asked whether a rotation of one shape could produce the other. In paper-folding, they are shown a line-drawing of paper and asked to imagine the results of unfolding (Figure 1C) or folding up (Figure 1D) the paper. Both tasks appear to measure spatial visualization, the ability to manipulate mental representations of images (McGee, 1979). There is evidence that the tasks are linked, with training on one improving performance on the other (Wright et al., 2008). However, many questions remain about what skills enable people to perform them quickly and accurately.

Here, we study the mental rotation and paper-folding tasks using a computational model. The model operates directly on 2D line drawings (sketches), automatically generating representations, transforming them, and evaluating the results of the transformation. We use the model to analyze the tasks, asking how much information must be encoded and carried through the transformations to
perform each task consistently. This analysis allows us to address a longstanding debate about the effects of shape complexity on mental rotation. It also provides hypotheses about the skills supporting fast, efficient mental rotation, and thus the skills underlying spatial ability.

We begin with background on mental rotation and the question of shape complexity. We show how paper-folding appears to violate many researchers' conclusions, as it involves simple shapes but requires great deliberation and effort. We next present our computational model, which builds on previous cognitive models of perception, comparison, and visual problem-solving (Falkenhainer, Forbus, \& Gentner, 1989; Lovett \& Forbus, 2011). We apply the model to the two tasks, determining the amount of information that must be carried through the transformations, and showing why paper-folding is a more difficult task. Finally, we discuss the results and consider the ramifications for spatial ability in general.

## Background

## Mental Rotation

Mental rotation is frequently used to evaluate spatial ability (Vandenberg \& Kuse, 1978). Typically the distractors-the shapes that aren't a valid rotation-are mirror reflections. When they are presented sequentially, there is often a cue indicating what the orientation of the second shape will be (e.g., Cooper \& Podogny, 1976; Figure 1B). A common finding across task variations is that the response time is proportional to the angle of rotation between the shapes. That is, response times increase linearly with angular distance. This finding has led to the claim that people use a mental space, analogous to the physical space, and that they rotate their representation through this space just as an object might rotate physically (Shepard \& Cooper, 1982).

One common question concerns how shapes are rotated through mental space. Are they rotated piecemeal, with one part rotated at a time, or are they rotated holistically, with every part rotated together (Bethell-Fox \& Shepard, 1988)? These two possibilities produce different predictions about how shape complexity interacts with rotation speed. If shapes are rotated piecemeal, then people should rotate complex shapes more slowly, because there are more parts to rotate. If shapes are rotated holistically, then shape complexity may not affect rotation speed.

Figure 1. Mental rotation (A, B) and paper-folding (C, D) tasks (A: Shepard \& Metzler, 1971; B: Cooper \& Podogny, 1976; C: Ekstrom et al., 1976; D: Shepard \& Feng, 1972).

The results on shape complexity provide evidence for both piecemeal and holistic rotation. Overall, it appears that rotation speed depends more on other factors, such as the familiarity of the objects (Bethell-Fox \& Shepard, 1985; Yuille \& Steiger, 1982), the similarity of the distractors (Folk \& Luce, 1987), and the strategy and overall ability of the participant (Yuille \& Steiger, 1982; Heil \& JansenOsmann, 2008). These findings suggest that dealing with shape complexity may itself be a spatial skill. Skilled participants may apply heuristics to simplify shapes for rapid rotation. However, when these heuristics fail, they are reduced to rotating one piece at a time, which is slower.

One straightforward heuristic for simplifying a shape is to ignore parts of it. When Yuille and Steiger (1982) told participants they could complete a mental rotation task using only the top halves of the shapes, participants rotated the shapes more quickly. Alternatively, participants might utilize scalable representations (Schultheis \& Barkowsky, 2011) that support dynamic variation of detail based on task demands. Both the degree and the type of detail may vary. For example, while we can imagine both the locations and orientations of objects in space, a task might require considering only one of these. In this paper, we use the term spatial smoothing for any process that removes spatial detail, producing a simpler representation.

Participants may smooth out the details in complex shapes, producing representations with equal complexity to those of simpler shapes. However, when the distractors are particularly similar to the base shapes, participants may require additional detail, and so they may use more complex representations that are more difficult to rotate.

This hypothesis leads immediately to two predictions: 1) When similarity of distractors is kept constant and relatively low, people should rotate shapes at the same rate regardless of shape complexity. 2) As distractors become more similar,
people should rotate shapes more slowly, particularly when the shapes are complex. There is evidence supporting both predictions (1: Cooper \& Podgorny, 1976; 2: Folk \& Luce, 1987).

## Paper-Folding

In contrast with mental rotation, paper-folding has seen relatively little study. This is surprising, given that it is also often used to evaluate spatial ability (Ekstrom et al., 1976). Here, we focus on a version of paper-folding that emerged at about the same time as mental rotation (Shepard \& Feng, 1972). While this version is used less frequently in spatial ability evaluations, there is direct evidence linking it to mental rotation (Wright et al., 2008).

Figure 1D shows an example. The letters have been added for illustrative purposes and are not part of the stimulus. In this task, participants are shown six connected squares, representing the surfaces of a cube that has been unfolded. Two edges are highlighted by arrows, and one square is grayed out, indicating it is the base of the cube. Participants are asked whether the highlighted edges would align if the squares were folded back into a cube.

Unlike mental rotation, this task requires a sequence of rotations. For example, Figure 1D requires three rotations. One solution (Figure 2) would be: 1) Rotate squares A, B, and C up, so that they stick out from the plane. 2) Rotate squares $B$ and $C$ down to make the top surface of the cube. 3) Rotate square $C$ farther down, making the front surface of the cube. At this point, the two arrows align perfectly.

Surprisingly, even though each of these three rotations seems simple, they appear to be piecemeal rotations. Participants' response times are not a function of the number of rotations performed, but of the number of times every square is rotated. In this case, three squares are rotated (Figure 2B), then two squares (2C), then one square (2D),

Figure 2. Possible solution for Figure 1D.
so the overall number of squares rotated is $3+2+1=6$. The response times reflect the six rotations, suggesting participants rotate a single square at a time.

Why should participants require piecemeal rotation for such apparently simple shapes? We propose that, unlike many mental rotation tasks, little spatial smoothing can be performed. The precise location and orientation of every surface rotated is critical to performance. In Figure 2A, the location and orientation of square $A$ determines where the second rotation occurs, and the location and orientation of square B determines where the third rotation occurs.

If this proposal is true, it may shed light on how and when spatial smoothing can be applied, and what happens when it cannot be used. Understanding this requires determining how much spatial information must be rotated in each task. To better answer this question, we developed a computational model of the tasks.

## Model

The spatial ability model is built within CogSketch, a sketch understanding system. Below, we present CogSketch and its framework for cognitive modeling. We then describe how the model performs mental rotation and paper-folding.

## CogSketch

CogSketch is an open-domain sketch understanding system (Forbus et al., 2011). Users sketch a scene by drawing one or more objects. It is the user's responsibility to manually segment a sketch into objects, indicating when they have finished drawing one object and begun on the next.

Given a set of objects, CogSketch automatically generates a representation of the scene. While CogSketch does not model the process of visual perception, its representations are a model of those produced by human perception. The representations are based on two psychological claims: 1) Spatial representations include a qualitative or categorical component and a quantitative or metric component (Kosslyn et al., 1989; Forbus, et al 1991). When possible, people use the qualitative component during reasoning. CogSketch computes qualitative spatial relations between objects, e.g., indicating that one object is right of another or that two objects intersect. 2) Spatial representations are hierarchical, meaning they can represent a scene at different levels of abstraction (Palmer, 1977; Marr \& Nishihara, 1978). CogSketch can represent objects and the relations between them, or it can represent the edges of an individual object and the relations between those edges. To produce an edge-level representation, CogSketch segments an object's contour into edges at points of maximum curvature (e.g., Figure 3A; Lovett et al., 2012). Once edges have been
A)

B)

C)

Figure 3. A: Shape segmented into edges. B: Result of Gaussian smoothing. C: Result of selecting 4 longest edges.
computed, it generates qualitative spatial relations between the edges, e.g., indicating that two edges are parallel or that a corner between edges is convex.

CogSketch models visual comparison using the StructureMapping Engine (SME) (Falkenhainer et al 1989), a domain-general cognitive model based on Gentner's (1983) structure-mapping theory. SME compares two qualitative representations by aligning their common relational structure, highlighting commonalities and differences. For example, suppose SME is comparing two shapes like the one in Figure 3A. Each representation will contain entities (symbols representing each edge), attributes (features of the edges, such as straight vs. curved), first-order relations between edges (e.g., indicating that a corner between edges is convex), and higher-order relations between other relations (e.g., indicating that two corners are adjacent along the shape). By aligning the common relations, SME can determine the corresponding edges in the two shapes.

Modeling in CogSketch CogSketch possesses two key features that support modeling psychological experiments. First, in addition to sketching by hand, users can import shapes from another program such as PowerPoint. Perfectly straight line drawings from an experiment can be replicated in PowerPoint and imported into CogSketch, providing it with the same stimuli as those shown to human participants.

Second, CogSketch includes a Spatial Routines language for writing cognitive models. Spatial Routines, which builds on Ullman's (1984) concept of visual routines, provides modelers with a set of cognitive operations. These include visual perception, visual comparison, and spatial transformation operations. Modelers can parameterize these operations and combine them in different ways to produce a spatial routine. Each routine is both a theoretical model of how people perform a task and a fully automated computational model. The computational model can be run on visual stimuli, and its performance can be compared to human responses to evaluate the theoretical model.

We have previously modeled visual problem-solving tasks such as geometric analogy (Lovett \& Forbus, 2012), Raven's Progressive Matrices (Lovett, Forbus, \& Usher, 2010), and an oddity task (Lovett \& Forbus, 2011).

## Mental Rotation

We modeled a classic sequential mental rotation task because it presents the clearest evidence for efficient, holistic rotation. In this task (Figure 1B; Cooper \& Podogny, 1976), participants are presented with three stimuli in sequence: 1) They see the base shape. 2) They see an arrow indicating what the target shape's orientation will be. They are encouraged to mentally rotate the base shape to that orientation and press a button when they are done. 3) They see the target shape, and they indicate whether it is the same as the rotated base shape. The amount of time participants spend on step 2) indicates the rotation time. The key finding of the experiment was that rotation time did not increase as the shape complexity increased from a 6-sided
polygon to a 24 -sided polygon. Our model is designed to evaluate whether spatial smoothing can explain this finding.

Input In CogSketch, sequences of images can be input using a sketch lattice, a grid which divides the sketch space. For this model, we used a three-cell lattice to represent the three phases of each experimental trial. Stimuli were reproduced in PowerPoint. The experimenters traced over images of the original stimuli, ensuring that the number of sides in the new polygons was the same as in the original.

Representations CogSketch uses edge-level representations to perform two-dimensional shape transformations and comparisons. The qualitative edge-level representations describe spatial relations between edges, as summarized above. The quantitative representation includes for each edge: 1) The location of its center. 2) Its two-dimensional orientation. 3) Its length. 4) Its curvature.

When a shape is scaled, rotated, or reflected, each individual edge is transformed. This has little effect on the qualitative representation, but it can change each of the four features in the quantitative representation.

Shapes are compared in a two-step process. 1) Qualitative representations are compared using the Structure-Mapping Engine. This identifies the corresponding edges in the two shapes. 2) Each corresponding edge pair's four quantitative values are compared. If every pair is quantitatively the same, the shapes are identical.

Strategy Given a stimulus such as Figure 1B, the model automatically constructs an edge-level representation of each shape. It detects the orientation of the arrow and rotates the base (leftmost) shape accordingly. It then compares the rotated base shape to the target shape to determine whether they are identical.

Spatial Smoothing Recall that scalable representations allow two forms of spatial smoothing: spatial detail may be smoothed out, or certain types of spatial information may be removed entirely. There are many possible ways to smooth data, e.g. apply a Gaussian filter to the entire shape (Figure 3B). Such an approach would lose critical information about the nature of the edges making up the object. Here, we use a simple sampling strategy: we remove all but the four longest edges (Figure 3C). This operation produces representations of equal size for all shapes, regardless of their initial complexity, which is what we desire.

The quantitative representations contain four types of spatial information. We propose that spatial smoothing might remove three, leaving only a single type. In our evaluation, we test whether the task can be performed using only edge locations or using only edge orientations.

## Paper Folding

We modeled the paper-folding task shown in Figure 1D.
Input Each paper-folding stimulus was recreated in PowerPoint. The square representing the base of the cube
was given a solid gray fill (CogSketch can recognize elements by their color). CogSketch was given three objects: the unfolded cube and the two arrows pointing to the critical edges.

Representations This model required the development of a new representational level: surfaces. Surfaces are closed shapes making up the sides of three-dimensional objects. Each square of the unfolded cube is a separate surface. Surfaces can be computed easily using CogSketch's existing ability to find closed cycles of edges.

This model does not need to find corresponding elements, so it requires only quantitative representations. Each surface is represented with: 1) The location of its center. Locations are now in three-dimensional space, unlike with the previous model. 2) Its orientation, i.e., the orientation of a vector orthogonal to the surface. Three-dimensional orientations are unit vectors containing ( $x, y, z$ ) components, unlike the single value required for two dimensions. 3) A list of edges going around the surface. Each edge has its own individual location and orientation.

Three-dimensional rotations are performed about an axis in three-dimensional space. For example, in Figure 2B, surfaces $\mathrm{A}, \mathrm{B}$, and C are rotated about the edge connecting surface A to the base of the cube.

Strategy Given a stimulus, the model segments the object into edges and surfaces. Using the arrows, it identifies the two critical edges and their associated surfaces. In Figure 1D, the critical surfaces are the base of the cube and surface C. It folds each critical surface back into the cube shape via two spatial operations: 1) Trace along adjacent surfaces from the critical surface to the base surface. For surface C, this would produce the following trace: C->B->A->base. 2) Rotate $90^{\circ}$ about the edge between surfaces in the reverse trace order. First rotate surface A about the edge between the base and surface $A$. Because surfaces $B$ and $C$ are connected to A, they will also be rotated (Figure 2B). Next, rotate surface $B$ about the edge between surfaces $A$ and $B$. Because C is connected, it will also be rotated. And so on.

The model performs these two operations on each critical surface. In Figure 1D, the second critical surface is not rotated because it is already the base. The model takes the resulting shape and evaluates whether the two critical edges are aligned, i.e., have the same location and orientation.

Spatial Smoothing In this task, the location and orientation of most edges is irrelevant to the task; only the two critical edges matter. If an edge lies along only one surface, it can be ignored. If an edge lies between two surfaces (e.g., the edge between surfaces $A$ and $B$ ), it is important for determining the axis of rotation. However, because this task involves perfectly regular square shapes, a heuristic can be used: when rotating between two surfaces, place the axis of rotation halfway between the surfaces' centers, and orient it within the plane of those surfaces, perpendicular to the line connecting their centers. Due to this heuristic, all edges can be ignored except the two critical edges.

This means the following is being considered: the location and orientation of each rotated surface (and of the base), and the location and orientation of each critical edge. It may be possible, again, to consider only the location or orientation of the critical edges. However, both a surface's location and its orientation must be used in computing axes of rotation.

## Simulation

## Mental Rotation

The original experiment (Cooper \& Podogny, 1976) used five base shapes which varied in complexity from a 6 -sided figure to a 24 -sided figure. On each trial, participants were cued to rotate shapes some multiple of $60^{\circ}$ using the rotated arrow. They were then presented with a target shape at the new orientation. This could be: a) the same shape; b) a mirror-reflected shape; or c) a shape with some of the points permuted from the base shape. While distractors of type b) are commonly used, the distractors of type c) were added to test how carefully participants were rotating the shapes.

In this simulation, we ran the model on all six base shapes. However, we used only a single rotation value $\left(60^{\circ}\right)$, and only the mirror-reflected distractors. The single rotation was used because other rotations are mathematically equivalent and should not place additional demands on the model. The mirror-reflected distractors were used because they are the most common distractors found across different mental rotation tasks. In Future Work, we consider the challenge of recognizing permuted distractors.

Results Recall that the model spatially smoothed each shape, removing all but the four longest edges. This proved sufficient for recognizing that same shapes were the same and mirror-reflected shapes were different. Furthermore, when only edge orientations or only edge locations were used, either was sufficient for performing the task. We can conclude that when the distractors are sufficiently different, very little information must be rotated to perform mental rotation, and the complexity of the shapes is irrelevant.

## Paper-Folding

Shepard and Feng (1972) identify ten different classes of paper-folding problems, based on the number of folds and the number of squares per fold. For example, Figure 1D is a class I problem, in which $3+2+1$ squares must be rotated for one critical edge and no squares must be rotated for the other. Their paper provides one example of each class.

In this simulation, we ran the model on the single example of each class. Other instances of a class are mathematically equivalent. As in the original study, there was one nonmatch problem (where folding did not cause the critical edges to align) for each match problem. Nonmatch problems were created by randomly rotating an arrow so that it pointed to an adjacent edge in the same square.

Results Recall that the model rotated each surface's center and orientation. The two critical edges were rotated also, but
all other edges were ignored. This proved sufficient for solving all problems-the model correctly distinguished between matches and nonmatches. Furthermore, when only edge orientations or only edge locations were used to compare the critical edges, either was sufficient.

## Discussion

Having successfully modeled both tasks, we can now consider how much data must be transformed to perform mental rotation and paper-folding. The mental rotation model required only four values: the orientations or locations of the four longest edges.

Now, suppose the model were rotating two surfaces during paper-folding. This would require five values: the location and orientation of the two surfaces, and the location or orientation of the critical edge. Furthermore, these values are three-dimensional, whereas the mental rotation values were two-dimensional. In the computational model, threedimensional values are far more complex-for example, an orientation is a vector with ( $\mathrm{x}, \mathrm{y}, \mathrm{z}$ ) components. Spatial data is likely implemented differently in the brain, but there still may be increased processing demands for three dimensions (see Jolicoeur et al., 1985 for a discussion; but see Shepard \& Metzler, 1988).

These results support our initial hypothesis. Rotation rate appears to depend less on shape complexity than on the degree and type of detail required by the task. Paper-folding requires that more information be transformed, even when only two surfaces are being rotated and the surfaces are perfect squares. We propose that paper-folding overwhelms people's spatial working memory, forcing them to rotate one surface at a time in a piecemeal fashion.

## Conclusions and Future Work

This paper demonstrates how visual stimuli can be encoded, transformed, and compared. The computational model builds on existing cognitive models of visual representation and comparison. While we wish to avoid strong conclusions about how spatial information is represented and transformed in the brain, the model provides valuable information on the constraints of the modeled tasks.

In particular, the model suggests much of the spatial detail in a shape can be ignored during transformation. The detail needed depends on the task. In a task like mental rotation, where a single transformation is applied to all edges, very little detail is required. In a task like paper-folding, where the results of one rotation determine the axis for the next rotation, more detail must be carried through each transformation. Of course, even in mental rotation more detail will be required as the distractors become more similar to the shapes being rotated (Folk \& Luce, 1987; Yuille \& Steiger, 1982).

These findings are important for understanding spatial ability. Fast, holistic spatial transformations require spatial smoothing. Thus, a key component of spatial ability must be spatial abstraction: the ability to identify and encode critical spatial details while ignoring irrelevant features.

Questions remain about how skilled rotators perform spatial abstraction. The present approach of selecting the four longest edges, while effective, is only one heuristic. Others might include studying the distractors to determine which parts of a shape are most diagnostic (Yuille \& Steiger, 1982) and segmenting shapes into larger-scale parts (Hoffman \& Richards, 1984). In the future, we would like to study a larger stimulus set with distractors that vary in their similarity to the base shapes (Cooper \& Podogny, 1976; Folk \& Luce, 1987). By evaluating different spatial smoothing heuristics in the model, we can better understand the skills supporting spatial abstraction and spatial ability.

#### Abstract

Past research has uncovered evidence of social influences on a wide variety of behaviors. Everything from our choice of clothing to smoking appears to be shaped by the people we know. However, little is known about the mechanisms that underlie these influences. Here, we report a series of agentbased simulations demonstrating that information diffuses across social networks in much the same way that behavior diffuses. These findings lead us to conclude that many previously observed social influences on behavior likely rely on a substrate of information transmission and representation.

Keywords: learning, memory, collaboration, social network, agent-based modeling

## Diffusion of Behavior

The idea of social influence has long been a topic of fascination for both scientists and the general public (Bartlett, 1932; Cialdini, 2001; Gladwell, 2000; Schelling, 2006). The general concept of social influence is an intuitive one. For instance, peer pressure is a factor in adolescents' tendency to drink, smoke, and engage in sexual behavior and some individuals slavishly follow the latest fashion trends, mimicking the styles seen on the runway or worn by celebrities. However, the intuition about social influence is far too narrow. The examples cited above are seen as exceptions; perhaps the susceptibility is restricted to a particularly impressionable population (e.g. adolescents) or perhaps influence is seen for relatively trivial behaviors (e.g., the clothes you wear). Such mindless imitation would not be seen, intuition suggests, concerning behaviors that are both deeply personal and of great consequence (e.g., suicide, how many children to have). Surprisingly, research has challenged this intuition, finding that social ties strongly influence a wide range of behaviors, including transformative life decisions (Christakis \& Fowler, 2009; Watts, 2003). For example, a program of research by Christakis and Fowler (2007) has revealed the surprising "contagion" of health-related attributes such as obesity and smoking.

In psychology, there is a long history of work exploring the influence of social context on behavior. Early work focused on the potentially deleterious behavioral effects of social influence. For example, Milgram (Milgram, Bickman, \& Berkowitz, 1969) examined social influences on arbitrary
behavior as a function of group size. In this study, groups of between one and 15 confederates stood on a New York street corner looking upward at a window overhead. Passing pedestrians were likely to mimic some aspect of the observed behavior (e.g., looking up) and this tendency increased with group size. The classic studies of Asch (e.g., Asch, 1951) demonstrate the power of social influence even more starkly because his participants were asked about matters of objective fact (e.g., the length of lines). Despite being accurate when making judgments individually, participants placed with confederates tended to conform, producing substantial errors.

Though past work has revealed the presence of social influences on a variety of behaviors, we know little about the mechanisms that underlie these influences. For example, it has been suggested that, "Social networks function...by giving us access to what flows within them" (Christakis \& Fowler, 2009, p. 91). But what does flow within our social networks that allows for these powerful influences on our behavior?

## Existing Models of Social Influence

Several mathematical models of social influence have been proposed (Easley \& Kleinberg, 2010; Jackson, 2008; Lopez-Pintado \& Watts, 2008). Among the most influential are linear threshold models (Granovetter, 1978). Such models assume that each individual has two mutually exclusive and exhaustive behavioral options available. For example, in Granovetter's classic example, each individual chooses whether or not to join a riot. In addition, each individual is assumed to observe the behavior of all other individuals. The decision of the individual is then a function of their own idiosyncratic threshold and the behavior observed in the group. If the number of other people observed to be rioting does not exceed the individual's threshold, she remains a bystander. If this number exceeds the individual's threshold, she begins to riot.

Several key details of the current crop of mathematical models should be noted. First, this work typically assumes "zero-intelligence agents" (Gode \& Sunder, 1993) that can do nothing but copy the behavior of their neighbors with some probability (e.g., Granovetter, 1978). This is undoubtedly convenient, but represents a substantial simplification, at least when attempting to model human behavior. Though some behaviors may be the result of
innate imitative mechanisms, many more behaviors are deliberative, relying on individuals' beliefs, goals, and desires. Second, many of the computational models of behavioral diffusion assume that individuals can occupy one of a small number of behavioral "states". For example, in the rioting example discussed above, individuals are assumed to either be rioting or not rioting, another vast over-simplification. Finally, because of these simplifications, previous models have largely avoided questions about the mechanisms by which behaviors are transferred between individuals. Indeed, these models expressly omit such mechanisms by assuming that mimicry is the critical basis of diffusion. To address the mechanisms themselves, the current study takes an agent-based modeling (ABM) approach (Smith \& Conrey, 2007; Stasser, 1988; Carley, Martin, \& Hirshman, 2009; Parunak, Belding, Hilscher, \& Brueckner, 2009; Coman, Kolling, Lewis, \& Hirst, 2012) in which agents are information processing units capable of representing information and learning.

The current study investigates the representation and transmission of information within social networks as fundamental mechanisms underlying these potent influences on our behavior. Specifically, we investigate how information is represented by individuals within a larger network and how the nature of social interactions shape the information as it flows through the network.

## Collaborative Memory in Small Groups

Recent behavioral work on the social transmission of memory in small groups has identified several key mechanisms that facilitate or inhibit information transmission in small groups, and how the interaction among these mechanisms shapes convergence amongst group members (what is referred to as collective memory). The collaborative memory paradigm provides a robust method for measuring the transmission of information in small groups of two or three participants (Rajaram, 2011). In this paradigm, each participant is first exposed to experimenter-provided stimuli (words, pictures, narratives). Participants then form groups and recall items collaboratively. Finally, participants recall items individually to assess the post-collaborative representations retained by each participant.

The consequence of collaboration on group memory is counterintuitive. Though a collaborating group recalls more than a given individual, the group recalls significantly less than its potential, a phenomenon called collaborative inhibition (Weldon \& Bellinger, 1997). To estimate the group's potential, performance is compared to that of a nominal group: the total, nonredundant recall of an equal number of participants who recalled individually (Blumen \& Rajaram, 2008; Weldon \& Bellinger, 1997). Although it seems reasonable to assume participants perform suboptimally because they feel less accountable while working in groups (social loafing; Latane, Williams, \& Harkins, 1979), experimental findings shows this is not the case (Weldon, Blair, \& Huebsch, 2000).

## Mechanisms Involved During Collaboration

The suboptimal performance of collaborative groups has been attributed to the retrieval disruption process where the output of one participant's recall disrupts other participants' attempts at recall, and as a result lowers the latter participants' output (B.H. Basden, Basden, Bryner, \& Thomas, 1997). Because each individual recalls less than her potential during collaboration, researchers have asked whether their post-collaborative representations would continue to exhibit this deficit. Though some forgetting does occur (Cuc, Koppel, \& Hirst, 2007) two mechanisms usually enhance the quantity and accuracy of postcollaborative representations; one, items not recalled during collaboration bounce back post-collaboratively (rebound) and, two, collaboration acts to expose each participant to items she might not have remembered otherwise (reexposure, Blumen \& Rajaram, 2008, 2009; Congleton \& Rajaram, 2011).
Several individual- and interaction-based properties influence these collaborative effects. One such change of note relates to increase in memory errors. As one example, social contagion errors arise when the stimuli activate plausible items for recall that were never presented (B.H. Basden et al., 2002; French, Gary,\&Mori, 2008; Reysen, 2007; Roediger, Meade, \& Bergman, 2001). Such contagion has been demonstrated in collaborative studies (B.H. Basden et al., 2002) using DRM stimuli (Roediger \& McDermott, 1995) in which a list of associatively-related words such as bed, rest, awake, tired, dream, wake, snooze, blanket, etc. leads participants to recall the never-presented lure (sleep) with great confidence. Propagation of memory errors in the real-world has been an enduring concern of cognitive scientists (e.g., Bartlett, 1932) but empirical investigations have remained elusive due to feasibility.
Memory representations in small groups are also characterized by the frequency with which information is processed before and during collaboration. For instance, the individual who dominates the collaborative discussion benefits most from rehearsal (Rajaram \& Pereira-Pasarin, 2010) and has the largest influence on the post-collaborative representations of other group members (Cuc, Ozuru, Manier, \& Hirst, 2006). Conversely, post-collaborative memory deficits occur for information not discussed during collaboration, either through omission (Cuc et al., 2007), rejection of correct responses (Merckelbach, van Roermund, \& Candel, 2007), or group conformity to incorrect responses (Reysen, 2005). We have further shown that frequency of discussion prior to or during collaboration changes both collaborative group recall and post-collaborative memory; when information is repeatedly processed prior to collaboration, it can reduce or even eliminate collaborative inhibition in group recall (Congleton \& Rajaram, 2011; Pereira-Pasarin \& Rajaram, 2011), and improve postcollaborative memory (Congleton \& Rajaram, 2011). Just as interestingly, when groups are given the opportunity to discuss more frequently this too reduces collaborative inhibition in group recall (B.H. Basden et al., 2000; Blumen
\& Rajaram, 2008). These behavioral outcomes raise intriguing questions about how frequency of discussion influences group-level representations in large social networks.

Yet another intriguing finding concerns the effects of group size. Even within small groups, research shows that as group size increases (from 2 to 3 or 4 members) collaborative inhibition increases with group size (B.H. Basden et al., 2000; Thorley \& Dewhurst, 2007). This raises the question about whether larger social networks would display an exaggerated version of this decline or whether the complex interplay of mechanisms would completely change how the group-level representation evolves.

## Current Approach

In the current study we investigate the processes that shape the transmission of information during both the collaborative remembering in the laboratory paradigm and more realistic social contexts. We take an agent-based modeling approach in which individuals are represented by computational agents and allowed to interact much as human subjects interact in the collaborative memory paradigm. The agents are endowed with simplified memory models capable of storing a set of $N$ items (e.g., words). The memory model consists of two separate representations. First, agents represent a set of inter-item associations that exist prior to any social interaction (a matrix denoted $S$ ). These associations represent pre-experimental knowledge such as the semantic associations between words. For the sake of simplicity, these inter-item associations were assigned random values (within the range $[0,1]$ ) in the current simulations. More systematic prior knowledge could obviously be constructed, particularly if such factors were important for specific research questions. For example, lists of categorized words can be simulated by constructing high within-category associations and low between-category associations, a strategy we have successfully used in recent modeling (Luhmann, Congleton, Zhou, \& Rajaram, 2013). The second representation is a set of $N$ activations (a vector denoted $A$, with elements bound to the range [ 0,1$]$ ), which allow for learning to occur during the experimental experience itself. For example, these activations capture recent experience studying experimenter-provided stimuli (e.g., word lists), items generated by collaborative partners, and even items generated by the agent itself.

Agents have two behaviors. First, they may encode a presented item by increasing the activation associated with the presented item (i.e., $\Delta A_{i}=\alpha\left[1-A_{i}\right]$, where $A_{i}$ is the activation of the item and $\alpha$ is a learning rate). This encoding occurs when items are presented by the experimenter (i.e., during the collaborative memory paradigm's initial study phase) and when agents are exposed to the items retrieved by other agents (e.g., during collaborative recall). Second, agents can retrieve an item. This is done by randomly selecting an item in proportion to the activation levels in $A$ (i.e., more active items are more likely to be generated). If the activity of the candidate item
is above the agent's recall threshold ( $\gamma$ ) and has not yet been generated by the group, then this item is successfully retrieved and generated (e.g., spoken out loud). Finally, associates of the retrieved item (from $S$ ) have their activations decreased (i.e., $\Delta A_{j}=-\beta S_{i j} A_{i}$ where $A_{i}$ is the retrieved item, $S_{i j}$ is the strength of the association between items $i$ and $j$, and $\beta$ is a forgetting rate).

Figure 1 - Simulations replicate the collaborative inhibition effect

## Simulation 1: Collaborative Inhibition

Our first investigation is of the most surprising finding to come out of the collaborative memory paradigm: collaborative inhibition. This was done for two reasons. First, the finding is elicited from a fairly simple experimental paradigm making these initial simulations relatively straightforward to construct. Second, to the degree we are capable of successfully replicating the least intuitive aspect of the empirical data, we can proceed with somewhat more confidence that our formalism has not overly simplified the cognitive processes involved.

To simulate the collaborative memory paradigm, we first presented the entire list of $N$ items to each agent in a random order. Three agents were then allowed to interact with one another. The interaction was structured such that each agent was given an opportunity to retrieve an item on each round. If an agent successfully retrieved an item, the retrieved item was encoded by the other two agents. Figure 1 illustrates the results of 1000 simulations of a collaborative condition and 1000 simulations of a nominal condition (i.e., total, nonredundant recall of three agents recalling individually) evaluated exactly as in the behavioral studies described above. As can be seen, the simulation results reproduce the collaborative inhibition findings describe above. This result is likely due to the fact that each agent is endowed with an idiosyncratic set of activations during the initial, individual study phase but then learns the contents of their peer's activations during the collaborative phase. Thus, the interaction between agents tends to increase the similarity of the agents' representations and minimize the idiosyncrasies that make the nominal groups more successful in generating greater quantity. Furthermore, exploratory simulations suggest that having individual agents repeatedly engage in isolated retrieval does not diminish the performance of the nominal group, suggesting that the collaborative inhibition is due to the social interaction (e.g., retrieval disruption, B.H. Basden et al., 1997) rather than repeated retrieval.

Figure 2 - Influence of group size on collaborative inhibition

## Simulation 2: Group Size

As mentioned above, prior work with the collaborative memory paradigm has manipulated a variety of different factors. One factor that has received surprisingly little attention is the size of the collaborating group despite its obvious real-world relevance. Only two studies have manipulated group size (B.H. Basden, Basden, and Henry, 2000; Thorley and Dewhurst, 2007), and both concluded that increasing group sizes produce more detrimental collaborative effects. Details of these studies limit interpretation, however. For example, Basden et al. (2000) tested 1-, 2-, and 4 -person groups. Though the 1-person groups recalled more than the 4-person groups, the 2-person groups were different from neither. Thorley and Dewhurst (2007) used DRM stimuli and were specifically interested in groups' tendency to falsely recall the lure items (rather than recall per se). Further, the group size tested was small in these studies (2-4 person groups) again limiting interpretation.

Here, we systematically manipulate group size and investigate the influence of this factor on collaborative inhibition. We simulated collaborative groups ranging in size from two to seven as well as nominal groups consisting of agents retrieving in isolation. As before, the entire list of $N$ items was first presented to each agent. The agents within a group were then allowed to interact with one another with the interaction structured as described above.

Figure 2 illustrates the results of 1000 simulations for each group size. The standard collaborative inhibition effect (measured here as Nominal - Collaborative) was found for all group sizes. However, the relationship between group size and collaborative inhibition was not entirely straightforward. As groups grew from two to four, collaborative inhibition increased (replicating Basden et al., 2000). However, as group size increased further, collaborative inhibition decreased. This non-monotonic relationship appears to be driven by the relative balance between the facilitative effects offered by collaboration (i.e., more agents increase the probability that the group will retrieve a given item) and the detrimental effects of retrieval disruption (i.e., more collaborators means more opportunities to be disrupted).

## Simulation 3: Diffusion of Collective Memory

The collaborative memory paradigms represent a realistic, real-world social network that is amenable to experimental study. However, the size of groups involved in this paradigm places obvious restrictions on the research questions that may be asked. The current simulation seeks to achieve substantially greater realism than the more traditional laboratory paradigms allow. Specifically, we wish to explore how the information represented by and shared between individuals makes its way through larger social networks.

To explore true social networks, we employed a larger population (60 computational agents of the kind described above), each of which was placed into a larger network structure. Though there are many potentially interesting network structures, we are most interested in those related to real world social networks. For this reason, the current simulation employs a so-called small world network (Watts \& Strogatz, 1998). Within such a network, the shortest distance between two nodes is short on average despite the network itself being relatively sparse (most nodes are not neighbors). These features give rise to the well-known "six degrees of separation" phenomenon. We further chose to set the average degree to 2 (meaning that agents were, on average, connected to 2 other agents).

As in the simulations reported above, each simulation began by presenting the entire list of 40 items to each agent individually. All subsequent interaction between agents occurred over this network. On each epoch of the simulation, a random agent was selected along with one of that agent's randomly selected neighbors. This pair was then allowed to interact just as the collaborative groups simulated above (each taking a turn to retrieve, etc.). To assess the diffusion of information across the network, we computed the similarities between pairs of agents' representations (i.e., the correlation between activation vectors, A) after the simulations were completed. This measure of similarity goes up with the overlap (both in what they represent strongly and what they have forgotten, i.e., collective memory) and goes down when one agent has forgotten an item that the other agent still remembers (i.e., is strongly active in $A$ ). We computed the similarity between all pairs of agents (i.e., both neighboring pairs and nonneighboring pairs) sorting these similarities on the basis of how close the two agents in each pair were to each other within the network (i.e., minimum distance). Neighboring agents would have a distance of 1 . Two non-neighboring agents that shared a common neighbor would have a distance of 2 and so on.

Figure 3 illustrates the results of a 60 -node small world network that was allowed to run for 1000 epochs. As can be seen, neighboring agents acquired very similar representations. This is not particularly surprising since neighboring agents will have interacted with each other and learned the contents of their neighbors' representations. What is surprising is that agents at a distance of two are highly similar as well. These agents never interacted with
one another, so direct communication cannot explain this similarity. Instead, the two agents' common neighbor presumably acted as a conduit through which information diffused, indirectly connecting the non-neighbors. Even more surprising then, is the fact that agents at distance three, separated by two intermediate agents, are also somewhat similar. After this point, the similarity between agents levels off, reflecting the boundaries of collective memory in large networks.

This similarity between non-neighboring agents is a phenomenon that has been observed in a variety of realworld social networks and is known as hyperdyadic spread (Christakis \& Fowler, 2009). For example, previous work has shown that people are 57\% more likely to become obese if a peer (e.g., friend) becomes obese and $20 \%$ more likely to become obese if a peer of a peer (e.g., a friend of a friend) becomes obese. Furthermore, in many of the behaviors studied within social networks, hyperdyadic spread from a given node in the social network has been found to extend to three "hops" from that node (e.g., to the friend of a friend of a friend) but not beyond - what Christakis and Fowler (2009) have termed the three degrees of influence rule. The fact that our simulations comply with this rule is interesting because the standard finding of hyperdyadic spread concerns the spread of behavior whereas the current results reflect the spread of information. Exploratory simulations employing other network structures (e.g., chains, trees) have either failed to uncover strong hyperdyadic spreading or failed to conform to the three degrees of influence rule. This suggests that this class of phenomena may be jointly driven by both the details of the social networks in which we live (e.g., small-world networks) and the constraints of human learning and memory.

Figure 3 - Hyperdyadic spread of collective memory in our simulation results

## Discussion

Broadly speaking, the goal of the current study has been to investigate social influence in real world social networks. Prior research has developed formal models to capture how behaviors diffuse amongst large groups, but these formalisms have been relatively agnostic about the underlying psychological mechanisms, instead modeling such behaviors as being literally contagious. Here, we have argued that the cognitive processes governing learning and
memory are likely candidates for such mechanisms as they are in prime position to influence the representations individuals hold and transmission of information between f

Past work using the collaborative memory paradigm has provided useful empirical data with which we can begin to explore our proposal. In this paradigm, groups of individuals first study items in isolation before collaborating in groups to recall these same items. Despite the practical limitations posed by this paradigm (e.g., small group sizes), the literature has provided a wealth of insights into the social influences on learning and memory. These insights include the role of retrieval disruption, re-exposure, and error correction, the influence of group size, and phenomena such as collaborative inhibition and error propagation.

In the current study, we have taken an agent-based modeling approach, simulating individuals as relatively simple information processing units capable of representing information, learning from experience, and interacting with other agents. In order to evaluate our proposal, we selected three different phenomena to explore. We first investigated the robust collaborative inhibition effect. Our simulations replicate the standard pattern of results, with collaborative groups under-performing relative their controls. We next simulated the somewhat less thoroughly studied role of group size on the collaborative inhibition effect. Here, we found that our simulations were capable of replicating the effects observed in the literature (increasing collaborative inhibition with increasing group size) but also made predictions about the boundary conditions of these effects. Finally, we extended our findings beyond the collaborative memory paradigm to investigate agents in a larger social network. Here, we found that our simulations exhibited hyperdyadic spread, a standard empirical finding in the diffusion of behavior across social networks.

We take the success of the current simulations as evidence in favor of our proposal. Our simulations demonstrate that the spread of information across connections in a social network mirrors the way in which behavior spreads across those same connections. Thus, it seems likely that social influence, and particularly the diffusion of behavior, relies on a substrate of information transmission and representation.

# The effect of social roles on gaze cue utilisation in a real-world collaboration 

Ross G. Macdonald (rgmacdonald@dundee.ac.uk)<br>School of Psychology, University of Dundee, Nethergate, Dundee, DD1 4HN, UK

Benjamin W. Tatler (b.w.tatler@activevisionlab.org)<br>School of Psychology, University of Dundee, Nethergate, Dundee, DD1 4HN, UK

#### Abstract

During collaboration, people communicate using verbal and non-verbal cues, including gaze cues. Social factors can affect gaze allocation, however most research on gaze cueing has not considered these factors. The presence of social roles was manipulated in a collaborative task whilst eye movements were measured. In pairs, participants worked together to make a cake. Half of the pairs were given roles ("Chef" or "Gatherer") and the other half were not. Across all participants we found, contrary to the results of static image experiments, that participants spent very little time looking at each other, challenging the generalisability of the conclusions from lab-based paradigms. When given spoken instructions, listeners in the roles condition looked at the speaker significantly more than listeners in the no roles condition. We conclude that our tendency to seek the gaze cues of collaborators is affected either by our social perceptions of the collaborator or their perceived reliability.

Keywords: eye movements; joint attention; real world; gaze cues; social interaction.

## Introduction

When collaborating with another on a task, we need to communicate. As well as using spoken language, there are a number of non-verbal cues we can use, with the directional gaze cues given by the eyes being the most well-researched of these. Gaze cues are first used very early in life and continue to be given and followed throughout adulthood. People have a tendency to orient to and follow the gaze cues of others and can to do this with ease. However, there is evidence that the language accompanying a gaze cue and the social context of the cue can affect how people orient to and follow gaze cues. In the real world, gaze cues will always occur within a social context, yet this context is removed in most studies. The aim of the present study is to measure eye movements in a real-world setting to observe how the utilisation of gaze cues can be affected by social context in a natural collaboration.

When viewing images of faces, people have a tendency to look at the eyes (Yarbus, 1967) and when viewing images of social scenes people will seek out faces and eyes (Birmingham, Bischoff \& Kingstone, 2007; 2009) even when the person being fixated is not visually prominent and has no role for understanding the scene (Zwickel \& Võ, 2010). As well as orienting to these cues, people show a tendency to follow them. Friesen and Kingstone (1998) showed that incongruent gaze cues presented at fixation
could slow down responses in a Posner (1980) task, suggesting that the artificial gaze cue stimuli automatically shifted attention away from the target. Variants of this study looking at eye movements have found that participants will also look in the direction of the distracting gaze cue, even though they know there is no reason to do so (Ricciardelli, Bricolo, Aglioti, \& Chelazzi, 2002; Galfano et al, 2012). These findings have been used to suggest that humans are "hard-wired" to automatically follow the gaze cues of others (Emery, 2000).

The above research shows that people look at eyes and follow gaze cues when viewing isolated static images of others. However, in the real world, gaze cues usually occur alongside spoken language. There appears to be an intimate link between gaze allocation and spoken language, with people making anticipatory eye movements to objects that relate to what they hear (Altmann \& Kamide, 1999). Gaze cue utilisation in particular has been shown to be affected by spoken language; changing the syntactic structure of a sentence, whilst maintaining meaning changes the timing of gaze following (Knoeferle \& Kreysa, 2012). Reciprocally, Stuadte and Crocker (2011) showed the gaze cues can affect the understanding of spoken language; participants were shown videos of a robot describing the spatial and featural relations between a series of visible objects, whilst providing gaze cues. The robot made mistakes in his descriptions that could have been corrected in two different ways. The experimenters found that participants would correct in the way that was congruent with the gaze cue, suggesting that they were inferring meaning from the robot's gaze and assuming that the robot meant to refer to the object that it was gazing at. Given the effect gaze cues and language have on each other, it is important to use language in a paradigm investigating how gaze cues are used naturally in collaboration.

As well as mostly occurring alongside language, all gaze cues in the real world are provided in a social context. When interacting with another, where we look can be affected by our proximity to this other person (Argyle \& Dean, 1965). Social effects specifically on gaze seeking were investigated by Laidlaw, Foulsham, Kuhn and Kingstone (2011), who found that participants sitting in a waiting room were significantly more likely to look at a person on a monitor than the same person present in the room. Gallup et al (2012) found similar results for gaze following rather than seeking. They observed people walking past an attractive
item in a hallway and found that people were more likely to look in the same direction as somebody walking in front of them than somebody walking towards them. The results of these studies were explained by their respective authors as being due to participants trying to avoid potential interactions with strangers, which might be triggered by any gaze seeking or following behaviour detected by the oncoming person. These findings indicate that social factors can affect the way we utilise the gaze cues of strangers, which suggests that social context may have an effect on gaze utilisation in one-to-one interactions and collaborations.

Macdonald and Tatler (2013) considered gaze seeking and following behaviour in a real world communicative task, involving one-to-one interaction between an instructor (the experimenter) and a participant. The instructor manipulated his use of gaze as well as the specificity of his instructions in a simple block-building task. Participants were found to only seek and follow gaze cues when the language was ambiguous (it did not specify which single block the participant was meant to pick up), suggesting that gaze cues are used flexibly, depending on other information that is available. It was also noted that even when gaze cues supplied the only unambiguous information about which block to pick up (because the spoken instructions were ambiguous) participants did not seek and follow these all of the time. It was speculated (Macdonald \& Tatler, 2013) that social factors may have played a part in these results. More specifically, the social cost of looking at the instructor frequently in each trial may have deterred participants from seeking and following these gaze cues. Although this is speculation, these results make a case for manipulating social factors in a real-world gaze-cueing experiment.

One way to manipulate social factors in a gaze cueing task is to manipulate what the participant knows about the entity with which they are interacting. Participants carrying out a Posner (1980) task in Italy were shown distracter gaze cueing stimuli made from the faces of Italian political figures, including Silvio Berlusconi (Liuzza et al, 2011). The gaze of Berlusconi was found to cause significantly more interference in the task for right-wing voters (ingroup) than left wing voters (out-group). These results suggest that people may be more prone to following the gaze cues of others with shared beliefs. Crosby, Monin and Richardson (2008) showed that participants were more likely to look at an individual on a monitor if they thought the individual could hear comments that were potentially offensive to that individual. These results show that social factors such as beliefs about another individual can affect how others look at them as well as how others look at external objects whilst communicating with them. Although, these results show effects of prior beliefs about others on gaze behaviour, it is still unclear how beliefs about the role or knowledge of another affect the use of gaze cues in natural collaboration.

The present study manipulates participants' perception of their collaborator by assigning them roles in a task.

Participants, in pairs, were given a recipe to follow in order to make the batter for a cake. During this collaboration their eye movements were recorded using portable eye-trackers. When coding the data we were particularly interested in the time participants spent looking at each other (interpersonal gaze) or at the same object simultaneously (mutual gaze). Half of the pairs were given roles (chef or gatherer) to fulfil and the other half were not. By manipulating this we are able to investigate whether the perception of another's role in collaboration has any significant effect on the extent to which we seek and follow their gaze cues in a real-world interaction.

## Methods

## Participants

Twenty-four students from the University of Dundee participated in this experiment. They were split into twelve pairs to carry out the task. Six pairs were allocated to the roles condition and six were allocated to the no roles condition (see design).

## Materials

The experiment took place in a kitchen area on the University of Dundee campus. The kitchen was fully equipped with standard kitchen appliances, but only the oven and microwave were used. All items and foodstuffs that could be removed were removed before testing and the experimental materials were arranged carefully around the kitchen. This included the items and foodstuffs that were to be used for the procedure as well as a selection of distractor items. All of these items were placed in the same location for each pair of participants. A Recipe Procedure sheet was provided for each pair. This sheet explained, step-by-step, how to make the batter for a Victoria Sponge. There was also a Chef Guidelines sheet and a Gatherer Guidelines sheet for those in the roles condition. These sheets explained the responsibilities and duties for participants in the chef and gatherer roles.

## Design

This experiment had a between subjects design. The two independent variables for the analysis of mutual fixations and time participants spent looking at each other (interpersonal gaze) were the use of roles (roles or no roles) and the allocation of roles within the roles condition (chef or gatherer). For the analysis of the instruction statements the independent variables were the use of roles (roles or no roles) and the identity of participant (speaker or listener).

## Procedure

This experiment required two participants. The experimenter began by fitting a portable eye tracker to the first participant. At this point in the roles condition the first participant was given the Chef Guidelines and the second participant was given the Gatherer Guidelines. They were both instructed to read over their sheet and make sure they understood their roles. The Chef Guidelines informed the chef that they were in charge of preparing the recipe and that the gatherer was there to assist them. The sheet explained that the chef was expected to mix and prepare ingredients, following a recipe which they could not show to the gatherer. The chef would not be expected to collect any items or foodstuffs, but to delegate those duties to the gatherer. The chef would also be able to ask the gatherer to assist them with any aspect of the preparation they wished. The Gatherer Guidelines explained that the gatherer would not be expected to make any decisions concerning the preparation, but should instead do as instructed by the chef. Once the participants declared they understood their roles the gatherer was asked to remain outside whilst the experimenter and the chef entered the kitchen. The experimenter then gave the chef the Recipe Procedure sheet and told the chef where all of the necessary items and foodstuffs were located. The chef was then told they would have approximately three minutes to familiarise themselves with the kitchen and the locations of the items. During these three minutes the experimenter fitted another portable eyetracker to the gatherer. In the no roles condition the second eye-tracker was fitted straight after the first. At this point, in both conditions, both participants were brought into the kitchen and the eye-trackers were switched on.

The cameras were synchronised and the eye-trackers calibrated. Once calibration was complete, those in the no roles condition were directed to the Recipe Procedure sheet and informed that all of the items they would require were located around the kitchen. All participants were informed that the experimenter would be standing outside the kitchen, out of sight and that the participants must make no attempt to interact with him. The experimenter then told the participants that they may begin as soon as he was out of the room. The experimenter left and the procedure began. The procedure ended when the participants put the batter mixture in the oven.

## Eye movement and sound recording

Participants' eye movements were tracked using two Positive Science LLC mobile eye trackers, which allowed free head movement. Each eye tracker has two cameras mounted on the frame of a pair of spectacles: one records the scene from the participant's point of view and the other records the right eye. Data from these cameras were captured on digital camcorders. For one of the eye-trackers these camcorders were stored, alongside a power supply for the eye-tracker, in a lumbar pack worn by the participant. The camcorders connected to the second tracker were again
stored alongside a power supply, but were stored in a light backpack worn by the participant. This eye tracker also has a small microphone attached to the frame. This microphone recorded sound throughout the experiment and was able to pick-up the voices of both participants. Gaze direction was estimated off-line using Yarbus software provided by Positive Science, LLC, which tracks the pupil and corneal reflection. Calibration was carried out in two stages, one looking down at a counter and the other looking across the room. These two stages were used because by tracking one eye we are not able to directly measure the vergence of the eyes that occurs as participants focus on objects at different distances. Instead we fit the model to fixations on both proximal and distal points. If the tracker estimates in the scene video fell on the correct calibration positions the calibration was deemed adequate. Eye movement data were recorded at 30 Hz with a spatial accuracy of about 1 degree. Once videos for both participants were rendered with the eye movement information, Quicktime Pro was used to synchronise both videos in to one movie file, ready for analysis.

## Analysis

Eye tracking data were coded manually offline using Quicktime Media player and audio information was extracted using Audacity sound editing software. The first two dependent variables considered were (1) the proportion of time both participants fixated the same object (mutual fixations) and (2) the proportion of time a participant spent looking at their partner (interpersonal gaze). For these analyses, in each pair, one participant was labelled person A and the other was labelled person B . In the roles condition person A was the chef and B was the gatherer. Since there were not any defined roles in the no roles condition, participants in this condition were arbitrarily allocated as person A or B. The frame-by-frame coding of these data was split between the lead experimenter and three undergraduate volunteers from the School of Psychology. To begin, all four coders coded the same movie file and these were all compared by the lead experimenter to ensure a consistent and high quality of coding. Mutual fixations were compared across conditions by a t-test and the proportion of time spent on interpersonal gaze was analysed using a 2 (roles or no roles) by 2 (person A or person B) independent measures ANOVA.

The individual instructions were also coded and analysed. These were coded by the lead experimenter alone, using audacity sound editing software and the Quicktime movie files. For each pair, each instruction statement was numbered and transcribed, noting the speaker. The time that the speaker first looked (if at all) at the listener and vice versa was coded for each instruction statement. In the roles condition, the speaker was always the chef and the listener always the gatherer. In the no roles condition the participant who gave the instruction was considered to be the speaker. Therefore the identity of the speaker and listener would
switch throughout each movie in the no roles condition. From coding these data we considered the percentage of instructions in which the participant looked at the other participant. This was analysed using a 2 (role or no role) by 2 (speaker or listener) ANOVA.

## Results

## Overview of eye movements in collaboration

The first set of results is focused on the general eye movement behaviour of participants in the roles and no roles conditions. To investigate this behaviour we measured the proportion of time participants spent mutually fixating objects and the proportion of time spent fixating on the coparticipant (interpersonal gaze).

The mean proportion of time in which both participants fixated on the same item (mutual fixation) is shown in Figure 1.

Figure 1: The mean percentage of time in which mutual fixation occurred for participant pairs in the roles and no roles condition (with standard error bars).

A larger mean percentage of time was spent on mutual fixation in the roles condition (27.23\%) than the no roles condition (20.69\%). However this difference was not found to be significant $(\mathrm{t}(10)=1.37, \mathrm{p}=0.200)$

The mean percentage of time spent engaged in interpersonal gaze is shown in Figure 2. This plot shows the percentage of time that A spends looking at $B$ and vice versa for the roles and no roles conditions. The amount of time when participants A and B simultaneously looked at each other is also shown in Figure 2, for the roles and no roles conditions.

Figure 2: The mean percentage of time participants spent on interpersonal gaze for Person A, Person B and A and B simultaneously for both the roles and no roles conditions
(with standard error bars)
It can be seen from Figure 2 that on average person B spent more time looking at person A (3.77\%) than viceversa (1.92\%) in the roles condition, whilst participants spent only $0.43 \%$ of the total time on simultaneous interpersonal gaze. In the no roles condition, Person A was found to spend slightly more time looking at person B ( $2.62 \%$ ) than vice versa ( $2.31 \%$ ) and only $0.27 \%$ of the time was spent simultaneously looking at one another. A two (roles, no roles) by two (person A, person B) ANOVA was carried out on these results. No main effects of role condition $(\mathrm{F}(1,20)=0.171, \mathrm{p}=0.683)$ or participant $(\mathrm{F}(1,20)=0.701, \mathrm{p}=0.412)$ were found, nor was there any significant interaction $(F(1,20)=1.381, p=0.254)$.

## Analysis of eye movements during instructions

These results consider the eye movement behaviour during the periods when one of the participants was giving spoken instructions to the other. For the roles conditions the spoken instructions were always provided by the chef. For the no roles conditions, any instructions could have been provided by either participant. We investigated the mean percentage of (spoken) instructions in which interpersonal gaze occurred. For each of the roles and no roles conditions, we considered cases when the speaker looked at the listener, the listener looked at the speaker or both speaker and listener looked at each other at the same time (Figure 3).

Figure 3. The mean percentage of instructions in which interpersonal gaze occurred for speakers, listeners and both speakers and listeners in the roles and no roles conditions (with standard error bars).

A two (roles, no roles) by two (speaker, listener) ANOVA showed a main effect of identity of participant (speaker or listener) $(\mathrm{F}(1,20)=12.00, \mathrm{p}=0.002)$. The main effect of role condition was not significant $(\mathrm{F}(1,20)=3.21, \mathrm{p}=$ 0.089 ), however, there was a significant interaction ( $\mathrm{F}(1,20$ ) $=4.92, \mathrm{p}=0.038$ ). Post-hoc t-tests showed that listeners looked at speakers during significantly more instructions in the roles condition (50.20\%) than the no roles condition ( $20.28 \%, p=0.010$ ), but there was no significant difference found between speakers' looks to listeners across the roles ( $7.78 \%$ ) and no roles ( $10.97 \%$ ) conditions ( $p=0.766$ ).

## Discussion

The aim of this study was to investigate the effect of manipulating social context on the utilisation of gaze cues in a real world collaborative social interaction. Using portable eye trackers we were able to measure the eye movements of both collaborators for the duration of the task. The time participants spent looking at each other in this real world paradigm was much less than expected, given the results of experiments using static social scenes (Birmingham et al, 2007; 2009). Social context was actively manipulated in this paradigm by the presence or absence of roles as there is evidence from lab based studies (Crosby et al, 2008; Liuzza et al, 2011) that beliefs about a collaborator can affect gaze behaviour. The amount that listeners looked at speakers during instructions was affected by our manipulation of the roles of the two participants, providing evidence that the tendency to look at another individual during a real world interaction may be influenced by the social context provided by the roles of the individuals. This result is consistent with previous suggestions that gaze seeking and following may depend on the social context of the gaze cues (Gallup et al, 2012; Laidlaw et al, 2011; Macdonald \& Tatler, 2013).

There was no significant difference found between the percentage of time in which mutual fixations occurred in the roles and no roles conditions, with collaborators spending approximately one-quarter of task time mutually fixating on the same objects. There was also no significant difference
between the percentage of time that interpersonal gaze occurred across roles conditions. However, participants spent far less time (between $2-4 \%$ ) looking at each other than they spent mutually fixating other objects. This is notable as it appears to be at odds with the results of some previous lab-based studies. People have been shown to have a preference for looking at eyes when viewing pictures of people (Yarbus, 1967) or social scenes (Birmingham et al, 2009; Zwickel \& Võ, 2010), however in this task participants spent very little time looking at their partners. Given the potential informativeness of the eyes (Tomasello et al, 2007) and the ease with which people can interpret gaze direction (Anderson, Risko \& Kingstone 2011) this finding may seem surprising. However, studies using real people as stimuli may offer an explanation. Laidlaw et al (2011) showed that people were less likely to look at a present confederate than the same confederate on a video monitor and Gallup et al (2012) found that people were less likely to follow the gaze of strangers that could see them than strangers who could not. They concluded that this was due to there being potential consequences (social interaction) to looking at the present confederate or the oncoming stranger. A collaborator in the present study could potentially react to the looks of a participant, whereas the static and video images in lab based paradigms could not. Therefore, these lab-based studies may have over-estimated the tendency of people to look at eyes and faces in social settings.

These results present an obvious question; if people rarely look at each other in an interaction, can they still utilise gaze cues? Although our results cannot lead us to a definite answer, there are three main arguments for the ability to utilise gaze cues in these circumstances. Firstly, it has been shown that gaze cues can be followed and affect language comprehension, even when they are not directly fixated (Knoeferle \& Kreysa, 2012). Secondly, when gaze cues are fixated, the fixations do not necessarily involve long periods of time viewing the eyes. Looks to gaze cues may be very brief, but very informative. Thirdly, it may be the case that eyes are generally not sought out during a task, but are used effectively when required, for example, during instructions.

From our findings it is possible to speculate about the third possibility. Listeners were found to look at the speaker during significantly more instructions in the roles condition than the no roles condition. This finding shows that our preference for looking at others can be affected by social context. In the roles condition the listener was always the gatherer, following instructions given by an informed chef, who was in charge. In the no roles condition the identity of the listener would switch between the two equal partners, depending on who was giving the instruction. Macdonald and Tatler (2013) found that the degree of informativeness of gaze cues affected the extent to which the cues were sought out, with highly informative cues being sought most often. One possible interpretation of the present findings could be that our manipulation of the roles of the participants effectively manipulated the perceived
informativeness of the cues provided by the chef: listeners in the roles condition may consider the gaze cues of the chef to be highly informative, whereas the gaze cues of the speaker in the no roles condition may be considered less informative.

Alternatively, our pattern of results could arise from a social effect of authority. Liuzza et al (2011) found that right-wing voters were more heavily influenced by the gaze cues of their political leader than the gaze cues of the opposition leader. In the roles condition, the chef is in charge of the procedure and is therefore the leader of the gatherer. It is possible that, as well as being more inclined to follow the gaze cues of a leader, people are also more inclined to orient to the leader's gaze cues. Although the results do not allow us to favour one explanation over the other, these findings provide good evidence that the social context of collaboration can affect the extent to which collaborators look at each other during communication. A more controlled future experiment may be able to distinguish between the effects of the perceived reliability of a person and the perceived social role of a person.

This experiment investigated the effect of social roles on eye movement behaviour in a natural collaboration by using dual portable eye-trackers. We manipulated the roles of the participants to investigate the effect on gaze behaviour. Listeners were found to look more at a speaker providing verbal instructions if the speaker was playing the role of a chef. This suggests that our tendency to look at others is either affected by our social perceptions of a person or by our perception of their reliability. Additionally, we found that in this real social collaborative setting, people spent very little time looking at each other, challenging the generalisability of the conclusions from lab-based paradigms (Birmingham et al, 2007; 2009; Zwickel and Võ, 2010). Our results provide a strong case for investigating gaze cueing behaviour in highly naturalistic environments as well as providing evidence for the effect of social context on the utilisation of gaze cues.

## Acknowledgments

This paper was supported by an EPSRC Studentship awarded to Ross Macdonald. The authors would like to thank Anne-Joanna MacGregor, Julia McVean and Nicole Spittle for assistance with video coding.

# Social pragmatic factors in reasoning from disjunctions of numerical estimations 

Robert Mackiewicz (rmackiew@swps.edu.pl)<br>University of Social Sciences and Humanities<br>Chodakowska 19/31, 03-815 Warsaw, Poland

Pawel Koniak (pkoniak@swps.edu.pl)<br>University of Social Sciences and Humanities<br>Chodakowska 19/31, 03-815 Warsaw, Poland

#### Abstract

The paper presents two studies that investigated how individuals reason from disjunctive statements that use numerical estimations. In the experiments two types of such statements were used. In the first type both constituents of a disjunction could be a logically correct answer. That is, if "The average life time of a fruit fly is either 9 or 27 days", any of those numbers is logically possible. In the second type that truth of one constituent excluded the truth of the other, e.g. "The average time of holidays in the EU is either higher than 9 days or else higher than 27 days". A simple repetition of any of those figures is an illusory inference as it renders both constituents true. The results of Experiment 1 proved that although the participants showed a tendency to repeat one of the disjuncts as their answer, this tendency was smaller when the content of the statements referred to politics and social life in comparison with the general knowledge questions. The results of Experiment 2 showed that individuals reveal the tendency to repeat opinions coming from speakers who are more likeable, even if such opinions are incorrect illusory inferences. The results of both studies show that illusory inferences appear also in the domain of numerical cognition but they may be reduced by pragmatic factors such as the content of the message and the knowledge about its source.

Keywords: reasoning, mental models, persuasion, illusory inferences, social pragmatics

## Introduction

Imagine that you heard the following statements from two different politicians:
Politician A: The average number of holiday days in The European Union is lower than 19 days.
Politician B: The average number of holiday days in The European Union is lower than 32 days.
How would you answer a question about the average number of holiday days in the EU, if you were informed that one of the above statements is definitely true and the other is definitely false? If both politicians are equally likely to be speaking the truth, it seems quite reasonable to expect one of their statements to be the correct answer. However, assuming that both options are equally possible would be a logical mistake as the truth of one of them excludes the truth of the other. Therefore, the correct estimate of the number of holiday days in the EU must lie between 19 and 32 days, which comes from the fact that the statement of politician A is false and the statement of politician B is true. This is the only possible answer because an assumption that the
statement of politician B is false leads to a contradiction, i.e. the average holiday time is both lower than 19 days and higher than 32 days.

## Mental models and the principle of truth

When two statements are presented in the form of a disjunction, one has to represent the fact that if one of them is true, then the other must be false. But naïve individuals seldom do this, as they typically represent only what is true at the expense of what is false. Forgetting about false possibilities is one of the principles of the theory of mental models (the model theory for short, Johnson-Laird, 2007).

The basic assumption of the model theory is that mental representations are iconic and they represent different possibilities as different mental models. Specifically, models represent what is common in all "possible worlds" when a certain type of relation holds. Therefore, the structure of models corresponds to the structure of what they represent (Johnson-Laird, 2006). The same objects may be represented by different types of mental models depending on the relation that was made salient in a given context. For example, if one is informed that the average life of a common fruit fly is three times longer than 9 days, he or she will understand this expression as a multiplication problem and will know that the correct answer is 27 , even though an experimenter has not yet started to ask any questions. On the other hand, if a participant of a psychological study was informed that:

The average life of a fruit fly is either shorter than 9 days or else it is shorter than 27 days.
he or she might see this expression as a disjunction of two possibilities, and represent them as two separate mental models:
shorter than 9 days

## shorter than 27 days

As none of those mental models represent false cases (i.e. not shorter than 27 days in the first model and not shorter than 9 days in the second model), the model theory predicts that individuals without training in logic should see both possibilities as equally probable. But choosing any of them as the correct answer is a so-called illusory inference as shorter than 9 means also shorter than 27 and shorter than 27 does not exclude it being shorter than 9 .

The model theory predicts such illusory inferences in all those reasoning tasks when models fail to represent what is false (e.g. Johnson-Laird \& Savary, 1999). Such illusory inferences have been proved to exist in different domains of the study of reasoning, e.g. conditionals (Barrouillet \& Lecas, 2000), probabilistic reasoning (Johnson-Laird \& Savary, 1996), quantified reasoning (Yang \& JohnsonLaird, 2000), and relations (Mackiewicz \& Johnson-Laird, 2012). All those studies prove that illusory inferences are quite compelling and in some of them all the participants succumb to drawing erroneous conclusions.

## Pragmatic modulations of reasoning process

Some researchers have tried to find antidotes to illusory inferences. The typical experimental manipulation in such studies provides some of the participants with an opportunity to learn how to falsify certain premises. For example, in the study of Newsome and Johnson-Laird (2006) the participants were explicitly asked to find conditions that make different statements false. Another method is to make the distinctive character of two premises more visible. Santamaria and Johnson-Laird (2000) used this type of manipulation by informing the participants that they should treat different pieces of information as different physical objects; in this case it was different advertisements cut from a newspaper. All such manipulations are semantic in nature as they aid the process of constructing fully explicit models.

The process of reasoning can be also modulated in a pragmatic way (Johnson-Laird \& Byrne, 2002). That is, general knowledge in the long-term memory or some information available from the context may help in forming the expanded representation of a problem (Sperber \& Wilson, 1995). In such a case reasoners may go beyond the logical form of the premises presented to them. For example, if you are informed that

The average time required to fulfill legal requirements necessary to open a new company is less than 9 days or else it is less than 27 days.
you may invoke from your memory a program recently presented on TV that urged for shortening the period of establishing a new company. Although you may not remember the details of this program, you might think that the whole process is definitely longer than a week and shorter than a month, and you could estimate its length at, say, 14 days. Such an answer is logically correct as it renders the first disjunct false and the second true. However, the process of arriving at this conclusion would be not a result of the analysis of what is true and what is false about the possibilities. Indeed, based on the same kind of recollections one would probably give the same estimation of 14 days, even if the disjunction was presented in the following way:

The average time required to fulfill legal requirements necessary to open a new company is less than 9 days or else it is more than 27 days.

In this case 14 days makes both disjuncts false and therefore it is logically incorrect. There is still a possibility that one may know that different types of companies require different legal formalities. Such a person would probably withdraw from giving any estimate of the time necessary to start a new business, claiming that the information given in the premises is incomplete.

As the study of Gigerenzer, Hoffrage, and Kleinbölting (1991) shows, people may use different types of background knowledge in order to arrive at numerical estimations of different facts. For example, they may think that a city that has a soccer team in the first league should be larger than one which team plays in the lower league. We believe that many such cues are available when numerical estimations refer to the domain of social life (e.g. percent of households connected to internet, average time of holiday in the EU) or governmental fiscal policy (e.g. public debt per capita, unemployment rate, percent of the EU funding used in the recent year). We used statements from those domains in our first experiment. As they are frequently mentioned in media coverage of politics, we refer to such statements as political in the rest of the paper. On the other hand, when no pragmatic clues are available, naïve reasoners should more often repeat one of the figures available from the premises as their own answer. We refer to such statements as general knowledge questions and in our studies we included in this group estimations of different facts of natural life (e.g. number of wolves hunting alone, average height of trees) and everyday human activities (e.g. number of words in the average email, number of letters in the average sentence).

We predict that naïve individuals rarely go beyond the principle of truth and in most cases they should err when the correct answer requires envisaging the situations in which some statements are false. However, it should happen less often in the case of political than general knowledge questions because pragmatic knowledge may suffice in recalling correct information from memory in the first type of questions. We verified this prediction in our first experiment.

Pragmatic modulations may also help individuals to see a certain set of premises not as a logical inference but rather as an attempt at persuasion. Recently, Mercier and Sperber (2011) have put forward a hypothesis that the main goal of reasoning is argumentation. Therefore, the main purpose of reasoning is to provide a set of logically related arguments that would support certain thesis. Or, if one is the target of a persuasion attempt, reasoning might be used in order to falsify the statements that other person uses to convince someone to his or her beliefs. Such social pragmatic factors may also include inferences about the intention or credibility of the source of a persuasive message (Bohner, Ruder, \& Erb, 2002) or its truthfulness (Eisend, 2006). In the case of reasoning in the political domain, some individuals might even rely on peripheral clues such as personal attractiveness of a politician (Bohner, Moskowitz, \& Chaiken, 1995) or potential gains and losses that he might attain (Priester \& Petty, 1995). In our second experiment we
wanted to check if reasoners are more likely to choose as their own answer an opinion presented by a person who is more likeable. So in this study we dissociated the content of the problem (politics vs. general knowledge questions) and the source of the message (likeable vs. non - likeable politician).

## Experiment 1

The first experiment compared how naïve individuals reason through disjunctions of general knowledge and political statements. We used two versions of both types of such disjunctions. In the first version, repetition of one of the disjuncts led to an illusory inference. We shall call them illusory problems throughout the rest of the paper. Two examples of such problems were given in the introductory section. Apart from the statements of the form
$A$ is lower than $X$ or else $A$ is lower than $Y$.
we also used statements:
A is bigger than X or else A is bigger than Y .
In all such statements the correct answer is any number that lies between X and Y as the principle of truth excludes all other possibilities.

The second set of disjunctions used pairs of statements that could not be both true at the same time but the falsity of one of them did not exclude the other as a possibly correct answer. We used two types of such statements:
$A$ is lower than $X$ or else $A$ is higher than $Y$.
A equals X or else A equals Y .
An example of the second type would be:
Either the average life time of the fruit fly equals 9 days or else it equals 27 days.
Given that one of those statements is true and the other is false, one cannot give any precise estimate of the average life time of the fruit fly. If the first disjunct is true than the other is false and vice versa. Such statements are typically tagged as control problems in the model theory research and so we will use this label throughout the rest of the paper.

## Method

Participants. 27 undergraduate psychology students from the Warsaw University of Social Sciences and Humanities took part in the study in exchange for a course credit. Although none of them had participated in a higher - level course in logic, it must be noted that an elementary course in this subject is obligatory at all higher education institutions in Poland. Participating in such a course should not, in fact, influence the results of our studies as it provides only basic level knowledge.

Design and materials. Participants acted as their own controls and were asked to give their own numerical estimations for twelve problems presented in the form of disjunctions "Either $X$ or else $Y$ ". Half of them were illusory, as in the examples described in the introduction to this experiment, and the other six were the control
inferences. Three of the illusory inferences used "higher" relations in both disjuncts and the other three used the predicate "lower". Three of the control inferences used "higher" - "lower" relations and the other three used exact numbers. Our main independent variable: general knowledge or political content was manipulated as a between group factor. Therefore, half of the participants were presented with general knowledge problems and half with political ones.

We used different contents for each of 12 general knowledge problems and for each of the political statements. Examples of both types of content are provided in the introductory section. The pairs of numbers presented in each of those problems were different. Nevertheless, each pair from the political domain matched one pair of numbers from the list of those presented with the general knowledge questions.

All problems were presented in the form of a small booklet. The instructions informed that the experiment was not a test of either intelligence or the personality of the participants. The instructions informed the participants that they would see different pairs of statements and that in each pair one of the statements is true and the other is false, but it is not possible to say which is true and which is false. The participants were also informed that they should give their own estimations only on the basis of the content that was used in each pair of statements. The two key instruction sentences were phrased in the following way: "Try to give your own estimate in each of the situations described below only on the basis of the information provided here. (...) Please write a number that reflects your estimation or, if you are not able to give your own answer, write " $X$ " in the answer line".

## Results and discussion

Our main concern was to investigate how often the participants repeat the figures provided in the disjunctive statements. In all control problems such repetitions should be considered as possibly correct answers, while in illusory problems a simple repetition was considered as an incorrect answer. Table 1 presents percentages of different types of answers for illusory and control problems with the general knowledge and the political content.

Similarly to all studies investigating illusory inferences, we obtained a strong effect of the type of disjunction. In general, the participants were more often correct on control than on illusory problems: $73 \%$ and $14 \%$, respectively (Wilcoxon test $z=4.02, p<.001$ ). As we predicted, the participants were more likely to repeat numerical estimates from the general knowledge statements than from those pertaining to the world of politics. As repetitions were correct in the control problem, this resulted in a bigger number of correct answers in the control problems with the general knowledge content in comparison with the political ones (Wilcoxon test $z=2.43, p=.008$, one tailed). However, in the case of illusory inferences repetitions were logically incorrect and so there were more such answers
with the general knowledge questions than with the political content (Wilcoxon test $z=2.16, p=.015$, one tailed). The participants did not show any regular tendency to choose the first or the second disjunct as their answer. However, the first one was chosen slightly more often in abstract (47\% choices of the first vs. $39 \%$ choices of the second disjunct) than in political problems ( $24 \%$ for the first one and $34 \%$ for the second one).

Table 1. Percentages of answers repeating and not repeating the numbers provided in disjunctive statements in
Experiment 1. (The column for the correct non repetitions in control problems is empty, as only repetitions could be
considered as correct answers; the percentages of logically correct answers are marked by italics.)

|  | Control problems |  |  |
| :---: | :---: | :---: | :---: |
| Content | Correct <br> repetitions | Correct non- <br> repetitions | Incorrect <br> non- <br> repetitions |
| Political <br> General <br> knowledge | $49 \%$ |  | $51 \%$ |
|  | $85 \%$ |  | $15 \%$ |
|  | Incorrect <br> repetitions | Correct non- <br> repetitions | Incorrect <br> non- <br> repetitions |
| Political <br> General <br> knowledge | $61 \%$ | $23 \%$ | $16 \%$ |

As all illusory problems were of the form: "A is higher (lower) than X or else A is higher (lower) than Y , the correct answers to all of them were estimates that fell between those two numbers provided in the statements. We called all such answers "correct non - repetitions" in Table 1. Very rarely did the participants gave such estimates in the general knowledge problems but they did it more often in the political ones (Wilcoxon test $z=1.72, p=.043$, one tailed).

In sum, the results of Experiment 1 proved our hypotheses. The participants were less likely to repeat numbers from the statements referring to broadly defined political issues than in the general knowledge problems. Although, generally there were more correct answers in control than in illusory problems, the caution evoked by the political content resulted in a smaller number of incorrect repetitions in illusory problems and more logically correct answers in those problems.

## Experiment 2

The previous study examined the influence of social pragmatic modulation on the tendency to repeat numbers provided in the form of a disjunction. Our Experiment 2 investigated whether it was possible to convince the participants to use the statements provided by some
speakers as participants' own estimations. As many of the studies from persuasion research show, one of the key factors that makes a message more persuasive is the attractiveness of its source (Petty \& Wegener, 1998). Following that, we hypothesized that participants would more often repeat the statements provided by more than less likeable speakers, even though endorsing the conclusions of such speakers may be logically incorrect.

## Method

Participants. We recruited a group of 27 participants from the same population as those described in Experiment 1. They were tested in small groups in exchange for a course credit.
Design and materials. We used the same two sets of 12 general knowledge and 12 political problems as those in Experiment 1. The design of this study was exactly the same as that of Experiment 1 with one exception. Both in political and general knowledge settings we wrote in the instructions that all the statements came from two different politicians. We manipulated their likeability by informing our student participants that one of them said in a television interview that "students are more mature than it is commonly believed", while the other said that "students are spoiled and do not know the true life". We assigned those two descriptions at random to both politicians, so the statements within each pair were assigned once to a likeable and once to a non - likeable politician. We also measured the sympathy for those two politicians by asking the participants to rate their likeness on a five-point scale with higher numbers meaning higher liking. The key instruction sentences were the same as in Experiment 1, so the participants were asked to give their own estimates only on the basis of the information provided in the experiment, and write "X", only if they were not able to figure out their own answers.

## Results and discussion

Again, we proved that there is a strong tendency to repeat numerical estimations provided in the form of disjunctions. As in Experiment 1, this led to correct answers in the control problems (57\%) and incorrect in the illusory problems (31\%). Only in $14 \%$ of their answers to illusory problems did the participants gave correct estimations that fell between two figures provided by the politicians depicted in the instructions (Wilcoxon test for comparison with correct answers in control problems yielded a significant result: $z=3.4, p=.001$ ). In comparison with the previous experiment the difference between the repetitions in general knowledge and political problems was not significant, though it was in the predicted direction: 69\% versus $52 \%$ (Wilcoxon test $z=1,49, p=.07$, one tailed). And also there was no difference between numbers of correct answers in illusory problems concerning general knowledge (18\%) and those connected with the world of politics (10\%).

As our main objective was to see if the participants tended to repeat the statements from a likeable politician more
often than from a non - likeable one, we first checked the effectiveness of our manipulation. Indeed, a politician presented as a person who liked students scored on average 3.96 on a five-points sympathy scales. This number was significantly higher than the average for a person who did not seem to be fond of students: 2.04 (Wilcoxon test $z=$ 3.97, $p<.001$ ). To check our main prediction for this experiment we calculated the Spearman correlations between the attractiveness scores of a likeable politician and the tendency to repeat his statement as the correct answer. The correlation coefficients are given in table 2.

Table 2. Correlations between the ratings of likability of a politician and the frequency of choosing his answer by the participants in Experiment 2. Correlations marked with an asterisk are significant at $p<.05$.

|  | Type of relation between <br> disjunctions |  |
| :--- | :---: | :---: |
| Inference <br> content | Control <br> General | Illusory <br> problems |
| knowledge | $.62^{*}$ | $.63^{*}$ |
| Political |  |  |

As Table 2 reveals, we observed significant positive correlations between the sympathy ratings of a politician who was presented as likeable and the frequency of choosing his statements as answers in both control and illusory problems that required some general knowledge. However, the participants were more skeptical about the expertise of a politician in illusory problems that used the content for the political domain. Only in this case the results did not follow our prediction but it was mainly due to a bigger frequency of participants' refraining from giving any estimates. From the logical point of view, this is also an incorrect answer but we counted the correlations only for answers that repeated the opinion of one of the politicians described in the instructions to this experiment.

The results of Experiment 2 repeated our findings from Experiment 1: the participants were more likely to repeat one of the statements as their own answers. This led to illusory inferences in those problems where the truth of one statement excluded the truth of the other. As our correlations show, there was quite a strong tendency to choose more often the estimates given by a more likeable politician. Our manipulation could seem somehow suspicious to the participants of the study: it is hard to believe that a politician knows anything about the life span of a fruit fly. We observed a smaller tendency of repetitions in illusory problems in this experiment than in the previous one. But possible skepticism did not lead to a bigger number of correct answers in illusory problems in comparison with Experiment 1. It seems as the participants in Experiment 2 more often refrained from giving any numerical estimates in comparison with those taking part in Experiment 1.

## General Discussion

The main purpose of the current study was to investigate how naïve individuals solved problems that used a pair of numerical estimations presented in the form of a logical disjunction. We used two versions of such problems. In the first version, one example being $A$ is lower than $X$ or else $A$ is higher than $Y$, the verbatim repetition of any of the statements had to be considered as a logically correct answer. However, in the second set of trials, including for example $A$ is lower than $X$ or else $A$ is lower than $Y$, the correct answer fell between X and Y and simple repetition of one of the disjuncts did not take into account that in such a case both disjuncts are true at the same time. Following the tradition in the psychological study of reasoning (Johnson-Laird \& Savary, 1996) we referred to such problems as illusory inferences.

A number of researches have tried to find an antidote to illusory inferences. Most of the previous research used direct exemplifications of situations in which logical statements are false. We used a different approach and manipulated the pragmatic factors that led our participants to look for alternative possibilities. In Experiment 1 we compared frequencies of illusory answers for disjunctions in which the statements referred to the general knowledge questions (e.g. the average life of a fruit fly) with the problems referring broadly to social life and politics (e.g. the average time necessary to open a new company). We assumed that social and political issues trigger more cues from the long term memory that participants could use to arrive at their own answers. Our predictions were confirmed. In Experiment 1 the participants were significantly more often correct in illusory problems from the political domain than the general knowledge problems that did not induce pragmatic cues. The "illusory effect" was also present in our Experiment 2 in which we wanted to cue the participants to repeat an opinion presented by a more likeable politician. In this experiment the difference between the proportions if illusory answers in political and the general knowledge questions was lost but indeed we observed a significant tendency to repeat an opinion of a more likeable politician. Our manipulation of the likeability that we used in Experiment 2 might seem suspicious to our student participants, so they more often avoided direct repetitions of opinions coming from a politician who may know nothing about the subject matter of a given question. We guess, however, that it is possible to design a manipulation that would more directly cue the participants to choose one of the provided opinions. Therefore the current results of Experiment 2 provide a useful stepping stone for future research.

Both experiments showed that illusory inferences can be elicited in the domain of numerical cognition. Although there are many studies in the cognitive psychology of reasoning that explicitly use numbers in experimental materials (cf. Oaksford, Chater, \& Larkin, 2000), they mainly use them as labels of probabilities or frequencies. Our study differs from such accounts as we investigated
how individuals reason from relational predicates such as "higher than X" or "lower than X". As it seems they do not only treat numbers as the representations of abstract numerical quantities, but are also able to treat numerical statements as entries into logical arguments.

Our study also differed from those typical for the area of persuasion research. Such studies normally measure the change of attitudes between and after the presentation of a persuasive message (e.g. Bohner, Einwiller, Erb, \& Siebler, 2003). In our research we asked the participants to draw logically valid conclusions taking into account only the information given in the premises. As it turned out, the reasoners were more likely to go beyond the logical form of the problem when its content provided pragmatic cues that triggered the search for available facts in the long term memory (Exp. 1). Although they tended to repeat more often an opinion from a person who was presented as more likeable, it did not help them when it came to finding the logically correct answers (Exp. 2).

As asserted by Gilbert (1991), understanding the message entails believing that it is true at least until it is falsified by some other clues or statements. The results of our experiments show that indeed people believe that two statements that are not overtly contradictory can be both true at the same time. Individuals do not assume that one of them can be false and, what is more, they do not follow the consequences of such assertions. Such an attitude may have an important influence on the world of politics and the role of democratic institutions. It is quite likely that during election campaigns voters do not analyze the relations between statements of different politicians but they rather choose those they would like to believe on the basis on pragmatic factors, such as the likeability of the source of the message.

## Acknowledgments

This research was made possible by The Polish Ministry of Science and Education grant no .2836/01/E/560/S/2012 to both authors. We are grateful to Wojciech Cwalina and Phil Johnson-Laird for discussions and advice.

# The Role of Cognitive Niches in Mediating Knowledge, Entropy \& Violence 

Lorenzo Magnani (lmagnani@unipv.it)<br>Department of Humanities, Philosophy Section<br>University of Pavia, ITALY

Tommaso Bertolotti (bertolotti@unipv.it)<br>Department of Humanities, Philosophy Section<br>University of Pavia, ITALY

#### Abstract

The aim of this paper is to briefly illustrate how the theoretical framework of cognitive niches can prove useful to frame not only the cultural development of human beings, but the naturalization of morality as well.

Keywords: Cognitive niches; Coalition enforcement hypothesis; Violence; Morality; Naturalization.

## Human Beings as Eco-Cognitive Engineers

Human beings usually make decisions and solve problems relying on incomplete information (Simon, 1955). Having incomplete information means that 1) our deliberations and decisions are never the best possible answer, but they are at least satisfying; 2) our conclusions are always withdrawable (i.e. questionable, or never final). That is, once we get more information about a certain situation we can always revise our previous decisions and think of alternative pathways that we could not "see" before; 3) a great part of our job is devoted to elaborating conjectures or hypotheses in order to obtain more adequate information. Making conjectures is essentially an act that in most cases consists in manipulating our problem, and the representation we have of it, so that we may eventually acquire/create more "valuable" knowledge. It is obvious that a great part of human conjectural activity is devoted to guessing hypotheses (that can be moral as well) about situations and events able to help subsequent decisions and actions. Conjectures (and thus "moral" conjectures) can be either the fruit of an abductive selection in a set of pre-stored hypotheses or the creation of new ones: in this sense, abduction - a term from the Peircean tradition - must be understood in an eco-cognitive perspective, which has been fruitfully applied in studies concerning Distributed and Embodied Cognition (Hutchins, 1995; Magnani, 2009). In order to make conjectures, human beings often need more evidence/data: in many cases this further cognitive action is the only way to simply make possible (or at least enhance) a way of reasoning that relies on "hypotheses" that are often hard to produce successfully.

Consider, for instance, diagnostic settings: often the information available does not allow a physician to make a precise diagnosis. Therefore, she has to perform additional tests, or even try some different treatments to uncover otherwise hidden symptoms. In doing so she simply aims at increasing her chances of making the appropriate decision. There are plenty of situations of that kind: for example, scientists are continuously engaged in a process of manipulating their research
settings in order to get more valuable information (Magnani, 2009). Most of this work is completely tacit and embodied in practice. The role of various laboratory artifacts is a clear example, but also in everyday life people face complex situations which require knowledge and manipulative expertise of various kinds - no matter who they are, whether teachers, policy makers, politicians, judges, workers, students, or simply wives, husbands, friends, sons, daughters, and so on. In this sense, human beings can be considered chance seekers, because they are continuously engaged in a process of building up and then extracting latent possibilities to uncover new valuable information and knowledge (Magnani \& Bardone, 2008).

Furthermore, as chance seekers, humans are also ecological engineers. Not only technologies and other artifacts are part of this ecology but also morality and, of course, violent modes of problem-solving. That is to say, humans (like other creatures) do not simply live in their environment, but they actively shape and change it while looking for suitable chances. In doing so, they construct cognitive niches through which the offerings provided by the environment in terms of cognitive possibilities are appropriately selected and/or manufactured to enhance their fitness as chance seekers (Tooby \& DeVore, 1987; Pinker, 1997, 2003). Hence, this ecological approach aims at understanding cognitive systems in terms of their environmental situatedness (Clancey, 1997; Magnani, 2005). Within this framework, "chances" are that kind of "information" which is not internally stored in memory or already available in an external resource, but that has to be "extracted" and then picked up upon occasion.

It is well-known that one of the main forces that shapes the process of adaptation is natural selection. That is, the evolution of organisms can be viewed as the result of a selective pressure that renders them well-suited to their environments. Adaptation is therefore considered as a sort of top-down process that goes from the environment to the living creature (Godfrey-Smith, 1998). In contrast to that, a small fraction of evolutionary biologists have recently tried to provide an alternative theoretical framework by emphasizing the role of niche construction (Laland, Odling-Smee, \& Feldman, 2000, 2001; Odling-Smee, Laland, \& Feldman, 2003).

According to this view, the environment is a sort of "global market" that provides living creatures with unlimited possibilities. Actually, not all the possibilities offered by the environment can be exploited by the human and non-human an-
imals populating a peculiar environment. For instance, the environment provides organisms with water to swim in, air to fly in, flat surfaces to walk on, and so on. However, there are no creatures able to take full advantage of all of those possibilities. ${ }^{1}$ Moreover, all organisms try to modify their surroundings in order to better exploit those elements that suit them and eliminate or mitigate the effect of the negative ones.
This process of environmental selection (Odling-Smee, 1988) allows living creatures to rebuild and shape "ecological niches". An ecological niche can be defined, following Gibson, as a "setting of environmental features that are suitable for an animal" (Gibson, 1979). It differs from the notion of habitat in the sense that the niche describes how an organism lives its environment, whereas the habitat simply describes where an organism lives.

In any ecological niche, the selective pressure of the local environment is drastically modified by organisms in order to lessen the negative impacts of all those elements toward which they are not suited. Indeed, this does not mean that natural selection is somehow halted, rather, this means that an adaptation cannot be considered only by referring to the agency of the environment, but also to that of the organism acting on it. In this sense, animals are ecological engineers, because they do not simply live their environment, but they actively shape and change it (Day, Laland, \& Odling-Smee, 2003).

It is well-known that, from the point of view of physics, organisms are far-from-equilibrium systems relative to their physical or abiotic surroundings. ${ }^{2}$ Apparently they violate the second law of thermodynamics because they stay alive, the law stating that net entropy always increases and that complex and concentrated stores of energy necessarily break down. It is said that they are open, dissipative systems (Prigogine \& Stengers, 1984), which maintain their status far from equilibrium by constantly exchanging energy and matter with their local environments. Odling-Smee, Laland and Feldman quote Schrödinger, contending that an organism has to "feed upon negative entropy [...] continually sucking orderliness from its environment" (Schrödinger, 1992, p. 73). To create cognitive niches is a way that an organism (which is always smartly and plastically "active", looking for profitable resources, and aiming at enhancing fitness) has to stay alive without violating the second law: indeed it "cannot" violate it. In this sense

[^141]cognitive niches can be considered obligatory: "To gain the resources they need and to dispose their detritus, organisms cannot just respond to their environments [...] to convert energy in dissipated energy" (p. 168).

Evolution is strictly intertwined with this process and so it has consequences not only for organisms but also for environments. Sometimes the thermodynamic costs are negligible (like in the heat loss caused by photosynthesis that is returned to the universe, "which is in effect infinite"- p. 169), sometimes they are not, in this case abiota of the environment have no capacity to contrast the niche-constructing activities of organisms (like for example, the atmosphere, which is in a new physical state of extreme disequilibrium in relation to exploitation of the Earth's limited resources). The only no-costs exception is when organisms die - and lose their far-fromequilibrium status). In this case the dead bodies are returned to the local environment in the form of dead organic matter (DOM), still a kind of niche construction, so to say, also called "ghost niche construction" (Odling-Smee et al., 2003, p. 170). Of course biota can resist most thermodynamic costs imposed on them by other niche-constructing organisms, often performing counteractive niche-constructing activities.

## Cognitive Niche Construction and the Mediation of Aggressivity

It is important to clarify the concept of cognitive niche that is at the basis of the possibility to grasp human moral and axiological systems in a naturalistic way, and the intertwined violence, which in this perspective still appears in all of its "banality". A recent book by Odling-Smee, Laland and Feldman (Odling-Smee et al., 2003) offers a full analysis of the concept of cognitive niche from a biological and evolutionary perspective. "Niche construction should be regarded, after natural selection, as a second major participant in evolution. [...] Niche construction is a potent evolutionary agent because it introduces feedback into the evolutionary dynamics" (Odling-Smee et al., 2003, p. 2). ${ }^{3}$ By modifying their environment and by their affecting, and partly controlling, some of the energy and matter flows in their ecosystems, organisms (not only humans) are able to modify some of the natural selection pressure present in their local selective environments, as well as in the selective environments of other organisms. This happens particularly when the same environmental changes are sufficiently recurrent throughout generations and selective change: "Even though spiders' webs are transitory objects [...] the spiders' genes 'instruct' the spider to make a new one" (Odling-Smee et al., 2003, p. 9). The fact that spiders on a web are exposed to avian predators suggests that webs can be a source of selection that produces further phenotype changes in some species, such as the marking of their webs to enhance crypsis or the creation of dummy

[^142]spiders probably to divert the attention of the birds that prey on them. Hence, also spiders adopt what humans call cheating and cognitively alter their cognitive niches to this aim. Cheating is part and parcel of aggressive predatory behavior (Bertolotti, Magnani, \& Bardone, 2013). It is of course not appropriate and clearly anthropomorphic to call these kinds of non human animal behavior "violent", but it remains clear that both in human and non human - especially gregarious - animals the construction of cognitive niches is related to the importance of triggering cooperation and of attacking, more or less violently, other living beings. So the cognitive niches also play, constitutively, the role of carriers of aggressiveness, and in humans, who intentionally build them, they can be legitimately called "moral" and "violent". This general description of cognitive niches is extremely interesting if matched with Gibson's definition of a niche as a "set of affordances" (Gibson, 1977). Relying on his concept of affordance, Gibson stresses how the niches characterizes how a peculiar individual acts within the niche itself and can be summed up in that individual's possibilities for action: one's cognitive niche is indeed made up of a series of possibilities extending between the agent and her environment.
While general inheritance (natural selection among organisms influences which individuals will survive to pass their genes on to the next generation) is usually regarded as the only inheritance system to play a fundamental role in biological evolution, niche construction may play a role over various generations, thus introducing a second general inheritance system (also called ecological inheritance by Odling-Smee). In the life of organisms, the first system occurs as a one-time, unique endowment through the process of reproduction (sexual for example); on the contrary, the second system can in principle be performed by any organism towards any other organism ("ecological" but not necessarily "genetic" relatives), at any stage of their lifetime. Organisms adapt to their environments but also adapt to environments as reconstructed by themselves or other organisms. ${ }^{4}$ From this perspective, acquired characteristics can play a role in the evolutionary process, even if in a non-Lamarckian way, through their influence on selective environments via cognitive niche construction. Phenotypes construct niches, which then can become new sources of natural selection, possibly responsible for modifying their own genes through ecological inheritance feedback (in this sense phenotypes are not merely the "vehicles" of their genes). Of course we have to remember that humans are not unique in their capacity to modify their environment, as we have already seen when referring to the case of the spiders that build "dummy spiders" (Wilcox \& Jackson, 2002): other species are informed by a kind of proto-

[^143]cultural and learning process that is very often intrinsically social, even if we have to say that animals seem to lack the ability to accumulate information as seen in the human cultural/technological case: Andy Clark ranks human language as one of the most powerful cognitive niches ever developed (Clark, 2006).

Indeed, it has to be noted that cultural niche construction alters selection not only at the genetic level, but also at the ontogenetic and cultural levels as well. For example the construction of various artifacts challenges the health of human beings:

Humans may respond to this novel selection pressure either through cultural evolution, for instance, by constructing hospitals, medicine, and vaccines, or at the ontogenetic level, by developing antibodies that confer some immunity, or through biological evolution, with the selection of resistant genotypes. As cultural niche construction typically offers a more immediate solution to new challenges, we anticipate that cultural niche construction will usually favor further counteractive cultural niche construction, rather than genetic change (OdlingSmee et al., 2003, p. 261).

With a broader explanatory reach than sociobiology and evolutionary psychology, the theory of niche construction simultaneously explains the role of cultural (and so moral) aspects (transmitted ideas), behavior (and so moral behavior, which directly orients the construction of niche construction itself), and ecological inheritance (artifacts, to be intended also as moral/violent mediators). Of course niche construction may also depend on learning. It is interesting to note that several species, many vertebrates for example, have evolved a capacity to learn from other individuals and to transmit this knowledge, thereby activating a kind of proto-cultural process which also affects niche construction skills: it seems that in hominids this kind of cultural transmission of acquired niche-constructing traits was ubiquitous, and this explains their success in building, maintaining, and transmitting the various cognitive niches in terms of moral systems of coalition enforcement. "This demonstrates how cultural processes are not just a product of human genetic evolution, but also a cause of human genetic evolution" (Odling-Smee et al., 2003, p. 27). From this viewpoint the notion of docility (Simon, 1993) acquires an explanatory role in describing the way human beings manage ecological and social resources to make their own decisions.
(Lahti \& Weinstein, 2005) and (Magnani, 2011, chap. 6) refer to the concept of viscosity to provide an explanation of the gap between the absolutism of morality and the empirical evidence that moral regulations are often infringed with no major consequences either for the whole moral system, or for the very individual who performs the infraction - alas, generating conflicts and violence. Viscosity is certainly constrained by docility, which favors the formation of "the state of being thick, sticky" but also of the state of being "semifluid in consistency, due to internal friction". We said that
the fact that morality is viscous hints at its thickness and being glue-like, thus meaning its capability to be deformed, stressed, pulled apart and reassembled without showing decisive harm to its own stability and reproducibility: this aspect also relates to docility. Viscosity and docility explain how our objectified moral cognitive niches are stable, and at the same time also vulnerable and modifiable. Thus it is easy to see in, a human individual, the stability of moral convictions depending on his stable moral niches, together with the spontaneous attitude to "disengage" them - for example resorting to a "re-engagement" in other moral conducts which are not dominant in his present moral cognitive niche, but still present as vestigial traces of previous - no longer dominant moral cognitive niches (Bandura, 1999; Magnani, 2011).
(Woods, 2013) touches a similar problem, related to docility, when, analyzing fallacious reasoning, he stresses the fact that "Whether full or partial, belief states are not chosen. They befall us like measles", in other words, "say so" induces belief (doxastic irresistibility). Similarly moral cognitive niches too "befall us like measles". The problem is related to the effect of what Gabbay and Woods call ad ignorantiam rule: "Human agents tend to accept without challenge the utterances and arguments of others except where they know or think they know or suspect that something is amiss" (Gabbay \& Woods, 2005, p. 27). The individual agent also economizes by unreflective acceptance of anything an interlocutor says or argues for, short of particular reasons to do otherwise, by applying the ad verecundiam fallacy. Accordingly, the reasoner accepts her sources' assurances because she is justified in thinking that the source has good reasons for them (the fallacy would be the failure to note that the source does not have good reasons for his assurances). Peirce contended, in a similar way, that it is not true that thoughts are in us because we are in them; "beings like us have a drive to accept the say so of others" (Woods, 2013).

It is noteworthy that all these information resources do not only come from other human beings. This would clearly be an oversimplification. Indeed, the information and resources that we continuously exploit are - so to speak - humanreadable. Both information production and transfer are dependent on various mediating structures, which are the result of more or less powerful cognitive delegations, namely, niche construction activities. Of course, it is hard to develop and articulate a rich culture as humans did, and still do, without effective mediating systems (writing, artifacts, material culture, etc.). Hence, we can say that, first of all, docility is more generally concerned with the tendency to lean on various ecological resources, which are released through cognitive niches. Secondly, social/moral learning cannot be seriously considered without referring to the agency of those mediating structures, whose efficiency in storing and transmitting information far exceeds, from many perspectives, that - direct and non-mediated method - of human beings.

## Cognitive Niches as Moral Niches

In the previous section we have tried to show that the concept of cognitive niche is an extremely appropriate intellectual instrument to grasp human cultural and moral systems, and their violent punishment counterparts, in a naturalistic way. It is important to present the moral and potentially violent dimension of cognitive niches. We have said that the activity of niche construction may enter evolution insofar as it modifies the selective pressures humans and other animals have to cope with. From this we can draw two major consequences.
First of all, the activity of cognitive niche construction potentially affects all those who participate and live in the same local environment in terms of cognitive chances made available (or not). That is, eco-cognitive modifications - brought about collectively (like herd-like behaviors) or by certain groups - may affect our shared cognitive repertoire amplifying it but also constraining or even impoverishing it. On certain occasions, eco-cognitive modifications may be considered by some individual (or particular groups of individuals) as threatening, impoverishing, or detrimental for their possibility to solve problems. Basically, they can perceive their cognitive system as if it is externally hacked so that they have to partly re-engineer their relationship with the environment, for instance, by modifying their previous habits or simply forcing them to cope with habits perceived as maladaptive or threatening for them or their group.

The second point deals with the role of the coalition enforcement hypothesis in cognitive niche maintenance. In fact, the construction of cognitive niches and the preservation and their maintenance through coalition enforcement has indeed a moral (and thus violent) dimension: that is, punishment, control and persecution of in-group free riders, and regulation of out-of-group conflicts (Magnani, 2011). The coalition enforcement hypothesis, put forward by Bingham (Bingham, 1999), aims at providing an explanation of the "human uniqueness" that is at the origin of human communication and language, in a strict relationship with the spectacular ecological dominance achieved by H. Sapiens, and of the role of cultural heritage. From this perspective, and due to the related constant moral and policing dimension of Homo's coalition enforcement history (which has an approximately two-million-year evolutionary history), human beings can be fundamentally seen as self-domesticated animals. In hominids, cooperation in groups (which, contrary to the case of non-human animals, is largely independent from kinship) fundamentally derived from the need to detect, control, and punish social parasites, who for example did not share the meat they hunted or partook of the food without joining the hunting party (also variously referred to as free riders, defectors, and cheaters) (Boehm, 1999). These social parasites were variously dealt with by killing or injuring them (and also by killing cooperators who refused to punish them) from a distance using projectile and clubbing weapons. In this case injuring and killing are cooperative and remote (and at
the same time they are "cognitive" activities). According to the coalition enforcement hypothesis, the avoidance of proximal conflict reduces risks for the individuals (hence the importance of remote killing). Of course, cooperative morality that generates "violence" against unusually "violent" and aggressive free riders and parasites can be performed in other weaker ways, such as denying a future access to the resource, injuring a juvenile relative, gossiping to persecute dishonest communication and manipulative in-group behaviors or waging war against less cooperative groups, etc.

From this perspective, the role played by morality (and, thus, violent punishment) is manifold: any activity that involves and signals a commitment toward cognitive niche construction and maintenance is potentially perceivable as violent against concurrent niches. To develop and to maintain some eco-cognitive modifications typical of a certain community implies that those modifications are indeed worth being preserved because they are perceived as good and useful, which immediately clashes with other possible ways of organizing an homologue cognitive niche. If a cognitive niche displays a univocal relationship with the group who developed it and cares for its maintenance, participating in the niche also involves a more or less public endorsement of the group that supports it. Of course one can partake of several niches (and hence of several groups) as long as they do not compete (or are perceived as not competing) in the same area, since no matter how polite the context may be, any conflict is ultimately about violence.

Morality can be considered as part of the niche's distributed knowledge, and it precisely concerns violence insofar as it regulates (also violent) relationships between individuals in the niche and with those that are confronted with it without actually partaking of it. Such a regulating activity is permitted by the dimension of violence embodied in rules and regulations and related punishments but also tacitly conveyed by the cognitive as we just observed: the most patent case of such in-niche morals are deontological codes typical of highly specific cognitive niches, but to different degrees they are traceable in every cognitive niche. Of course, the explicit dimension of normativity is concerned in this characterization of the cognitive niche as moral knowledge expressed in the different registers of rules and regulations is one of the pillars of niche maintenance. Even if a niche is not primarily involved in prescribing certain behaviors to its members, a contextual decency is required in order to obtain a state of homeostasis in intersubjective relationships. Should a niche seem to be totally devoid of general normativity, it would thrive insofar as it was laid upon a wider cognitive niche that is in turn heavily concerned with morals and norms, namely, religions, political and legal institutions and so on.

## Concluding Remarks

It is easy to see that the violent potential constitutively embedded in any cognitive niche actually displays the underlying dimension of structural and symbolic violence (Magnani,

2011, chap. 1). Structural violence is seen as morally legitimate insofar as it plays a crucial role in the activities of niche maintenance. Immediately we have to note that when parents, policemen, teachers and other agents inflict physical or invisible violence for legal and/or moral reasons, those reasons do not cancel the violence perpetrated and violence does not have to be condoned in so far as it is not always perceived as such. On the other hand it must be analyzed how in the case of structural violence those perpetrating agents do not seem to act only on their own behalf but on that of larger institutions that can be political, industrial, economic or religious. Such institutions populate structural violence not with actors but rather with what we call "violent mediators" (or in the extreme case of human beings that have turned themselves into violence mediating socio-cultural "artifacts", as in the role of the policeman in the framework of structural violence). ${ }^{5}$

Structural violence may acquire its most subtle and omnipresent form as the symbolic violence perpetrated by language. As a device of social mediation language is necessarily a cognitive niche mediator (and hence distributor) of violence as well. The violent nature of language is a fact too easily admitted to allow serious reflection, as if every speaker were aware of this horrible truth and wanted to get rid of it as soon as possible, even by simply acknowledging it and leaving it at that. As we have already pointed out, a gentle cluster of speech forms innocently distributes harmful, abusive, destructive, and damaging roles, commitments, inclinations and habits. Language, which is the very moral medium of cooperation and non-violence, also involves unconditional violence even against the speaker herself, insofar as by language one acquires and imposes dominion not only over fellow human beings but also over one's conscious and less conscious self, framing thoughts and emotions in the rigid crystallization brought about by words. The importance of symbolic violence should not be disregarded for one very simple reason: the only requirement to become a perpetrator is easy to meet as it consists in a basic knowledge of the niche language, and the very fact of speaking a language makes the speaker both potentially and actually violent in the symbolic dimension. Culture, knowledge and more highly developed speech abilities may not necessarily help, but conversely they positively turn an agent into an even more subtle perpetrator of violence: we already mentioned Gibson's definition of a niche as a set of affordances: such definition could perfectly fit the case of a moral, violent niche. Knowledge externalizations may constitute moral affordances, becoming possibilities for an individual's moral acting. Yet, should an individual not develop, or acquire, the correct moral affordances, she might be perceived as violent by the rest of the obliging community populating and maintaining the niche - and hence be violently

[^144]punished: what should be further studied is whether defining a moral niche as a set of moral affordances leads us to label it, as the other side of the coin, a set of violent affordances, of chances for violence.

#### Abstract

In this article we demonstrate how algorithmic probability theory is applied to situations that involve uncertainty. When people are unsure of their model of reality, then the outcome they observe will cause them to update their beliefs. We argue that classical probability cannot be applied in such cases, and that subjective probability must instead be used. In Experiment 1 we show that, when judging the probability of lottery number sequences, people apply subjective rather than classical probability. In Experiment 2 we examine the conjunction fallacy and demonstrate that the materials used by Tverksy and Kahneman (1983) involve model uncertainty. We then provide a formal mathematical proof that, for every uncertain model, there exists a conjunction of outcomes which is more subjectively probable than either of its constituents in isolation.

Keywords: Conjunction fallacy; algorithmic statistics; likelihood judgments; surprise; subjective probability.

## Introduction

Breaking news: Pandemonium erupted today at the National Lottery headquarters as the numbers 1, 2, 3, 4, 5 and 6 were drawn for the third week in a row. Lottery officials, stunned by a sense of déjà vu, scrambled to release a statement insisting that the lottery drum selection mechanism meets the highest standards for randomness. Meanwhile thousands are celebrating after ignoring the opinions of mathematicians who had viewed the two previous draws as a statistical fluke. Commentators in the media are demanding an immediate investigation, describing the incident as a fiasco.

The mathematical concept of probability, originally formulated to describe the highly constrained environment of games of chance, has now found its way into everyday parlance, with people using it to quantify the likelihood of everything from the possibility of economic recession to the risk of global warming. Such has been the unquestioned adoption of the probability concept into mainstream culture that it has become the default assumption that probability theory provides the only logical way for people to think about likelihood.

For instance, Tverksy and Kahneman (1983) applied probability theory to real-world situations involving personality decisions, medical judgments, criminal motives and political forecasts. On observing consistent deviations from the mathematical theory, they interpreted their findings as evidence of a serious flaw in human reasoning (see Costello, 2009, for a review of the associated debate). In this article we adopt the alternative stance that consistent deviations between human reasoning and a simplified, artificial mathematical theory are far more likely to reflect deficiencies in the theory than they are to reflect sub-optimality in how people think about likelihood.

## Classical Probability

Probability theory was formalised by Kolmogorov in the 1930s through the notion of probability space, whereby a set of possible outcomes is mapped to a number that represents its likelihood by a probability measure function. For example, a perfect dice outputs the numbers from 1 to 6 with equal frequency. However, in the real world it is rarely feasible to identify the theoretical probability measure function which underlies the events we observe. Because we have to work backwards, using the events to deduce the original function, we can never be sure if the model we are using is correct.

For example, according to classical probability theory, no conceivable sequence of numbers produced by rolling a dice will ever lead us to revise our beliefs about the nature of the dice. Even if we rolled $1,1,1,1 \ldots$ the hypothesis of the sequence being a statistical fluke would always remain infinitely more likely than the possibility that the dice is biased.

In reality, nobody has beliefs which are strong enough to stand up to the requirements of classical probability theory. We strongly believe that the numbers drawn from the lottery are random, yet there are certain sequences which, as in the introductory lottery example, would cause us to question our assumptions and consider other possibilities. If the sequence
$1,2,3,4,5,6$ was drawn three weeks in succession, it might suggest that the balls were not equally weighted, the drum mechanism was defective, or that one of the lottery officials was playing a practical joke. The point where we start to ask questions reveals how strongly we hold our beliefs. But no matter how confident we are about a particular model of reality, there will always be some sequence of events which will cause us to change our mind.

This poses a crucial problem for probability theory. Let's consider the probability of $1,2,3,4,5,6$ being drawn in a lottery for three weeks in a row. If the draw is unbiased then this sequence of events is just as likely as any other. In a lottery with 45 numbers, the exact probability is $C(45,6)^{3}$. But if this sequence of events actually unfolded, it would lead us to believe that the draw mechanism is biased. Given the new updated belief, then the probability of getting $1,2,3,4$, 5,6 is actually far higher. So what is the true probability of this sequence of events?

To apply classical probability theory a single model of reality must be selected. We must assume either that the lottery draw is biased or that it isn't. But doing so would be a mistake because we don't actually know which world is the case. The situation involves model-outcome dependence, insofar as the outcome affects our beliefs about the system that generated it. Stating that the probability of drawing 1, 2, 3, 4, 5, 6 is $C(45,6)^{3}$ is misleading because, if this sequence of events actually occurred, we would no longer trust the assumptions involved in computing that probability.

## Uncertainty in the Real World

The issue here is that classical probability theory only applies to cases involving a definitive probability measure function, while models of reality always involve uncertainty. Though useful for reasoning about games deliberately engineered to generate pseudo-randomness, classical probability has less applicability to everyday life, where reducing uncertainty and optimising models of reality are the principal goals. In our previous work examining the difference between surprise and probability judgments (Maguire, Maguire, \& Keane, 2011) we presented a cognitive theory of uncertainty modeling which views the maintenance of an up-to-date representation of reality as the principal motivation guiding information seeking behaviour. People rely on observational data to continually refine their model of the environment, thus maintaining the optimality of their decision making. In particular, the signal that they rely on to diagnose discrepancies between their model and the real world is randomness deficiency.

The best model of a set of observational data is the one which describes it most concisely, so that the description of the data relative to the model is 'incompressible' or random (see Rissanen, 1978; Gács, Tromp, \& Vityányi, 2001). In the case that one's model of reality is optimal, then new sensory data should still be random with respect to it. The experience of randomness deficiency (i.e. a pattern which could be described more concisely using an alternative model) causes
alarm bells to go off, because it indicates that one's model is likely to be suboptimal. This is known as surprise.

When surprise occurs there are two potential resolutions. First, more observation data can be gathered, which might mitigate the randomness deficiency by revealing it to be a statistical fluke. If this does not resolve the discrepancy then the remaining alternative is to update one's model to fit the data. Either way, the resolution process necessitates urgent sampling of information from the environment. During the surprise response, eye widening, opening of the mouth and enlargement of the nasal cavity serve to facilitate the intake of sensory information (see Maguire et al., 2011).

Consider for example looking at the floor and seeing some crumbs which spell out the words "YOU ARE BEING WATCHED". When crumbs fall on the floor it is just as probable that they will arrange themselves into this pattern as any other. If we were certain that the crumbs had fallen randomly then it would not be interesting. However, where knowledge is uncertain then people respond to randomness deficiency. The pattern of crumbs is randomness deficient because there is another model which can explain it more concisely: Somebody might have deliberately arranged the crumbs in this way. The first strategy is to look at the rest of the floor. If the rest of the floor is covered in many crumbs which have no other patterns then the overall randomness deficiency is mitigated. If these are the only crumbs on the floor then finding a satisfactory explanation becomes critical.

People are motivated to seek out randomness deficiency in the world (Dessalles, 2006). The experience of randomness deficiency with subsequent resolution through representational updating is what makes subjects interesting, films entertaining and jokes funny (Schmidhuber, 2009). Accordingly, when people speak intuitively about likelihood and probability, it is the concept of representational updating which is relevant to them.

## Subjective Probability

Because it assumes a definitive probability measure function, classical probability theory cannot be applied to the concept of representational updating. This limitation means that the theory is, for the large part, irrelevant to everyday life and thus inappropriate for evaluating the nature of human reasoning.

Developments in algorithmic statistics have allowed probability theory to be extended to situations involving an uncertain probability measure function (see, e.g., Vityányi \& Li, 2000; Gács et al., 2001). The optimal model which can be derived from a set of observations is the one which maximizes the compression of that dataset, yielding the Minimum Description Length (MDL), a concept which formalizes Occam's razor.

Whenever an observation is no longer typical with respect to an MDL model it should be adjusted to lower the randomness deficiency of the data (see Li \& Vityányi, 2008, for details on how the updating process is carried out). We can quantify the extent of this representational adjustment in
terms of the amount of information that, given the original model, would be required to obtain the updated model. The more the information required, the more significant (and less likely) the update.

The model that people hold of reality represents the very best that they can do in representing their environment and provides the very best that they can achieve in terms of predictions. If we assume that our representation is a reliable predictor of events then the larger a potential update to that representation, the rarer it should be. Accordingly, we can apply probability theory to speak about the likelihood of an outcome requiring an update of a particular size. The uncertainty which precludes probability theory from being applied to real-world scenarios is circumvented by shifting the focus from an underdetermined probability measure function to the immutable mechanism of representational updating.

## Preliminaries

A computable probability density function $p$ can be interpreted as a model for a string generating device. Given such a device, described by $p$, there are some "type of strings" we expect to be output, whereas some others are surprising. String $x$ is said $p$-typical if it is a random string relative to the model described by $p$, i.e. the model already describes all the regularities in $x$.

Formally, let $\alpha>0$ be a constant, called the surprise threshold, which represents the level of randomness deficiency that necessitates representational updating. String $x$ is $p$-typical with surprise threshold $\alpha$ (or $(p, \alpha)$-typical) if the length of its shortest description given $p$ is at least the number of bits a Shannon-Fano code based on $p$ would require (an encoding where the more $p$-likely a string is, the shorter its encoding will be) after subtracting the surprise level $\alpha$, i.e.,

$$
K\left(x \mid p^{*}\right) \geq-\log p(x)-\alpha
$$

The idea behind the minimal description length (MDL) of a string $x$ (Gács et al., 2001) is to take the shortest (in description length) among all models for which $x$ is typical. To avoid overfitting (i.e. the model is specifically built for $x$ instead of for all "strings of type $x$ ") the description length of both the model and the string given the model, should be equal to the description of the string on its own. Formally, probability density function $p$ is optimal for string $x$ if the shortest description of $x$ has the same length (up to an additive constant) as the shortest description of $p$ plus the number of bits required for a Shannon-Fano encoding of $x$ based on $p$, i.e.,

$$
K(x)=K(p)-\log p(x) \pm O(1)
$$

where $O(1)$ means the equality holds up to an additive constant. The MDL of string $x$ is the shortest (description length) among all optimal probability density functions for $x$ for which $x$ is typical.

## Subjective information and probability

Suppose an observer experiences observations $d_{1}, d_{2}, \ldots$ generated by some source with computable probability density
$p_{\text {source }}$. The observer tries to learn the probability density $p_{\text {source }}$ by finding the shortest optimal model based on the observations made so far. Formally, after having observed strings $d_{1}, d_{2}, \ldots, d_{n}$, the observer seeks to construct a hypothetical model $p_{n}$ where

$$
\begin{aligned}
& p_{n}=\arg \min \left\{\left|p^{*}\right|: p \text { is optimal for } d_{1}, d_{2}, \ldots, d_{n}\right. \text { and } \\
& \left.\quad d_{1}, d_{2}, \ldots, d_{n} \text { are }(p, \alpha) \text {-typical }\right\}
\end{aligned}
$$

If the next observation $d_{n+1}$ is surprising, action may be required. Formally, observation $d_{n+1}$ is $\alpha$-surprising if the length of its shortest description given $p$ is less than the number of bits a Shannon-Fano code based on $p$ would require after subtracting the surprise level $\alpha$, i.e.,

$$
K\left(d_{n+1} \mid p_{n}^{*}\right)<-\log p_{n}\left(d_{n+1}\right)-\alpha
$$

If an update is performed, then the subjective information of $d_{n+1}$ (the "cost" of the update) is the amount of information needed to update the model to the latest, that is the length of the shortest description of the new model, given the old model, i.e.,

$$
\operatorname{subjective~information~}\left(d_{n+1}\right)=K\left(p_{n+1}^{*} \mid p_{n}^{*}\right)
$$

Subjective probability (the probability of the update) can then be quantified based on the amount of information it contains, i.e.,

$$
\operatorname{subjective} \operatorname{probability}\left(d_{n+1}\right)=2^{-K\left(p_{n+1}^{*} \mid p_{n}^{*}\right)}
$$

## Experiment 1

In the following experiment we investigated the hypothesis that people use subjective probability rather than classical probability to judge the likelihood for real-world events. We used an example for which the use of classical probability theory seems particularly compelling, namely lottery sequences (see Dessalles, 2006). A naive application of classical probability suggests that all lottery sequences are just as likely.

## Method

In a lottery system where 6 numbers are drawn from 45, each ordered sequence has a classical probability of $C(45,6)$. According to the theory outlined in the previous section, the subjective probability of an outcome is related to its randomness deficiency. People expect the lottery numbers to be Kolmogorov-random. The more they deviate from a typical random string, the lower the subjective probability that they reflect the output of a random source. The randomness deficiency of a string is quantified precisely by its MDL. However, since this theoretical construct is not computable in practice, we are obliged to create a heuristic compressor which approximates it.

We considered the patterns to which people are sensitive in discriminating predictable sequences from random ones. Overtly non-typical random patterns include ones in which
the numbers are consecutive (e.g. $3,4,5,6,7,8$ ) or where they increase in a constant step size. To compress these patterns we created a simple compressor which takes in an ordered sequence of six numbers, and computes the six step sizes between them (with the first number counting as the first step). A Huffman encoding scheme is then applied, which relates bit size to step size. A breakdown of the structure of the associated Huffman tree is provided in Table 1.

Using this system the sequence $10,32,33,35,39,45$ is transformed to step sizes of $+10,+22,+1,+2,+4,+6$ which is then encoded using $8+8+2+3+4+6=31$ bits. Analysing six years of bi-weekly Irish National Lottery draws revealed a mean compressed length of 30.9 bits, with a mode of 31 bits. The most randomness deficient of the 624 sequences was 2 , $4,32,34,36,37$ (description length of 20 bits), while the most random was $9,20,26,27,34,45$ (description length of 39 bits). The theoretical minimum description length of our system was 12 (e.g. $1,2,3,4,5,6$ ), while the theoretical maximum was 43 (e.g. $7,13,20,29,36,45$ ). The number of bits needed to perfectly encode an ordered random sequence of six numbers between 1 and 45 is 23.0 bits. Although our compressor cannot compute MDL, it delivers compression for randomness deficient outputs (i.e. it compresses below 23.0 bits for certain non-typical random sequences) and can therefore be used to evaluate the hypothesis that people use subjective rather than classical probability.

Table 1: Structure of Huffman encoding scheme.

| Level Depth | Leaves | \#Branches |
| :--- | :--- | :--- |
| 1 | - | 2 |
| 2 | +1, repeat | 2 |
| 3 | $+2,+3$ | 2 |
| 4 | +4 | 3 |
| 5 | +5 | 5 |
| 6 | +6 | 9 |
| 7 | $+7,+8$ | 16 |
| 8 | +9 up to +40 | - |

Participants 130 undergraduate students from NUI Maynooth participated voluntarily in this study.

Procedure As an initial step we purchased two quickpick (i.e. randomly selected) lottery tickets for the next week's Irish National Lottery, with six ordered numbers ranging from 1 to 45 . Participants were informed that we had purchased these tickets and that, for each of the two quickpick sequences, their goal was to identify it from among a group of five candidate sequences. No mention was made of how the other four sequences had been generated.

Each quickpick sequence was presented on a screen along with four other sequences randomly generated using our compressor algorithm. The four distractor sequences met the constraints of having compressed bit-sizes of between 15 and 18 bits, 19 and 22 bits, 23 and 26 bits, and 27 and 29 bits respec-
tively. As it happened, the first lottery ticket sequence had a compressed description length of 31 bits, and the second had a length of 30 bits. The ordering of the five sequences on the screen was randomized.

Participants ranked each set of five sequences in order of likelihood of being the quickpick sequence, from highest probability to lowest probability. After the process was complete participants were shown the actual lottery tickets so that, as promised, they could see if they had made the correct judgment or not.

Unfortunately for the experimenters, the lottery tickets did not turn out to be winning ones.

## Results and Discussion

An individual applying classical probability would view all sequences as equally likely and would thus only have a $20 \%$ chance of correctly identifying one quickpick sequence mixed with four others. However, $64 \%$ of participants correctly identified the numbers on the first ticket, and $66 \%$ on the second ticket (i.e. ranked these sequences in first place). When participants were shown the lottery tickets at the end of the experiment they were surprised that their intuition had, in the majority of cases, led them to make the correct choice.

Figure 1 shows the mean compressed bit size for sequences ranked from first to fifth place across the two presentations. The overall correlation between ranking and compressed description length was $0.965, p<.001$.

Figure 1: Mean compressed bit size according to rankings of likelihood.

These results demonstrate that, not only do people use subjective probability, they also enhance the accuracy of their judgments by using it. While the naive mathematician assumes all lottery sequences are equally likely, the savvy layperson realises there is an element of uncertainty involved in how those sequences were generated. The greater the randomness deficiency of a sequence, the greater the subjective probability that it was generated by a non-random generative mechanism.

Our central argument in this article is that, because models of reality always involve uncertainty, people apply subjective probability rather than classical probability in everyday life. In the following experiment we investigated whether the application of subjective probability can explain experimental observations which have previously been interpreted as examples of fallacious reasoning.

## Experiment 2

The conjunction effect is a situation in which people assert that a conjunction of two outcomes is more probable than either of those outcomes in isolation. According to classical probability theory this is a fallacy because requiring two outcomes to be validated is always a stricter criterion than requiring a single one to be validated (i.e. $P(x \wedge y) \leq P(y)$ ). The most celebrated example of the fallacy involves one of the materials used by Tverksy and Kahneman (1983), involving an individual named Linda.

Linda is 31 years old, single, outspoken, and very bright. She majored in philosophy. As a student, she was deeply concerned with issues of discrimination and social justice, and also participated in anti-nuclear demonstrations.

Which is more probable?
a) Linda is a bank teller
b) Linda is a bank teller and is active in the feminist movement.

Tverksy and Kahneman (1983) report that, when the two possible outcomes are listed together as above, $85 \%$ of people violate the conjunction rule by identifying $b$ ) as more probable. Tverksy and Kahneman's explanation is that people get confused by what they call 'representativeness'. They found that participants' responses reflect the extent to which the descriptions match a stereotype, with a correlation of 0.98 between mean ranks of probability and representativeness.

It is interesting to note that this correlation closely matches the observed correlation of 0.97 between mean ranks of probability and compressed description length in Experiment 1. This suggests the possibility that representativeness and randomness deficiency are closely related concepts.

In Experiment 1 we found that, when there is uncertainty as to the generative mechanism which produced an outcome, people rely on randomness deficiency to make judgments. The uncertainty in Experiment 1 concerned the fact that participants were given no information as to how four of the five lottery sequences were generated. Rather than assuming that all the sequences were generated randomly, they correctly used randomness deficiency to make inferences that resolved the uncertainty.

In the Linda example, some information about Linda is provided, but there is much about her that remains unknown (e.g. has she settled down since her student days?) In the case of uncertainty regarding the underlying probability measure function, then classical probability cannot be applied. For example, if we find out that Linda is a bank teller, then we might infer that she has settled down. In contrast, hearing that
she is still active in the feminist movement suggests that she has not changed much since her student days. Because these two models of Linda are quite different, there is no definitive probability measure function relative to which classical probability can be expressed.

## Method

In the following experiment we investigated whether the outcomes for the Linda scenario cause participants to adjust their model of Linda.

Materials For this experiment we altered the Linda scenario by including the outcomes as part of the description. We removed the information that she is single, outspoken and very bright and included at the end of the description either that "Linda is a bank teller" (Version 1) or "Linda is a bank teller and is active in the feminist movement" (Version 2). Participants were then asked to rate the probability of Linda having the attributes of being single, outspoken and very bright (from 0 to $100 \%$ ). In order for classical probability to be applicable, then the probabilities provided for Versions 1 and 2 should not differ significantly. Linda should be just as independent, outspoken and bright regardless of whether she is active in the feminist movement or not.

Participants 106 undergraduate students from NUI Maynooth participated voluntarily in this study.
Procedure Participants were randomly assigned either Version 1 or Version 2 of Linda's description and wrote down their probabilities for the three characteristics, which were randomly ordered along with three other filler characteristics (Linda plays golf, Linda is dyslexic, Linda suffers from anxiety).

## Results and Discussion

The mean probabilities for the three characteristics are shown in Table 2. When Linda was described as a bank teller and active in the feminist movement she was rated as significantly more likely to be single, demonstrating that the outcomes used in the Linda scenario cause participants to adjust their model of Linda.

Table 2: Mean probability ratings, t-test scores and significance for the two descriptions of Linda.

|  | Ver. 1 | Ver. 2 | t -test |
| :--- | :--- | :--- | :--- |
| Single | $47 \%$ | $64 \%$ | $t(104)=4.11, p<.001$ |
| Outspoken | $77 \%$ | $80 \%$ | $p>.05$ |
| Very Bright | $59 \%$ | $63 \%$ | $p>.05$ |

The numbers generated by a perfect dice never lead us to update our beliefs about the nature of the dice, yet finding out about Linda's current activities does lead people to update their beliefs about her. Because the model of Linda is uncertain, subjective probability must be applied. What people
are quantifying when they identify the conjunction as more probable is that the conjunction contains more subjective information, and that, relative to the process of representational updating, the likelihood of an outcome diminishes with the amount of subjective information it carries. Basing decisions on subjective probability is mathematically the correct approach when dealing with uncertainty regarding the underlying probability measure function.

In the following section we build on this result by proving that for every situation involving uncertainty (i.e. all real world scenarios) there is a conjunction of events which is more subjectively probable than either of its constituents in isolation.

## Proof that Conjunction Effect is not a Fallacy

In this section we prove that given any hypothetical model $p$, there are always two strings of events $x, y$ such that $x$ is a substring of $y$ but $y$ has higher subjective probability. The idea of the proof is that any long enough typical string of events can always be decomposed into a substring of events that carries greater subjective information.
Theorem 1. Let $E_{1}, E_{2}, \ldots E_{m}$ be $m$ independent events and let $p$ be the associated computable probability measure function. Let $\alpha>0$ be a surprise threshold. There exists a conjunction of events $A=A_{1} \wedge A_{2} \wedge \ldots \wedge A_{n}$ with a constituent $B$ (i.e. $p(A)<p(B))$ such that $B$ is $(p, \alpha)$-surprising (i.e. carries subjective information) and $A$ is $(p, \alpha)$-typical (i.e. has a subjective probability of 1).

Proof. Let $E_{1}, E_{2}, \ldots E_{m}, p$ and $\alpha>0$ be as above. Without loss of generality $m=2^{k}$ and $p$ can be seen as a probability on strings of length $k$ (each coding one event $E_{i}$ ) extended multiplicatively i.e., $p: 2^{k} \rightarrow[0,1]$ is extended multiplicatively by $p(x y):=p(x) p(y)$.

Let $n$ be a large integer. Let $y \in 2^{k n}$ be a $(p, \alpha)$-typical string. $y$ can be viewed as the concatenation of $n$ strings of length $k$ (i.e. the conjunction of $n$ events). By the pigeon hole principle, there must be such a string that occurs at least $n / 2^{k}$ times. Denote this string by $s$, and let $l$ be the number of occurences of $s$ in $y$, i.e. $l \geq n / 2^{k}$. Because $y$ is $(p, \alpha)$-typical we have $p(s)>0$. Thus $p(s)=2^{-c}$ for some $c>0$. Let $x$ be $l$ concatenations of $s$. Because $p$ is extended multiplicatively we have $p(x)>p(y)$.

Let us show that $x$ is $(p, \alpha)$-surprising. To describe $x$ it suffices to describe $l$ plus a few extra bits that say "print $s$ $l$ times". Since $l$ can be described in less than $2 \log l$ bits (by a prefix free program) we have $K(x)<3 \log l$ for $n$ large enough. We have

$$
\begin{aligned}
-\log p(x)-\alpha & =-\log p\left(s^{l}\right)-\alpha=-\log p(s)^{l}-\alpha \\
& =-l \log 2^{-c}-\alpha=c l-\alpha>3 \log l>K(x) \\
& \geq K\left(x \mid p^{*}\right)
\end{aligned}
$$

for $n$ large enough. Thus $x$ is $(p, \alpha)$-surprising, but $y$ is not.

## Conclusion

Although Tverksy and Kahneman (1983) identified an association between representativeness and the conjunction effect, they never provided an explanation for why such an association might exist, instead being satisfied to pass it off as an arbitrary reasoning fallacy. Had they questioned participants regarding their judgments, rather than dismissing them as fallacious, then the resultant findings may have facilitated the extension of classical probability theory. In sum, perhaps the most salient fallacy on display in Tverksy and Kahneman's (1983) study is the misplaced belief that mathematical theories which have been developed for precision models in the exact sciences retain their validity when used to describe complex cognition in the real world.

Tverksy and Kahneman (1983) posed the following question: "Why do intelligent and reasonably well-educated people fail to recognize the applicability of the conjunction rule in transparent problems?" Here, we have presented the answer: Because often it's not applicable.

#### Abstract

The mere presence of a co-actor can influence an individual's response behavior. For instance, a social Simon effect has been observed when two individuals perform a Go/No-Go response to one of two stimuli in the presence of each other, but not when they perform the same task alone. Such effects are argued to provide evidence that individuals co-represent the task goals and the to-be-performed actions of a co-actor. Motivated by the complex-systems approach, the present study was designed to investigate an alternative hypothesisthat such joint-action effects are due to dynamical (timeevolving) entrainment processes that perturb and couple the behavior of socially situated actors. To investigate this possibility, participants performed a standard Go/No-Go Simon task in joint and individual conditions. The dynamic structure of recorded response times (RTs) was examined using fractal statistics and instantaneous cross-correlation. Consistent with our hypothesis that participants responding in a shared space would become behaviorally coupled, the analyses revealed that RTs in the joint condition displayed decreased fractal structure (indicative of an interpersonal coupling perturbing and constraining participant behavior) compared to the individual condition, and were more correlated across a range of time-scales compared to the RTs of pseudo-pair controls. Collectively, the findings imply that self-organizing dynamic processes might underlie social stimulus-response compatibility effects and shape joint cognitive processes in general.

Keywords: joint action; stimulus-response compatibility; interpersonal coordination; pink noise; dynamical systems

## Introduction

Social interaction is a hallmark of everyday activity. Examples include a parent helping a child get dressed, a couple washing dishes together, people playing a team sport, or two workers carrying a heavy item up a flight of stairs. In each of these cases, a form of cooperation emerges such that the activity is coordinated across all participating
actors. Interestingly, coordination emerges even when no explicit coordination is required, for example when people are completing separate parts of the task. The present study aims to further investigate this latter form of coordination.

## Joint Stimulus-Response Compatibility (JSRC)

Over the past decade, a growing amount of research has been conducted investigating joint-action via so-called 'go/no-go tasks' (e.g., Sebanz, Knoblich, \& Prinz, 2005; Sebanz, Bekkering, \& Knoblich, 2006; Tsai, Kuo, Jing, Hung \& Tzeng, 2006). In such tasks, participants are instructed to 'go' when given a certain stimulus context (e.g., when they are presented with a red stimulus), and to 'not go' when given the alternative (e.g. a blue stimulus image). The compatibility aspect of these experiments lies in the spatial orientation of the stimulus relative to the location of the responding individual. For instance, if a stimulus is presented on the same side of a display with respect to where a participant is seated, the response is deemed "compatible". Alternatively, if a stimulus is presented on the opposite side of a display screen with respect to where a participant is seated, the response is deemed "incompatible".

To examine the effects of such stimulus-response mappings in a joint-action setting, the reaction times (RTs) are compared between two conditions: one in which the participant sits on one side of the display screen and responds alone to one stimulus type (the individual condition), and another where the task requirements are exactly the same except that another participant, seated on the opposite side of the display screen, responds to the alternative stimulus (the joint condition). The general finding is that even though participants in the joint condition are performing the exact same task as in the individual condition, a greater SRC effect exists when two people are completing the task in one another's presence compared to
when they complete the task alone. In other words, incompatible responses are significantly slower than compatible responses in joint conditions, but only marginally different (or not significantly different at all) for individual conditions.

These findings are generally taken as evidence for the co-representation of action goals during a joint-action setting, whereby actors form a shared representation of the collective task goal. That is, individuals mentally represent the actions of their co-actor and integrate them into their own action planning. This co-representation or action integration therefore results in slower RTs for incompatible stimulus situations compared to compatible stimulus situations. When completing the task alone, however, no such integration or co-representation occurs, and thus the spatial compatibility of the stimulus has little or no effect.

The JSRC effect has been observed across a wide range of stimulus and response manipulations, including hand posture (Cho, Proctor, \& Yamaguchi, 2007), non-biological response mechanisms (Buhlmann, Umilta, \& Wascher, 2007), orthogonality of stimulus location (Bae, Cho, \& Proctor, 2009; Figliozzi, Silvetti, Rubichi, \& Doricchi, 2010), and auditory stimuli (Buetti \& Kerzel, 2008). It is also known to be influenced by various social psychological variables, such as the facial features of a co-actor, and tasksharing paradigms (Philipp \& Prinz, 2010; Jung, Holländer, Müller, \& Prinz, 2011).

JSRC effects also appear to suggest that knowing what another person's task is during joint-action is the means by which an individual can understand others' action intentions and points to shared representations as the casual basis of this integration or modulation process. A consequence of this co- or shared-representation and action integration emphasis, however, is that no research has attempted to examine the time-evolution or behavioral dynamics of actors' responses during JSRC tasks, nor the degree to which JSRC effects are a result of the dynamical entrainment or coordination processes that are known to exist during co-present joint-action situations (Richardson et al., 2012; Schmidt et al., 2011). The aims of the present study were therefore to (i) examine the dynamical structure of JSRC task behavior and (ii) investigate whether the standard (visual) JSRC effect might be a result of dynamic coordination or entrainment processes coupling the response behavior of co-acting individuals.

## Examining the Dynamics of JSRC

At the crux of the traditional statistical analyses for JSRC experiments is a comparison of means, wherein each participant's time series of responses is represented as a single, unchanging number. The average RT response for each condition is understood as capturing the core and most meaningful aspect of the recorded RT behavior. The variability or time-evolution that occurs from trial-to-trial is simply discarded as error or mentioned only briefly in terms of how localized the mean is (for an exception see Vesper et
al., 2011). The temporal structure of RT variability (i.e., deviations from the mean over time), however, often provides additional and meaningful information about how behavior emerges over time (Gilden, 2001). For instance, there is evidence that the seemingly error-induced variation in responses may actually be reflective of how people execute discrete motor responses in a certain spatiotemporal context (Wing \& Kristofferson, 1973). Furthermore, even if the mean value and standard deviation are the same, the structure of RT time series that result in those means and standard deviations could in fact be quite different.

In order to examine the dynamic structure and unfolding variability of RTs over time, recent research has utilized fractal methods that provide deeper insight into the dynamics of an ongoing activity (Bassingthwaighte, Liebovitch, \& West, 1994; Gilden, Thornton, \& Mallon, 1995; Jensen, 1998; Van Orden, Holden, Turvey, 2003). Conceptually similar to geometric fractal patterns (Mandelbrot, 1982), fractal patterns in experimental timeseries data correspond to nested patterns of variability found across repeatedly measured behaviors. Instead of comparing the overall means, fractal analysis involves determining how the variability exhibited in a time-series changes with changes in time-scale. That is, fractal analysis involves determining if the structure of variability in an RT timeseries is statistically self-similar or scale invariant, such that small variations in the data have essentially the same structure as large variations (Brown \& Liebovitch, 2010; West \& Deering, 1995). As in geometrical fractal patterns, if one were to "zoom in" (i.e., examine a smaller scale) on the measurement time-series, one would discover essentially the same pattern of fluctuations evident at the larger scale (Holden, 2005). Accordingly, fractal statistical methods do not rely on partitioning the variability in measurement into different components, but rather assess the structure of the time-evolving variability observed.

A time-series containing random fluctuations (i.e., white noise) indicates that the observed variability is the result of unsystematic or unrelated changes from trial to trial (Van Orden, 2010). Alternatively, the variability in an RT time-series containing fractal or scale invariant structure contains trial-to-trial variability that is long-term correlated. In other words, the time-series contains nested patterns of variability wherein small variations in measurement have the same structure as large variations. Such structure in repeated measurements is often referred to as "pink noise" or $1 / f$ noise and are characteristic of a wide range of naturally occurring complex (interaction-dominant) systems and phenomena, from eye movement patterns (Aks, Zelinsky, \& Sprott, 2002) and heart rate variability (Eke et al., 2002), to self-reported mood change (Delignières, Fortes, \& Ninot, 2004).

There are numerous methods for determining the degree to which the variability in a behavioral or response time-series is scale invariant or pink (see Delignières et al., 2006 for a review). One of the most robust methods is detrended fluctuation analysis, commonly referred to as

DFA (Bassingthwaighte et al., 1994; Peng, Havlin, Stanley, \& Goldberger, 1995). DFA quantifies the long-term correlative properties of behavior by detrending the time series of adjacent bins, or collections of consecutive data points, at all time scales. The residual variance obtained from the least-square regression line subtraction of each bin is calculated for progressively larger bin sizes. Bin size is plotted against variance on a log-log plot, and the scaling exponent, $H$, is revealed by the slope of the best-fitting line. For DFA, $H \approx 1.0$ indicates that the response variability or "noise" is pink (i.e., fractal). White noise, however, corresponds to $H=0.5$.

Deviations away from 'perfect' pink noise (i.e., $H=$ 1.0) can result from changes in system flexibility (Kloos \& Van Orden, 2010). For instance, increasing task constraints or difficulty, such as coupling responses to external timers or events (i.e., metronomes), or increasing task speed, can whiten RT variability and result in $H \ll 1.0$ (Chen, Ding, \& Kelso, 2001; Delignières et al., 2009; Hausdorff et al., 1996). Changes in $H$ across conditions thus reveal how differing task manipulations result in processes that interact or constrain each other, as well as influence the overall organizational processes that underlie a series of behavioral responses (Van Orden, 2010). Accordingly, the question considered here was does the co-presence of an actor during a JSRC task change the fractal structure of an individual's RT behavior, and if so, how and why?

One possibility is that the behavior of individuals during joint-action conditions are subtly coupled or dynamically entrained and that this coupling or entrainment acts to constrain and/or perturb the behavioral responses of the individuals involved. There is a significant body of research demonstrating how the behaviors of co-present individuals often become dynamically coordinated or entrained (see Schmidt \& Richardson, 2008; Marsh, Richardson, \& Schmidt, 2009 for reviews) and that such processes can modulate and perturb individual behavior (Richardson et al., 2009, 2012; Riley, et al., 2011; Romero et al., 2012). If this is the case, then the fractal structure of the RT variability should be whiter in the joint condition compared to the individual condition.

To explore this possibility, we employed a standard SRC task, the Simon task (Craft \& Simon, 1970), and had participants complete the task under joint and individual go/no-go conditions. We performed a fractal analysis on the resting RT time-series using DFA, with the expectation that the joint condition would exhibit a whiter fractal structure ( $H$ closer to 0.5 ) compared to RT time-series in the individual condition. In addition to performing a fractal analysis, we also employed instantaneous cross-correlation (Barbosa, Yehia, \& Vatikiotis-Bateson, 2008) to index the degree to which the RTs of co-acting individuals were correlated (i.e., coordinated) with each other over time. If the behavioral responses of individuals are entrained during a joint-action situation, then the temporal correlation should be greater between the RT time series of individuals in the joint condition compared to RT time series of pseudo-pairs
created using RT time-series from participants who performed the task in the individual condition. We employed instantaneous cross-correlation because it allows one to determine how correlated two behavioral time-series are across multiple time-scales. The method is ideally suited for determining highly subtle non-synchronous coordination that occurs at variable time-lags. It essentially computes the correspondence between two signals recursively, generating a time-series of how past and future samples are correlated at all points in time. Setting a minimum $r$ value as a cut-off for what is considered to be correlated or not (i.e., $r=.25$ ) then allows one to calculate the percentage of points that resulted in correlation values greater than that cutoff. The resultant value is the proportion of correlated activity and can be understood as providing a measure of percent coupling.

## Methods

## Participants

Twenty-four undergraduate students from the University of Cincinnati ( 7 male, 17 female) participated in the study. They ranged in age from 18 to 22 years old and received class credit for participation in the experiment.

## Materials

A 19" Dell Flat Panel monitor was used to present stimuli. Stimuli included a blue " X " or red " X " ( 1 " high, $1 / 2$ " wide), displayed on the left or right of the screen (positioned $51 / 2$ " from the top and bottom of the screen, and 2 " from the left or right side of the screen, respectively). Stimulus presentation and data collection was controlled using Direct RT. An Apple keyboard, modified to be millisecond accurate, was used to collect reaction time data. The shift keys were used as response indicators on the keyboard. A red sticker was placed on the right shift key and a blue sticker was placed on the left shift key. The monitor and the keyboard were placed in the center of a desk, with the keyboard 7" from the front of the desk and 8 " from the monitor. Participants were seated in chairs that were placed next to each other in front of the keyboard. Each seated participant was positioned approximately 30 " from the display screen.

## Procedure

Participants completed a visual go/no-go Simon task in which they were instructed to respond with a key press to a specific stimulus color presented on the screen. Participants were assigned only one of the two stimulus colors (e.g. red) and were instructed to respond only to their designated color, regardless of location, while ignoring the alternative (e.g. blue). Participants completed the task in one of two experimental conditions: a joint condition or an individual condition. For the individual condition, participants performed the task alone. For the joint condition pairs of participants performed the task together. Similar to the procedure of Sebanz et al. (2003), subjects assigned to the
red key sat on the right, and subjects assigned the blue key sat on the left, regardless of condition (see Figure 1). A brief instruction screen was presented on the computer monitor prior to the start of the experiment. Clarifying instructions were administered verbally and an opportunity for questions or clarification was offered.

63).

Figure 2: Mean reaction time (RT) as a function of experimental condition and compatibility.

## Fractal Analysis

DFA was performed on the last 512 responses for each participant. Prior to analysis, the RTs were normalized by subtracting the relevant condition means for each participant in order to examine the variability of the residual fluctuations (see Gilden, 2001 for a detailed description of the rationale). Consistent with our hypothesis that participants responding in the joint condition would exhibit a whiter fractal structure of responses due to task constraints and coupling, a between samples one tailed $t$-test performed on $H$ values calculated using DFA revealed a significant effect of experimental condition, $t(22)=2.25, p<.05$, with the fractal structure of RTs in the joint condition being significantly lower $H(M=0.57, S D=0.06)$ than in the individual condition ( $M=0.63, S D=0.08$ ) (see Figure 2). One sample $t$-tests indicated that $H$ values were significantly different from a test value of 0.5 (hypothetical white noise) for both the individual, $t(11)=5.93, p<.01$, and the joint conditions, $t(11)=34.53, p<01$.

Figure 3: Mean Hurst $(H)$ as a function of experimental condition.

## Instantaneous Correlation

To determine the degree to which the RT time-series of participants in the joint condition were entrained or coupled to each other over time, we calculated the percentage of correlations within the time-series of instantaneous correlations for delays of -60 to 60 trials that had an $r>.25$. As mentioned above, the resultant value can be understood as a measure of percent coupling or the proportion of
correlated activity. We then used a between samples onetailed $t$-test to compare the percent coupling observed between participants in the joint condition to the percent coupling calculated between pseudo pairs of participants created by randomly pairing participants from the individual condition. Consistent with the hypothesis that the behavioral response of participants in the joint condition might be dynamically entrained or coupled, the analysis revealed that the percent coupling for the joint condition (\%30.9) was (marginally) significantly greater, $t(22)=1.65, p=.059$, compared to pseudo pairs (\%21.6) created from participants in the individual condition (see Figure 3).

Figure 4: The percent coupling calculated using instantaneous cross correlation as a function of experimental condition.

## Discussion

The experimental study present here was aimed at examining the behavioral dynamics of individuals during a joint-action stimulus-response compatibility task. We submitted recorded RT time-series during a JSRC task to both a standard comparison of means, and to various dynamical analysis methods in order to examine how RT variability evolved over time. We compared these patterns of variability between joint and individual conditions.

Consistent with previous research, we found a significant difference in the overall reaction times between the individual and joint conditions, as well as a significant compatibility effect in the joint condition. More importantly, by measuring the fractal structure of participants' RTs, we found that that the structure of variability in the joint condition was much whiter than in the individual condition, as predicted. The current results therefore extend previous research by demonstrating that the mere presence of another individual not only affects average RT, but also affects the dynamics of an individual's response behavior. This difference was theorized to be a consequence of the dynamical entrainment processes that mutually perturb and constrain the behavior of individuals in a shared environment (Schmidt \& Richardson, 2008).

To further examine whether the response behaviors of participants were dynamically coupled, an instantaneous correlation analysis was performed. We compared the degree to which the RT behavior of pairs in the joint condition was correlated to the degree of RT correlations that occurred for pseudo pairs created from participants who
completed the individual condition. The results of this analysis revealed that the response behavior of pairs in the joint condition exhibited greater temporal correlation compared to pseudo pairs, providing more evidence that the response behaviors of co-present individuals in the current go/no-go task were dynamically entrained. The magnitude of these temporal correlations was by no means large and occurred at non-synchronous time-lags. Thus, like most other forms of interpersonal entrainment or behavioral coupling (see e.g., Chartrand and Bargh, 1999; Schmidt \& Richardson, 2008; for reviews), the entrainment that occurred was most likely intermittent, rather than constant, and did not occur synchronously or at any fixed time lag. The weak and complex nature of the interpersonal influence should not be discounted, however, given the fact that the mean differences in RT are also relatively small (as is typically the case JSRC studies). Indeed, the relative change in mean RT, fractal dimension ( $H$ ), and \% coupling are all somewhat equivalent.

In conclusion, the current study provides the first evidence that the response behavior of co-actors during a JSRC task is dynamically entrained and that such dynamical entrainment processes operate to constrain and perturb the time-evolving response variability of co-acting individuals. Although not directly tested here, it is possible that these dynamic processes of constraints and coupling may underlie the JSRC effect, rather than some form of shared representation. In truth, the dynamical systems and representational accounts of such behavior are not mutually exclusive and may in fact provide complementary explanations for such joint-action phenomena. Future research should be directed towards investigating these issues in order to better understand how the dynamics of joint-action activity shape joint cognitive processes.

#### Abstract

How are we able to reason about abstract concepts that lie resolutely beyond the reach of perception? One strategy is to ground understanding in space. Numbers, for instance, are known to interact with egocentric space during rapid numerical judgments. A range of experimental results have demonstrated that, among literate Western people, this "mental number-line" goes from left to right, with smaller numbers associated with left space, and larger numbers with right space. But what is the nature of this "space"? Previous work has conflated multiple possible egocentric frames of reference-head-based, eye-based, action-based-leaving it unclear which space is interacting with number. In the present paper, two studies investigated whether a single centrallylocated button, stationary in hand- and eye-based coordinates, can nevertheless exhibit different spatial properties in virtue of task-specific activity. In a go/no-go paradigm, participants judged the magnitude (Exp. 1) and parity (Exp. 2) of singledigit numbers. Crucially, they responded only with the index or middle finger of a single hand. While judging magnitude (Exp. 1), participants were faster to respond to smaller numbers with the more leftward finger, and larger numbers with the more rightward finger, regardless of the hand being used. This effect disappeared when judging parity (Exp. 2), replaced by finger-specific associations on the left hand only. In sum, in a task-sensitive way, participants associated numbers with egocentric space-but a behavioral space defined relative to embodied interaction rather than head- or eye-based reference frames. We discuss implications for number representation and the nature of "space" in embodied activity.

Keywords: number; space; action; SNARC; embodiment; go/no-go; frames of reference; Merleau-Ponty

## Introduction

"[The body's] spatiality is not, like that of external objects or like that of 'spatial sensations', a spatiality of position, but a spatiality of situation."- Merleau-Ponty (1962, p. 114).

How are we able to reason about abstract concepts that lie resolutely beyond the reach of perception? One strategy is to ground understanding in space. Numbers, for instance, are tightly linked with space across human activity. We recycle the language of space to talk about numbers, counting $u p$ to higher numbers and down to lower numbers, and use space

[^145]to reason about numbers as abstract concepts (Lakoff \& Núñez, 2000; Núñez \& Marghetis, to appear). Mathematical diagrams often associate numbers with particular locations. And number interacts with space in less explicit ways during the online performance of mathematical activities. In a seminal study, Dehaene and colleagues (1993) asked participants to judge the magnitude (greater or less than 5?) or parity (even or odd?) of single digit numbers. Participants were reliably faster to respond to smaller numbers when responding with a button in left space, and to larger numbers when responding in right space-as if they were spontaneously thinking of numbers along a left-to-right "mental number line." This interaction between numerical magnitude and spatial location has been dubbed the "SNARC" effect.

In the two decades since, the literature on such numberspace associations has exploded (Hubbard et al., 2005; Wood et al., 2008). Similar effects have been found with bipedal responses (Schwarz \& Müller, 2006) and saccades (Fischer et al., 2003; Schwarz \& Keus, 2004), further reinforcing the genuinely spatial nature of this effect. While the particular direction of this "mental number-line" is quite flexible, shaped by such factors as habitual reading direction (Shaki, Fischer, \& Petrusic, 2009) and recent experience (Fischer, Mills, \& Shaki, 2010), there is a growing consensus that number and space are intimately related.

But doubts remain. A number of authors have suggested that the effects have less to do with a stable spatial representation of number, and more to do with flexible or non-spatial associations (e.g., Fischer et al., 2010; Gevers et al, 2010; Santens and Gevers, 2006). Others have pointed out that most studies force participants to respond spatially, using buttons that are distinguished by their spatial location, and thus implicitly inject space in virtue of the experimental setup (Núñez, Doan \& Nikoulina, 2011). Indeed, when other response modalities are used-e.g., responding with higher or lower pitches-participants exhibit interactions that are SNARC-like but non-spatial (Marghetis et al., 2011). Number-space associations, therefore, may be more flexible and context-sensitive than first assumed.

Beyond these concerns, one additional question has been largely unaddressed: the nature of the "space" that sometimes, undeniably, interacts with number. Previous work has conflated the multiple egocentric frames of reference that we use to encode space, which include head-,
eye-, object-, and action- based frames of reference (cf. Cohen and Anderson, 2002). For instance, in the classic SNARC paradigm, the response buttons are placed to the left and right of the participant's body, and thus are distinguished similarly in multiple frames of reference: they are lateralized relative to participants' heads, eyes, and motor responses. When space is forced on the subject in this way, through a forced-choice paradigm where responses are spatially distinguished, it remains unclear as to which "space" is interacting with number.

One possibility is that numbers interact with behavioral space, i.e. the space defined relative to task-specific embodied activity. If this is the case, then observation of the SNARC effect may not depend on the presence of spatial responses distinguished externally in head- or eye-based coordinates, but rather on some juxtaposition of taskrelevant actions within the specific context of the task. Testing this possibility requires an experimental design that can isolate effects of behavioral space from those due to head- or eye-based coordinates. We took up this challenge by investigating whether SNARC-like effects could be elicited using only a single, centrally-placed response button, which remained in the same location relative to head- and eye-based spatial coordinates. By requiring participants to press the button with different fingers of the same hand, the stationary button can move relative to taskrelevant embodied activity-that is, in behavioral space.

In two studies, participants judged the magnitude (Exp. 1) and parity (Exp. 2) of single-digit Arabic numerals. Crucially, and in contrast to previous studies, we used a go/no-go paradigm in both tasks: participants responded by pressing a single centrally-located button with only their index or middle finger. The finger used was manipulated between blocks, as was the "go" response criterion, while response hand was varied between subjects. By using a central button, kept stationary relative to head- and eyebased frames of reference, and by using a go/no-go paradigm in which different response fingers were never juxtaposed spatially within a block, but only temporally across blocks, we were able to focus on one particular spatial frame of reference: behavioral space, the space defined by the possible embodied actions within the task as a whole. Moreover, by manipulating the response finger,

Figure 1: Paradigm for Experiments 1 and 2. Here, the "Go" criterion would be to respond with the index finger of the left hand, if less than 5 (Exp. 1) or even (Exp. 2).
identified only by name (e.g. "index finger"), we were able to avoid any explicit spatial instructions.

If the SNARC effect is driven entirely by visual head- or eye-based frames of reference, then participants should not exhibit any SNARC-like effects here, since at no point are two response options spatially juxtaposed relative to head or eye. If, on the other hand, number interacts with space as enacted by task-specific interactions-that is, behavioral space-then we may find numbers systematically associated with space relative to activity-based frame of reference, with the more leftward finger faster for smaller numbers, and the more rightward finger faster for larger numbers.

## Experiment 1: Magnitude Task

## Participants

Undergraduate students ( $\mathrm{n}=32$, mean age $=20,19$ females) from a major research university participated in exchange for partial course credit.

## Procedure

In a go/no-go paradigm, participants judged the relative magnitude of visually-presented single-digit numerals, responding only if the number presented was greater than [/less than] 5. Participants responded by pressing a single, centrally-located button on a Serial Response Box placed at a comfortable distance in front of them, using either the index finger or middle finger. Response finger (index or middle) and response criterion (greater or less than 5) were fully crossed within participants, so each run had four blocks. Block order was counterbalanced, except that no two consecutive blocks used the same response finger (to avoid muscle fatigue). Response hand (left, right) varied between participants, so each participant maintained the same response hand throughout the experiment. Each participant, therefore, responded with their index and middle fingers for two blocks each.

Each trial began with a central fixation cross ( 500 ms .), followed by a centrally-presented single-digit number between 1 and 9 (excluding 5). If participants responded, the number would disappear; otherwise it would remain on the screen for 3 s., after which the trial would end automatically. See Figure 1. Each block began with 8 practice trials, followed by 80 experimental trials.

## Results

One participant was removed for failing to complete the experiment. Accuracy for the remaining 31 participants was high ( $\mathrm{M}>.99, \mathrm{SD}=.004$ ). Mean accuracy was analyzed with a $2 \times 2 \times 2 \times 2$ mixed ANOVA, with Magnitude (greater or less than 5), Parity (even, odd), and Response Finger (leftfinger, right-finger) as within-subjects factors, and Response Hand (left or right) as a between-subjects factor ${ }^{2}$. There were no significant effects on accuracy.

[^146]Before analyzing response time, incorrect trials were removed, followed by trials with reaction times that were slower than three standard deviations above each participant's mean response time, or faster than 200 ms ( $\mathrm{n}=83,1.7 \%$ of total trials).

Reaction times were analyzed with a $2 \times 2 \times 2 \times 2$ mixed ANOVA, with Magnitude (greater or less than 5), Parity (even, odd), and Response Finger (left-, right-finger) as within-subjects factors, and Response Hand (left, right) as a between-subjects factor. There was a main effect of Parity, with responses to odd numbers significantly faster than responses to even numbers ( $\mathrm{M}_{\mathrm{odd}}=382 \mathrm{~ms}, \mathrm{M}_{\text {even }}=398 \mathrm{~ms}$, $F(1,29)=54.8, p<0.001$; cf. Dehaene et al, 1993, who found no effect of Parity). There was also a marginally significant-but difficult to interpret-interaction between Parity and Response Hand $(F(1,29)=4.1, p=.053)$.

Crucially, the only other significant effect was an interaction between Magnitude and Response Finger ( $F(1$, 29) $=4.95, p=0.034, \eta_{\mathrm{p}}^{2}=.015$ ). Responses with the leftfinger (i.e. index finger of right hand, or middle finger of left hand) were faster for numbers less than 5 , while responses with the right-finger were faster for numbers greater than 5 (Fig. 2). There was no three-way interaction between Magnitude, Response Finger, and Response Hand $(F(1,29)=0.5, p=0.46)$, suggesting that the effect is due not to finger-specific associations, but to the location of the response fingers in each participant's behavioral space. The interaction between Magnitude and Response Hand, notably, was not significant $(F(1,29)=2.94, p=0.10)$.

## Discussion

When judging the magnitude of single-digit numbers, participants systematically associated smaller numbers with the left, and larger numbers with the right, even though the response button did not change location relative to head- or eye-based coordinates. Rather, magnitude was associated with locations in behavioral space, defined by the possible actions within the task: responding with one of two possible fingers. This was confirmed by the lack of a three-way interaction with Response Hand. In other words, numbers were not associated with particular fingers, as we might expect if participants were using a body-based frame of reference (e.g. DiLuca et al, 2006). Instead, they were associated with particular actions relative to task behavior: responses with the leftmost finger compared to responses with the rightmost finger. Moreover, this interaction arose despite the fact that left- and right-fingered responses were never juxtaposed within a single trial or block, but only manipulated between blocks and thus juxtaposed within the experiment as a whole.

Notably the interaction between Response Hand and Magnitude was not significant, contra the results of studies that have used bimanual responses (e.g. Dehaene et al, 1993; for review, see Wood et al, 2008). We attribute this to the fact that we manipulated response hand between subjects, not within. Responses with the left- and right-

Figure 2: Interaction between magnitude and finger-side in Experiment 1. (Error bars $=$ SE)
hands, therefore, were not contrasted within participants' task-internal embodied activity.

Does this effect arise automatically? The classic SNARC is often found even when magnitude is task-irrelevant, for instance when determining parity (even vs. odd) (Dehaene et al, 1993). This is taken to show that the interaction between magnitude and space is automatic and taskindependent, at least when responses involve lateralized buttons. Is this new action-based SNARC similarly automatic, or does it require explicit magnitude processing? Experiment 2 was designed to answer this question.

## Experiment 2: Parity Task

## Participants

Undergraduate students ( $\mathrm{n}=32$, mean age $=21,22$ females) from a major research university, who had not participated in the first experiment, participated in exchange for partial course credit.

## Procedure

The procedure was identical to Experiment 1, except participants had to respond based on the parity (even vs. odd) of each number, rather than the magnitude. For a given block, therefore, participants would only respond if the number was even [/odd] (Fig. 1). All nine numbers from 1 to 9 were used as stimuli, so each block began with 9 practice trials followed by 90 experimental trials.

## Results

Accuracy was high ( $\mathrm{M}=.99, \mathrm{SD}=.01$ ). Mean accuracy was analyzed with a $2 \times 2 \times 2 \times 2$ mixed ANOVA, with Magnitude (greater or less than 5), Parity (even, odd), and Response Finger (left-finger, right-finger) as within-subjects factors, and Response Hand (left or right) as a betweensubjects factor. The only significant effect was a main effect of Parity $(F(1,30)=10.1, p<0.01)$, with responses to odd numbers more accurate than those to even numbers $\left(\mathrm{M}_{\text {odd }}=98.6 \%, \mathrm{M}_{\text {even }}=97.6 \%\right)$.

Once again, before analyzing response times, incorrect trials were removed, followed by trials with reaction times that were slower than three standard deviations above each participant's mean response time ( $\mathrm{n}=85,1.7 \%$ of trials). Finally, trials where the target numeral was 5 were also removed, so we could include Magnitude (greater or less than 5) as a factor in our analysis.

In contrast with Experiment 1, numbers were not reliably associated with response side. Instead, while there was a marginal interaction between Magnitude and Finger Side $(F(1,30)=3.3, p=.08)$, this was complicated by a significant three-way interaction with Response Hand $(F(1,30)=9.3$, $p=0.005$ ). There was a similar effect for Parity: while there was no two-way interaction between Parity and Finger Side $(F(1,30)=2.1, p=0.16)$, there was a significant three-way interaction with Response Hand $(F(1,30)=4.9, p=.035)$. For both Magnitude and Parity, the effect was driven by the left hand, where the index finger was faster for odd or smaller numbers, and the middle finger was faster for even or larger numbers (Fig. 3). The only other significant effects were main effects of Parity and Magnitude $(F(1,30)=9.0$, $p=0.005$, and $F(1,30)=5.05, p=0.03$, respectively), and a hard-to-interpret three-way interaction between Magnitude, Parity, and Hand $(F(1,30)=4.2, p=0.05)$.

That the effect was driven by the left hand was confirmed by separate repeated-measures ANOVAs for each hand, with Response Finger (index, middle), Parity, and Magnitude as factors. For the right hand, Response Finger did not interact with Parity $(F(1,15)=0.2, p=0.90)$ or with Magnitude $(F(1,15)=0.02, p=0.88)$. But for the left hand there were significant interactions between Response Finger and Magnitude $(F(1,15)=5.07, p=0.039)$, and between Response Finger and Parity $(F(1,15)=7.1, p=.02)$.

## Discussion

When tasked with determining the parity of single-digit numbers, participants no longer exhibited the SNARC-like
 and magnitude (bottom), found on the left hand only, in Experiment 2. $($ Error bars $=\mathrm{SE})$.
effect found in Experiment 1. Instead, we found fingerspecific associations with both parity and magnitude, but only on the left hand. A change in task, therefore, induced new associations with numbers, tied to specific fingers rather than to a more general behavioral space. We return to the possible origins of these finger-specific associations in the General Discussion.

## General Discussion

What space do numbers inhabit? We conducted two studies to investigate the possibility that the form of "egocentric" space with which number interacts is behavioral space, the space of possible embodied interaction with the world. Indeed, contrary to what we would expect if number-space interactions are driven entirely by head- or eye-based coordinates, we found that numbers interacted with space even when participants responded with only a single, centrally-located button. This effect, moreover, was not driven entirely by body-based representations, since they were not specific to particular fingers or hands. Instead, responses to smaller numbers were faster with the more leftward finger of either hand, while responses to larger numbers were faster with the more rightward finger-a left-to-right "mental number line" defined entirely in terms of the embodied interaction between finger and apparatus.

This effect, however, was task-dependent, and disappeared when magnitude was not task-relevant. Instead, when participants were attending to parity, they associated specific fingers of the left hand with parity and magnitude: the index finger with odd or small numbers, and the middle finger with even or large numbers. The space with which numbers interacted, therefore, was flexibly tied to body and activity in a task-specific way.

## Task differences and finger-based representations

What might account for the different results of Experiments 1 and 2 ? One possibility is that parity and magnitude tasks require participants to attend to different information. Parity tasks, for instance, may activate linguistic and categorical representations, while magnitude tasks may activate analog visuospatial representations (van Dijk, Gevers \& Fias, 2009). It may be that the rather subtle spatial difference between fingers is sufficiently small that an interaction between magnitude and space requires the explicit activation of analog visuospatial representations of magnitude. Alternatively, since the classic bimanual Parity task explicitly distinguishes the response options by their positions on the left and the right, those linguistic labels may interact with categorical representations of numerical magnitude (cf. Proctor and Cho, 2006), explaining why the SNARC effect is seen in these types of Parity tasks but not in our deliberately modified setup.

Why, then, did magnitude and parity interact with specific fingers during the Parity task? One possibility is that the associations exhibited in Experiment 2 originate in culturally-specific gestures for numbers. In Quentin Tarantino's film Inglourious Basterds, an American spy
posing as a German is exposed when he orders two beers with the American rather than the German gesture: index and middle finger extended, instead of thumb and index finger. The participants at our American university, therefore, may have finger-specific associations as a result of the fingers they use to gesture for numbers: a single extended index finger for one, adding the middle finger for two. Within our task, these index-one and middle-two associations may have been extended to the rest of the numbers, with smaller or odd numbers associated with the index finger, and larger or even numbers associated with the middle finger-much like the relation between one (smaller and odd) and two (larger and even). This is only speculation, of course, although it does make a specific prediction: German participants should behave differently on our Parity task, responding faster with the thumb for smaller or odd numbers, and faster with the index finger for larger or even numbers, if we test these two fingers instead.

The results of Experiment 2 are illuminated further by recent research on finger-based representations of numbers. Fischer and colleagues, for instance, have suggested that stable finger-counting routines may explain cross-cultural variability in the direction of the SNARC; native English speakers, for instance, may count from left-to-right on their fingers, and also exhibit a left-to-right SNARC (Fischer, 2008; Lindemann, Alipour, and Fischer, 2011). Others, however, have found right-handed native English speakers to be ten times more likely to start counting on their right hand than on their left (Tschentscher et al., 2012), a pattern that we have also observed in pilot studies. Additionally, associations have been found (in the form of response-time facilitation effects) between specific numbers and the fingers used for those numbers in a habitual finger-counting routine (e.g. di Luca et al., 2006). The current study, by contrast, found categorical (i.e. magnitude and parity) rather than number-specific associations with finger. It may be that specific finger-number associations are only salient when multiple fingers are spatially juxtaposed at a single time.

## Which spaces?

The current results do not rule out the possibility that other spatial frames of reference also contribute to known interactions between number and space. Head- and eyebased coordinates may also play a role, and future studies should contrive to situate response-buttons in ways that tease apart the contributions of head- and eye-based coordinates, both from each other and from an action-based frame. Indeed, the classic SNARC effects may have been so pronounced exactly because they conflated multiple complementary frames of reference, which conspired to produce particularly strong effects.

Moreover, number may be associated with still other "spaces," including distinctions between peripersonal and distal space, although interactions between these spaces are still under-theorized and starkly under-explored. One study on the relation between peripersonal space and number bisection found an interaction between distance in
peripersonal space and number bisection, perhaps related to biases in lateral spatial attention (Longo and Lourenco, 2010), although the precise mechanism for this interaction is still unknown. In a study that contrasted finger-based and space-based representations of number, Riello \& Rusconi (2011) examined the possibility of a unimanual SNARC using a Two Alternative Forced Choice paradigm. Participants responded with the index and middle finger of the same hand, pressing buttons on either side of participants' midline. Response hand and orientation (face up or down) were also manipulated. They found co-existing hand-based and space-based representations of number, which were either complementary or incompatible depending on the hand and its orientation.

Two conditions in Riello \& Rusconi (2011) are of particular interest: responses with downward-facing left and right hands. In contrast with the results of the current studies, Riello and Rusconi only found a classic left-to-right SNARC effect on the right downward-facing hand. They explained this by positing an interaction between handbased (from thumb to little finger) and space-based (left to right) representations of number, which would be in conflict on the left hand when facing downward, but in accord on the right hand. The difference between our results and theirs may be due to a number of factors. For one, participants in Riello and Rusconi (2011) responded with two adjacent buttons-pressed by the index and middle finger of the same hand-that were placed on either side of the participants' midline, and thus were distinguished in multiple frames of reference (head-, eye-, hand-, and actionbased). Additionally, the simultaneous spatial juxtaposition of the two response options-unlike our design, in which different response options were only juxtaposed temporally between blocks-may have highlighted hand-based representations. Our results suggest that, when fingers are not spatially juxtaposed within a single block, behavioral space interacts spontaneously with number during magnitude judgments. Moreover, unlike previous studies (e.g. Dehaene et al, 1993), we did not find an interaction between hand side and magnitude. We attribute this to the fact that hand side was not contrasted within the task, but only manipulated between subjects, and thus this was not a salient distinction for the individual. Living organisms, after all, "enact a world as a domain of distinctions" (Varela, Thompson \& Rosch, 1993, p.140).

Previous attention to space, furthermore, has eclipsed attention to time. Existing studies have juxtaposed spatial responses within a single block, so that on any given trial there were always multiple spatial responses available. In our studies, which used a go/no-go paradigm, the different response options were contrasted across the experiment as a whole, rather than within a block, and so any particular trial involved only one possible spatial response (or lack of response). Said otherwise, the different possible spatial responses in our tasks were not juxtaposed at any particular slice of time in which a response was made. In spite of this, reliable associations between number and space emerged.

The relevant units of analysis, we conclude, are the behavioral contrasts within the temporally- and corporeallyextended cognitive ecology circumscribed by the task.

## Conclusion

In two experiments, we found that number interacts with space even when responses are not distinguished by their location in head- or eye-based spatial frames of reference. Numbers were associated with locations in behavioral space, enacted by the participant within the context of the task. This association between number and behavioral space, however, was task-specific, appearing only when numerical magnitude was directly task-relevant. While space is a ubiquitous and powerful cognitive resource (e.g., Kirsh, 1995; Tversky, 2011), it is neither fixed nor monolithic. The spaces of human activity are multiple, defined relative to varied frames of reference, and we deploy them flexibly during abstract though. As MerleauPonty (1962) argued a half century ago, the space that we inhabit is not pre-given, but constituted by the motility of the body. Our reasoning about abstract concepts is not grounded in some single, static, or stable representation of space, but in the space we enact through embodied activity.

## Acknowledgments

Thanks to Anthony Chan, Sarah Saturday, and Luke Eberle for data collection, and to Rafael Núñez for discussion.

#### Abstract

Technology has become integrated into many facets of our lives. Due to the rapid onset of this integration, many current K-12 teachers do not have the skills required to supply the sudden demand for technical training. This deficit, in turn, has created a demand for professional development programs that allow working teachers to learn computer science so that they might become qualified to teach this increasingly important field. Subgoal labeled worked examples have been found to improve the performance of learners in highly procedural domains. The present study tested subgoal labeled worked examples in an online learning program for teachers. Teachers who received the subgoal labels solved novel problems more accurately than teachers who received the same worked examples without the subgoal labels. These findings have implications for the use of subgoal labels in professional development, other types of lifelong learning, and online learning.

Keywords: subgoal learning; worked examples; computer programming, K-12 teacher training.

## Introduction

As technology becomes ubiquitous, being technically trained is frequently necessary for individuals to be effective in their professional and personal lives. Technology has advanced at such a rapid pace, however, that many of our educators are not qualified to train students in technical fields. Thus, it is important to train teachers, who have full schedules and possibly no technical training, to become qualified to teach technical subjects. Fortunately, because technical subjects tend to be highly procedural, methods used for teaching other highly procedural subjects like mathematics can be used in technical education.

One of the methods that has been effective for teaching procedural domains (e.g., statistics and physics) is to manipulate the format of worked examples that students receive (e.g., Catrambone, 1996). Catrambone (1998) found that worked examples that included subgoal labels were effective for helping students learn to solve problems in a new domain. This intervention has also been found to be effective for teaching computer programming (Margulieux, Guzdial, \& Catrambone, 2012). Most of these subgoal
studies, however, have been conducted with undergraduate students in face-to-face learning environments. These are not the conditions that would be ideal for K-12 teacher professional development. The present study explores the effectiveness of the subgoal intervention for K-12 teachers interested in learning computer science in an online learning environment (i.e., with no face-to-face interaction).

Worked examples are an important instructional tool for learners in highly procedural domains like math or computer programming. Worked examples help learners because they provide specific information about how to apply domain principles to problem solving (Bassok, 1990). Furthermore, worked examples provide a step-by-step solution to a problem from which students can learn before they are able to solve problems independently (Atkinson, Derry, Renkl, \& Wortham, 2000). When learners are presented with all of the steps of an example solution at once, however, they often have difficulty determining what information is important for solving problems in that domain (i.e., structural information) and what information represents details relevant for solving only that problem (Catrambone, 1994).

Using subgoal labels to group steps of worked examples into meaningful units can help learners recognize structural information in the examples. Subgoals are functional components of complex problem solutions; each subgoal is a necessary part of the solution. How a subgoal is achieved might vary between and within problems, but the subgoals needed to complete a problem do not. Subgoals are specific to a domain, but not to a problem; a multitude of problems in a domain might have the same subgoal structure, so by learning the subgoals in a domain, students can learn to solve problems in that domain (Catrambone, 1994).

Learners who study materials that label the subgoals of a worked example are more likely to solve novel problems than learners who study the same examples without the subgoal labels (Catrambone, 1998). There are several possible theoretical explanations for this phenomenon. Subgoal labels can help learners chunk problem-solving steps which might reduce the cognitive load required to learn them (Catrambone, 1994). Furthermore, subgoal labels might help learners create mental models in a domain by
providing them with a framework (i.e., the set of subgoals) that they can use to organize information in a way that can guide transfer to future problems (Atkinson et al., 2000, Catrambone, 1996). Moreover, apprising learners of the structure of worked examples can help them recognize similarities among examples and promote self-explanation (Catrambone, 1998; Renkl \& Atkinson, 2002).

Expanding upon previous work (e.g., Catrambone, 1998), Margulieux et al. (2012) applied subgoal labeled worked examples to a previously untested domain, computer programming. They found that subgoal labels improved participants' performance on novel computer programming construction tasks (i.e., creating applications (apps) for Android devices). The present study expands upon this work by testing the intervention in a new environment and with a new population.

## Present Study

The present study manipulated the materials that K-12 teachers received to help them teach themselves how to program. Participants received either subgoal labeled worked examples or conventional worked examples (i.e., list of the steps of the solution with no labels). The conventional worked examples were adapted from material in the projects sections of the ICE Distance Education Portal (http://ice.cc.gatech.edu/dl/?q=node/641). The subgoals of the examples were determined using the TAPS procedure developed by Catrambone, Gane, Adams, Bujak, Kline, and Eiriksdottir (2013) and consultation with subject-matter experts (see Figure 1). The only difference between the materials that participants in the two conditions received was the added subgoal labels (see Figure 2).

```
Subgoal Labels
    1. Create components
    2. Set properties
    3. Handle events from My Blocks
    4. Set outputs from My Blocks
    5. Define variable from Built-In
    6. Set conditions from Built-In
    7. Emulate app
```

Figure 1. Subgoals Used In Instructional Material
The programming language that was used for the study is Android App Inventor, which is used to develop apps for Android devices. App Inventor is a drag-and-drop programming language; users are given pieces of code that they can drag from a menu and piece together in a programming area to make programs. Drag-and-drop programming languages can be useful for teaching novices because, instead of writing code, users select sections of code and piece them together like puzzle pieces. This type of code creation is easily understood by novices (Hundhausen, Farley, \& Brown, 2009).

## Subgoal labeled Materials

## Handle Events from My Blocks

1. Click on "My Blocks" to see the blocks for components you created.
2. Click on "clap"
3. Drag out a when clap.Touched block

## Set Output from My Blocks

4. Click on "clapSound" and
5. Drag out call clapSound.Play
6. Connect it after when clap.Touched

## Conventional Materials

Click on "clap"
Drag out a when clap.Touched block
Click on "clapSound"
Drag out call clapSound.Play
Connect it after when clap.Touched
Figure 2. Sample Materials from Two Groups
Over four sessions participants learned to make apps using App Inventor. In each session, participants received instruction for how to make one app and assessments asking them to modify or make new parts of an app (see Table 1).

Table 1: Sections of experimental sessions

| Session | $1^{\text {st }}$ section | $2^{\text {nd }}$ section | $3^{\text {rd }}$ section |
| :--- | :--- | :--- | :--- |
| 1 | Introduction | Instruction | Assessment |
| $2,3,4$ | Assessment | Instruction | Assessment |

In the first session, participants learned to make an app that played sounds when the user interacted with objects on the screen. In the second session, participants learned to make an app that selected and displayed text when a button was pressed. In the third session, participants learned to make an app that counted the number of times the user pressed a button in a time frame. In the fourth session, participants learned to make an app similar to the game Pong.

Instructional materials for each app included both a video demonstrating how to make an app and a text guide detailing how to make an app. Palmiter and Elkerton (1993) found that videos demonstrating how to complete tasks using a direct-manipulation interface can quickly and naturally teach users how to use the interface. They also concluded that only watching videos can lead to superficial processing while reading text instructions leads to deeper processing. Given that video demonstrations are a useful aid for learning to complete tasks using an unfamiliar interface and that text instructions lead to better transfer and retention for these tasks (Palmiter \& Elkerton, 1993), both types of instruction were used in the present study. Subgoal labels were presented in the videos as callouts to present the information succinctly without overshadowing any verbal instructions (see Figure 3, arrow added).

Figure 3. Sample of Subgoal Callout in Video
To assess participants' ability to solve problems using App Inventor, participants were asked to write the steps that they would take to program new features of an app. These assessment tasks were developed based on material that participants were exposed to during the sessions, but some assessment tasks required participants to use aspects of App Inventor that they had not used before to measure their ability to transfer their knowledge. Hints were given for tasks that required participants to use these unfamiliar features. The hints guided participants to the correct features but did not tell them how to use that feature (see Figure 4).
> "1.5 Write the steps you would take to make the screen change colors depending on the orientation of the phone; specifically, the screen turns blue when the pitch is greater than 2 (hint: you'll need to make an orientation sensor and use blocks from "Screen 1" in My Blocks)."
> "3.3 Write the steps you would take to create a list of colors and make the ball to change to a random color whenever it collided with something."

Figure 4. Sample of Assessment Tasks
Two types of assessments were given. One type was given at the end of each session and intended to measure participants' ability to solve novel problems, so it included near and far transfer tasks. The other type was given at the beginning of each session starting with the second session and intended to measure participants' retention of problem solving procedures, so it included only near transfer tasks.

Near transfer tasks required participants to follow an identical procedure that they had used in the instructional session but substituted blocks or components of the same type. For example, one task asked participants to program the clap sound to play when the phone was tilted up. To complete this task, participants could follow the same steps that they used in the instructional session to program the drum sound to play when the phone was tilted to the right,
but they had to replace the drum sound with the clap sound and the $x$-axis acceleration sensor with the $y$-axis acceleration sensor.

Far transfer tasks required participants to follow the same general scheme that they had used in the instructional session but substituted blocks or components of a different type. For example, one task asked participants to program an ImageSprite to move 5 pixels to the right when touched. The steps to do this task were different than the steps in the instructional session because the type of block was different, but the subgoals that needed to be completed were the same.

Participants were not permitted to use the video or text guides during the assessment period, but participants were encouraged to use the App Inventor interface to help them complete the assessment tasks. Participants were also allowed to access the apps that they had made during the session to serve as memory cues for the complex procedures they had learned in the session. Participants were instructed to not review instructional material between sessions, so their retention of problem solving procedures could be measured consistently.

## Method

## Participants

Participants were 18 K-12 teachers recruited through mailing lists for teachers interested in computer science education. Teachers with prior experience with Android App Inventor could not participate in the experiment, but they were not restricted by any other prior experience. The teachers had backgrounds that varied on a number of factors such as education, years as a teacher, years teaching computer science, level of computer science taught, and professional development completed. There were no correlations between participant performance and prior experience, so this issue will not be discussed further.

## Procedure

The experiment was conducted online with no face-to-face interaction. Instructions and media for the apps were emailed to participants, and the sessions were hosted on surveymonkey.com. Each SurveyMonkey survey gave participants instructions for completing the instructional session and assessment tasks (first session survey: http://www.surveymonkey.com/s/RVCWTBX, use "test" as participant number). Through the survey, participants were asked to record how long they spent on each instructional session and each assessment task. Participants were also asked how difficult they thought each instructional session and assessment task was on a Likert-type scale from "1Very Difficult" to "7-Very Easy."

The experiment comprised four sessions which were given one week apart. The timestamp on the surveys were checked to ensure participants completed the sessions at least six days apart. The sessions were similar to those in Margulieux et al. (2012) but adapted for online use. The major difference between the Margulieux et al. (2012) and
present administration of sessions is that the moderator instructions were given through text instead of speech. Each session taught participants how to make an app using a video and text guide. The video guide showed participants how to create the app, and the text guide gave step-by-step instructions for creating the app. After participants made the app for that session, they worked on the assessment tasks. Starting with the second session, participants also completed the retention assessment at the beginning of the session before they started making the app (see Table 1).

Completion rates for the sessions decreased during the study with a high level of participation for the demographic survey and low level for the last two sessions. Though the participants volunteered to be in the study, they did not receive any compensation for their time except instruction about App Inventor. Additionally, the assessment tasks were designed to be difficult in order to avoid a restriction of range problem caused by all participants performing well. Many participants commented that they were frustrated with the tasks. The teachers might have lost motivation to complete the sessions without more compensation. Few teachers experienced unforeseeable conflicts that ended their participation. There was not a recognizable pattern that distinguished participants who completed the study from those who did not. Data from only the first two sessions were analyzed due to low completion rates of the last two sessions.

These attrition rates are similar to those seen in other online learning environments such as Massive Open Online Courses (MOOCs). In an analysis of nearly 500,000 courses taken by over 40,000 students, Xu and Jaggars (2013) found that many of the factors that predict success in face-to-face learning environments also predict success in online learning environments (e.g., women were more successful, and students with higher GPAs were more successful). This finding suggests that attrition in online courses is similar to attrition in face-to-face courses but on a larger scale. However, the number of students that online courses can reach is much larger, so the number of students who complete an online course is generally greater than the number of students who complete an equivalent face-to-face course (Whiteman, 2013).

## Results and Discussion

Each solution of the assessment tasks was deconstructed into the components necessary to complete the solution; that is, the subgoals of the solution. As discussed earlier, the subgoals are inherent in the solutions, but the tasks did not provide any information about which subgoals were necessary to complete the solution. Because the solutions for the assessment tasks are complex, scoring the pieces of each solution instead of scoring the entire solution as correct or incorrect allowed for more sensitivity in the measurement.

Problem-solving performance is represented by two scores: a "correct" score and an "attempted" score.

Participants were given a point for each subgoal that they completed correctly and each subgoal that they attempted. Attempting a subgoal was operationally defined as listing at least one of the steps required to complete the subgoal, listing an incorrect step that would achieve a similar function, or describing the purpose of the subgoal in some way. Participant responses were scored by multiple raters, and interrater reliability was high with a one-way random model intraclass correlation coefficient of agreement (ICC(A)) of .87. There were 32 subgoals across the assessment task solutions, so participants could get a maximum score of 32 for both the attempted and correct problem-solving measurements.

## Correct Subgoals

Participants in the subgoal group ( $n=9$ ) completed $81 \%$ more subgoals correctly ( $M=26.6, S D=5.08$ ) than the conventional group ( $n=9, M=14.7, S D=6.63$ ), $F(1,16)=$ 18.23, $M S E=34.89, p=.001, \omega^{2}=.53, f=1.01$. These results mean that $53 \%$ of the variance for correct subgoals was accounted for by group. Furthermore, this is a very large effect size considering the amount of instruction that participants received (i.e., two, 30-45 minute instructional sessions). These findings suggest that the subgoal labeled worked examples, compared to conventional worked examples, can help people learn more efficiently to solve programming problems.

The difference between groups in this experiment is about twice as large as the difference between groups in Margulieux et al. (2012), $f=1.01$ vs. $f=.53$, respectively, even though the present study was conducted in a less controlled environment and its participants had more varied backgrounds. Participants in the present study also had as much time as they wanted to work on the assessments instead of being limited like in Margulieux et al. (2012).

One explanation for this larger effect could be that participants in this study were teachers who volunteered because they wanted to learn the material to further their career while participants in the Margulieux et al. (2012) studies were undergraduates who were less likely to be motivated to learn the material. Therefore, this difference could mean that the subgoal intervention is more effective for learners who are motivated to learn the material for the long-term than it is for lab participants who might only try to learn the material for the duration of the experiment.

Another possible explanation is that the participants in Margulieux et al. (2012) were students whose skills for learning new material were sharper than those of teachers who might have been out of school for decades. The difference between groups for the undergraduate sample might be smaller than for teachers because the students had better strategies for studying conventional worked examples than the teachers. Therefore, undergraduates who received the conventional worked examples would have performed better than teachers who received the conventional worked examples, thereby creating a smaller difference between groups in Margulieux et al. (2012) than the present study.

For both near and far transfer tasks, the subgoal group completed more subgoals successfully (Near: $M=10.6, S D$ = 1.94; Far: $M=7.1, S D=2.26$ ) than the conventional group (Near: $M=5.2, S D=3.70$; Far: $M=3.3, S D=2.35$ ), Near: $F(1,16)=14.65, M S E=8.74, p=.001, \omega^{2}=.48, f=$ .90, Far: $F(1,16)=12.11, M S E=5.31, p=.003, \omega^{2}=.43, f$ $=.82$. These results suggest that subgoal labels help performance on both near and far transfer tasks. Given the nature of the near and far transfer tasks, these findings could mean that the subgoal labels helped participants learn the material better (near transfer) and apply the material to novel problems (far transfer).

On the first end-of-session assessment tasks, participants in the subgoal group completed $223 \%$ more subgoals correctly ( $M=9.7, S D=1.41$ ) than the conventional group ( $M=3.0, S D=3.02$ ), $F(1,16)=27.04, M S E=5.56, p<$ $.001, \omega^{2}=.63, f=1.23$. These results mean that $63 \%$ of the variance for correct subgoals was accounted for by group. On the second end-of-session assessment tasks, participants in the subgoal group completed $70 \%$ more subgoals correctly ( $M=8.0, S D=2.83$ ) than the conventional group $(M=4.7, S D=3.57), F(1,16)=4.82, M S E=10.38, p=$ $.043, \omega^{2}=.23, f=.50$. These results mean that $23 \%$ of the variance for correct subgoals was accounted for by group.

The two series of assessments suggest the subgoal group was better at solving novel problems than the conventional group. Because the effect size of the second assessment was smaller than that of the first assessment $(f=.50$ vs. $f=1.23$, respectively), the difference between groups might decrease with repeated exposure to the same type of material. This decrease would be expected because as learners gain more knowledge, they are better able to identify important information and need less external guidance. This finding suggests that the subgoal labels are fulfilling the purpose for which they are intended: to highlight the information on which learners should focus so they can learn more effectively. Over time, both groups might achieve the same problem solving ability, but the learners who receive subgoal labels would reach a higher level faster than those who do not. This finding does not mean that subgoals are not valuable later, but it suggests that they are most effective when learners are first introduced to new material.

On the start-of-session assessment tasks (i.e., to measure retention of problem solving procedures), participants in the subgoal group completed $48 \%$ more subgoals correctly ( $M=$ 9.0, $S D=1.70$ ) than the conventional group ( $M=6.1, S D=$ 3.22), $F(1,16)=6.17, M S E=6.41, p=.024, \omega^{2}=.27, f=$ .57. These results mean that $27 \%$ of the variance for correct subgoals was accounted for by group. All of the tasks in this series were near transfer tasks, so to complete the tasks participants had to use procedures that they had learned in the previous session. This result suggests that the subgoal intervention promotes retention of the procedures.

## Attempted Subgoals

Participants in the subgoal group attempted $25 \%$ more subgoals ( $M=28.6, S D=3.50$ ) than the conventional group
( $M=22.8, S D=7.19$ ), $F(1,16)=4.70, M S E=31.70, p=$ $.046, \omega^{2}=.23, f=.51$. By attempting a subgoal, participants could be demonstrating that they know the solution needs a particular component. Therefore, this finding could mean that subgoal participants recognized more of the necessary components of the solutions than the conventional participants regardless of whether they were able to correctly complete the task.

## Time on Task and Difficulty

There were no statistically reliable differences between the groups on the time and difficulty measures (viz., time spent on instructional periods, difficulty rating of instructional periods, time spent on assessment periods, and difficulty rating of assessment periods; see Table 2). These results suggest that participants in the subgoal group performed better than the conventional group without taking longer to complete the instructions or tasks and without finding the instructions or tasks more difficult.

Table 2: Difference between groups for time and difficulty measures; time in minutes, difficulty on 7-pt. scale (1-Very Difficult and 7-Very Easy)

| Category | $M$ <br> subgoal | $M$ <br> conv | $\overline{S D}$ | $F$ | $p$ |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Time on <br> Instruction | 77.3 | 87.8 | 37.8 | .37 | .55 |
| Difficulty of <br> Instruction | 4.9 | 4.5 | 1.0 | .23 | .64 |
| Time on | 76.6 | 56.7 | 33.1 | 1.44 | .25 |
| Assessments <br> Difficulty of <br> Assessments | 4.3 | 3.8 | 1.1 | .66 | .43 |

This conclusion is supported by linear regression models. Group ( $\beta=.58, p=.005$ ) and time ( $\beta=.41 p=.031$ ) are both significant predictors of correct subgoal score suggesting that they account for different parts of the variance. When predicting attempted subgoal scores, group is no longer a significant predictor, and time ( $\beta=.54 p=$ .032) becomes the sole predictor. This model accounts for participants who spent relatively little time on the assessment tasks and did not write solutions (i.e., who did not attempt to solve the task). Furthermore, group ( $\beta=.62$, $p=.002$ ) and difficulty rating ( $\beta=.42 p=.024$ ) are both significant predictors of correct subgoal score suggesting that they also account for different parts of the variance in scores. When predicting attempted subgoal scores, however, group is no longer a significant predictor, and difficulty rating ( $\beta=.63 p=.009$ ) becomes the sole predictor. This model accounts for participants who did not attempt to solve the problems and rated the difficulty of the tasks as high. Due to a high correlation between time on task and difficulty rating ( $r=.60, p=.015$ ), these two predictors were analyzed in different models to avoid multicollinearity.

## Conclusion

Subgoal labeled worked examples have been effective for teaching students to solve problems in procedural domains such as statistics (Catrambone, 1998) and computer programming (Margulieux et al., 2012). Most of these studies have taken place in a laboratory with undergraduates. The present study extends prior work with results that suggest subgoal labeled worked examples are effective for K-12 teachers learning App Inventor in an online learning environment. These findings demonstrate that subgoal labels can be effective in a learning environment outside of the laboratory with a different population of learners.

It is encouraging that the subgoal intervention improved online learners' performance. The purpose of labeling subgoals in worked examples is to succinctly give the learner extra information to help them recognize the structure of the example. This type of extra information is what an instructor, who is an expert in the subject matter, might ideally provide to students in face-to-face instruction. Unfortunately, instructors are not always aware that they should provide this extra information, and even if they are aware, they do not necessarily know how to impart the information. In an online learning environment in which students rarely interact with an instructor, such as the one in this experiment, this extra information needs to be built into the instructions. Extra information could increase learning time. However, the present study demonstrates that, in the absence of an instructor, subgoal labeled worked examples provide enough extra information to help students learn more effectively without increasing the amount of time students take to learn.

The results of the experiments also imply that the subgoal intervention can be effective for populations other that undergraduates. The sample in the present experiment was heterogeneous in terms of age, education, and experience, so the amount of variance in the participants' performance scores that was accounted for by experimental group (over $50 \%$ in some cases) was surprisingly large. This finding can justify the use of resources to implement subgoal interventions in professional development, classrooms, and other instructional environments, including those online.

The present study demonstrates that subgoal labeled worked examples can be an effective intervention for teaching highly procedural domains outside of the laboratory. Additional experiments can examine the intervention in a variety of learning environments.

## Acknowledgments

Our thanks to Georgia Tech's GVU Center and IPaT for the grant that made this research possible. We also thank Barbara Ericson for her consultation and Andrea Crews for help scoring data.

#### Abstract

We explored people's reactions to expert categorizers who expressed difficulty in making a categorization decision. Specifically, we compared people's impressions of expert health professionals who either expressed certainty, uncertainty, or ambivalence about a categorization decision in the form of a diagnosis. We found that ambivalence resulted in the most negative impressions of these experts, including lower ratings of competence and decisiveness (Experiment 1). Impressions of ambivalence did not improve when the complexity of the decision was explicitly manipulated (Experiment 2). Implications for categorization are discussed.

Keywords: expert; categorization; decision-making; ambivalence.

## Introduction

People view the world as existing in clear, definable categories (Gelman, 2003). For example, when attempting to identify a bird sitting in our yard, we take as granted that there are clear delineations between different species of birds and that with enough knowledge a given bird can be neatly categorized into its appropriate category (Diesendruck \& Gelman, 1999; Estes, 2003). Believing the natural world is organized and divided in this way suggests that there are right answers to categorizing things that are accessible given enough knowledge. The people we turn to that possess this knowledge we call experts. Laypeople perceive that for different domains in the world, experts exist and possess knowledge specific to that domain (Wilson \& Keil, 1998). People defer to these experts when information or a decision is needed (Braisby, 2001, 2003; Danovitch \& Keil, 2004; Danovitch \& Keil, 2007; VanderBorght \& Jaswal, 2009). This deference has been described as a division of cognitive labor that allows a given person to be able to interact with elements of the world she does not understand because of the belief that there are experts that exist that do understand those elements (for a discussion see Wilson \& Keil, 1998).

Experts play an obviously important role in allowing people to survive in the modern world. Given the importance of experts, what happens when an expert expresses difficulty in making a categorization decision? For example, imagine a mechanic who can not decide if a car is malfunctioning because of a transmission problem or because of an exhaust problem, or a bird authority who cannot decide which of two species is the correct
categorization for a bird, or a doctor who is torn between two possible diagnoses for a patient. In short, how do we react to these experts who we have turned to for help when they express difficulty in making a categorization decision? Furthermore, are there differences in our reactions, depending on the type of difficulty experts are expressing? We delineate three different possible states a person making a categorization decision could experience: knowing the correct answer (certainty), not being clear at all as to what the correct answer is (uncertainty), and having narrowed the correct answer down but feeling tension and conflict as to which answer is the correct choice (ambivalence). In our study, we are specifically interested in this state of ambivalence. In the following we describe how people may react to ambivalent experts and then contrast this with possible reactions to uncertain experts.

How do we react to an expert who expresses being ambivalent about a categorization decision in her domain of expertise? One possibility is that ambivalence in experts is not perceived as problematic, but instead as a sign of effective decision-making. Seeing an expert express being torn over the correct categorization may verify our initial deference; this is a complex decision that is beyond our ability. Furthermore, expressions of ambivalence are often taken as a positive sign of more deliberative, and flexible thinking (Rothman, 2011). In addition, experiencing ambivalence is related to more creative (Fong, 2006) and more accurate (Rees, Rothman, Lehavy, \& Sanchez Burks, 2013) final decision-making. As such, an expert categorizer who is torn between placing something in one of two categories may be seen as a creative, deep thinker and valued for her expertise.

We believe it is much more likely that people react negatively to ambivalent experts. People largely act as if categories in the world exist with clear, delineable boundaries. That is, something is not partially a bird, or part of the bird and cat category. This belief in clear categorical boundaries has been linked to essentialism, or belief that a category has a causal essence that underlies the category, creates the features of that category, and must be possessed to be a member of that category (Gelman, 2003). Previous work has claimed that it is exactly this belief that categories possess essences that allows us to be willing to defer to experts in making a categorization decision; people are believed to defer to experts because they believe experts have the correct knowledge to recognize and identify the
causal essences that underlie category membership (Braisby, 2001; 2003). Now imagine this expert who is supposed to be able to recognize the essence underlying categorization being torn as to which of two categories something belongs. Because of the implications of essentialism, category membership should be all-or-none, with the item to be categorized only being in one of the two possible categories. ${ }^{1}$ Also, if anyone should be able to identify that causal essence, it should be this expert. In this way, an expert expressing ambivalence may elicit negative reactions because ambivalence does not mesh well with our beliefs about essences and the ability of experts to identify those essences. For these reasons, we predict that experts expressing ambivalence in making a categorization decision should be viewed negatively.

An interesting alternative to ambivalence in categorization decision-making is uncertainty. Previous literature on decision-making has distinguished uncertainty and ambivalence as two separate emotional and decisional states. Uncertainty is a state of not knowing the correct answer to a problem, whereas ambivalence reflects a state of being torn between two possible alternatives (Rothman, 2011). Said another way, a decision maker may be uncertain because not enough information is known to make a decision or because the person does not have enough expertise to know the correct answer. However, a decision maker who is ambivalent appears to have all of the information needed to make a decision but is torn between two possibilities. In our paradigm using expert decision makers, we predict that an uncertain expert may look like someone who just needs more information before a decision is possible. However, an ambivalent expert will seem to have all or at least more of the needed information since she is actively considering two possibilities. This should result in the ambivalent expert looking relatively more unable to make correct decisions. If this holds, we would expect that ambivalent experts could be viewed more negatively than uncertain experts.

In the following two experiments, we investigate how people view expert categorizers making a categorization decision. To ensure participants' familiarity with the type of expert categorizer and the decision domain, we presented participants with descriptions of a health professional making a difficult diagnostic decision. Interacting with this type of expert categorizer should be easy for participants to think about. We described the professional as deciding between two possible diagnoses and displaying one of three levels of categorization certainty: certain of the correct diagnosis, completely uncertain as to which of two

[^147]diagnoses is correct, or torn and conflicted as to which of two diagnoses was correct. We then measured participants' impressions of these expert categorizers.

## Experiment 1

In Experiment 1, we manipulated the levels of categorization certainty of an expert decision-maker and then measured people's perceptions of the quality of that decision-maker. If ambivalence is inherently unsettling for the reasons discussed above, participants should view ambivalent experts as lower quality and more indecisive than certain or even uncertain experts. However, if ambivalence is taken as a sign of the expert being thoughtful, then perceptions of these experts should be more favorable.

## Methods

Participants Sixty participants recruited through Amazon's Mechanical Turk participated for payment. Participation was restricted to Mechanical Turk workers in the United States.

Materials and Procedure Participants read a description of a hypothetical patient who was seeking advice from a health care professional for an ongoing health problem. Participants read that the patient was given a series of tests, the results of which suggested two potential diagnoses, labeled A and B . Participants were randomly assigned to read one of three statements that described the health professional as being certain the patient had diagnosis A and not B (Certain condition; $n=20$ ), uncertain as to whether diagnosis A or B was correct (Uncertain condition; $n=18$ ), or torn as to whether diagnosis A or B was correct (Ambivalent condition; $n=22$ ). We used the torn descriptor for the ambivalent condition because it conveys how the subjective state of ambivalence is likely to be expressed (see Rothman, 2011 for a more detailed discussion of this point). Participants were randomly assigned either to read that the person was seeking help from a physician and the diagnosis was one of two infections ( $n=27$ ) or was seeking help from a mental health clinician and the diagnosis was one of two mood disorders $(n=33)$. After reading the health interaction description, participants completed a series of different ratings that asked them to rate the provider on different dimensions or rate how a patient would react to the provider. We were specifically interested in three issues: how indecisive and how competent the provider from the previous exchange was seen to be, as well as how positively or negatively participants reacted to the provider. Indecisiveness was measured by asking participants to rate to what extent the physician possessed a series of personality traits, in which were embedded the following 8 traits related to indecision: Confused, Unsure, Uncertain, Indecisive, Hesitant, Not Definite, Faltering, and Wavering. Mean ratings across these 8 measures were used as a measure of indecisiveness. To measure competence, we asked participants to rate their agreement with a series of
statements assessing how likely they thought the physician would be to engage in a series of behaviors related to being well informed (mean of three statements: attend professional conferences, be aware of current research, be asked for an opinion by other professionals) and be seen as a quality practitioner (mean of three statements: be a high quality expert, make accurate diagnoses, create accurate treatment plans). We also measured participants' predictions of how a patient would react to the given expert through ratings of how likely the patient would be to recommend that others defer to this expert (mean of three statements: refer a friend to the health care professional, provide a strongly positive rating on a referral website, take his/her children to see this health care professional) and how likely the expert would be to be sued by a patient (assessed through a single question). These ratings were intermixed with other ratings of the professional that were unrelated to the measures we discuss here. All ratings were made on seven-point agreement scales with the exact anchor points of the scales varying by task (e.g., Not at all likely to Extremely likely).

Participants also made ratings related to behaviors of the patient, but we do not present those results here and these measures are not discussed further. The order of rating tasks was randomized for each participant.

## Results

There were no significant differences between the mental and medical health professionals on any of our measures, $p \mathrm{~s}$ $>.12$. As such, we collapsed across that manipulation. For all of the following analyses, we conducted one-way ANOVAs with categorization certainty (Ambivalent, Certain, Uncertain) as a between-subjects variable.

Decision Indecisiveness We first assessed perceptions of the expert's indecisiveness. We compared the mean ratings for participants in the ambivalent condition to ratings in the certain and uncertain conditions. Participants' perceptions of the expert's indecision differed significantly by condition, $F(2,57)=14.43, p<.001$. Planned contrasts demonstrated that the Ambivalent physician was judged as significantly more indecisive $(M=4.45, \mathrm{SD}=1.31)$ than the Certain physician $(M=2.47, \mathrm{SD}=0.94 ; t(57)=5.36, p<.001)$. Interestingly, the Ambivalent expert was also perceived as significantly more indecisive than the Uncertain physician ( $M=3.62$, $\mathrm{SD}=1.30 ; t(57)=2.19, p=.033)$. Not surprisingly, the Uncertain physician was perceived as more indecisive than the Certain physician, $t(57)=2.95, p=.004$.

Expert Competence Participants' perceptions of the expert's level of being informed differed significantly by condition, $F(2,57)=6.19, p=.004$. Planned contrasts demonstrated that the Uncertain and Certain experts were seen as equally informed, $p=.43$. However, the Ambivalent expert was judged as significantly less well informed ( $M=$ 4.14, $\mathrm{SD}=1.29$ ) than the Certain expert $(M=5.33, \mathrm{SD}=$ $0.97 ; t(57)=3.37, p=.001)$, or Uncertain expert $(M=5.04$, $\mathrm{SD}=1.15 ; t(57)=2.46, p=.017)$.

Similar results obtained with perceptions of the expert's quality. Expert's perceived quality differed significantly by condition, $F(2,57)=5.39, p=.007$. Planned contrasts found that Uncertain and Certain experts were seen as equal in quality, $p=.37$. As predicted, the Ambivalent expert was judged as significantly lower quality $(M=3.89, \mathrm{SD}=1.24)$ than the Certain physician ( $M=4.77, \mathrm{SD}=1.34 ; t(57)=$ $2.29, p=.026)$ or the Uncertain physician $(M=5.13, \mathrm{SD}=$ $1.10 ; t(57)=3.15, p=.003)$.

Reactions to the Expert Participants' perceptions of whether the patient would refer the expert differed significantly by condition, $F(2,57)=12.17, p<.001$. Planned contrasts demonstrated that the Ambivalent expert was judged as significantly less likely to be referred ( $M=$ 2.73, $\mathrm{SD}=1.11$ ) than the Certain expert $(M=4.47, \mathrm{SD}=$ 1.32; $t(57)=4.74, p<.001)$. The Ambivalent expert was also perceived less likely to be referred than the Uncertain expert $(M=4.02, \mathrm{SD}=1.13 ; t(57)=3.42, p=.001)$. Predicted referrals did not differ for the Uncertain and Certain experts, $p=.25$.

Participants' ratings of the likelihood the expert would be sued differed significantly by condition, $F(2,57)=7.54, p=$ .001. Planned contrasts demonstrated that the Ambivalent expert was judged as significantly more likely to be sued ( $M$ $=4.86, \mathrm{SD}=1.52)$ than the Certain expert $(M=3.15, \mathrm{SD}=$ $1.46 ; t(57)=3.77, p<.001)$. The Ambivalent expert was judged as more likely to be sued than the Uncertain expert ( $M=3.67, \mathrm{SD}=1.41 ; t(57)=2.56, p=.013)$. Likelihood to be sued did not differ for Certain and Uncertain experts, $p=$ . 28 .

## Discussion

Our results show that ambivalent experts are perceived uniformly more negatively than certain and uncertain experts. If this negative impression was just in reaction to the expert being anything but completely certain in his/her decision making, then we would expect to see uncertain experts being viewed more in line with ambivalent experts. Our findings instead support that uncertainty does not produce the same negative reactions as ambivalence. In fact uncertain experts were viewed as positively as certain experts, except for not surprisingly being viewed as more indecisive. One explanation for this finding is that uncertainty is interpreted as a case in which more information is simply needed before a decision can be made, rather than a sign of ineptitude. Conversely, ambivalence may be interpreted as a case in which all of the information is available, but the expert is simply inept. It is a question for future research as to whether these interpretations are what are driving our demonstrated results.

Given previous research on the benefits of ambivalence to the decision-making process (e.g., Fong, 2006; Rees et al., 2013), it may seem surprising that ambivalence is viewed so negatively. As we discussed earlier, laypeople may assume that categories exist and can be identified as long as the person has enough expertise. As such, experts should be
able to do this task easily. However, when experts express ambivalence (even more so than uncertainty), it appears from our results that such an expression conveys the expert's inability to make a decision. It seems possible, however, that such negative responses to ambivalent experts may be alleviated when the decision is described as complex. That is, because ambivalence is a typical reaction to complexity (e.g., Larsen, McGraw, \& Cacioppo, 2001; Tiedens \& Fong, 2002), expressed ambivalence may be more palatable to observers when observers are told that the decision/diagnosis is complex rather than simple. This may obtain because complexity provides a causal explanation for any ambivalence that is experienced (i.e., this is a complex case and it therefore makes sense it is hard to distinguish between two alternatives). This explanation may in turn make the decision-maker seem more justified for expressing the state of ambivalence (see Ahn, Novick, \& Kim, 2003). The same may hold true for expressions of uncertainty. However, this complexity could actually negatively influence impressions of certain experts because it may be difficult to understand how an expert is so certain even when the problem is complex. To investigate this possibility, we manipulated the stated complexity of the decision task in Experiment 2.

In Experiment 1 we ended the description of the health care interaction before a final diagnosis was provided. We did this because we were interested in how the expression of ambivalence is interpreted as it is first encountered, regardless of what decision the expert finally comes to. However, an alternative explanation for our results is that the certain provider was viewed more favorably than the ambivalent provider because the certain provider was perceived to have actually suggested a diagnosis whereas the ambivalent provider had not. ${ }^{2}$ In Experiment 2 we accounted for this issue by adding - across all conditions -the delivery of an actual diagnostic decision at the end of the health care interaction. It is possible that providing a diagnosis may make all decision states seem equally unproblematic; people may not care how an expert decisionmaker arrives at a decision once the decision is final. If this is true, perceptions of ambivalent experts may be equated to certain and uncertain experts. However, if people are focused on the process by which the decision maker arrives at a decision, then providing an actual diagnosis may not matter for the effects of certainty.

## Experiment 2

Experiment 2 expands from the basic design of Experiment 1 by equating all conditions on the delivery of a final diagnosis. We used the same manipulations as in Experiment 1 but added that all providers came to the same final diagnosis at the end of the interaction. We also manipulated the described complexity of the decision in Experiment 2, such that we would be able to assess if

[^148]describing a categorization decision as complex changes how ambivalence is perceived. As such, in the following analyses we will compare the effects of complexity within each certainty manipulation to see if it differentially influences impressions of each expressed decision state.

## Methods

Participants Ninety-two United States based participants recruited from Amazon's Mechanical Turk participated for payment.

Materials and Procedure The same basic materials and procedure was used as in Experiment 1 with the following exceptions. Because no differences were found between medical and mental health experts in Experiment 1, we used only medical experts. In addition, we manipulated the complexity of the decision: half of the participants received information that the diagnostic decision was complex in nature (Complex condition; $n=47$ ). The remaining participants did not receive this additional information (Control condition). Finally, all participants read that the physician made a decision of one diagnosis at the end.

After reading the description, participants went on to make the same ratings as in Experiment 1 related to their perceptions of the health care provider and the patient's follow up behaviors. To measure participants' conceptions of how long people spend in different certainty states during decision-making, we asked the following: "Think about the amount of time between learning about a problem and announcing a decision related to that problem. What percent of the time do people typically experience the following states in that time period?". Participants made ratings for three states: certain, uncertain, and torn and conflicted. For each state, participants dragged a slider bar to indicate the percentage time spent in that state, with percentages for all three states adding to 100 . Participants made these ratings once with the above prompt and then again while thinking of a complex decision. Finally, participants completed a series of post-test measures that asked them to indicate if they were a health care professional, how difficult they believed medical issue diagnosis to be, the level of expertise required to practice for several different types of medical professionals, an assessment of their desire to have final decisions (i.e., the Need for Closure scale), and their political leanings. For space purposes, we do not report the findings of the time spent deciding measure or the post-test measures.

## Results and Discussion

For the following analyses, we conducted 3 (Categorization Certainty: Ambivalent, Certain, Uncertain) x 2 (Complexity: complex vs. control) between-subjects ANOVAS with simple effects analyses within each certainty level comparing the complexity conditions. Bonferroni corrections were used in all of these analyses. In all ANOVAs, there was a significant main effect of Categorization Certainty, suggesting that adding the actual
diagnosis did not equate impressions of experts across the certainty manipulation. Importantly, in all ANOVAs we found a significant interaction between Categorization Certainty and Complexity. For simplicity sake, we focus on these interactions and present only the follow up simple effects analyses. Figure 1 depicts these analyses.

We first analyzed whether describing a decision process as complex altered perceptions of experts expressing uncertainty. Impressions of Uncertain experts were more positive when the decision was described as complex relative to the control condition: They were seen as marginally less indecisive $\left(M=4.07_{\text {control }}, \mathrm{SD}=1.54 \mathrm{vs} . M\right.$ $=3.33, \mathrm{SD}=1.10 ; p=.098)$, more informed $\left(M=3.31_{\text {control }}\right.$, $\mathrm{SD}=1.05$ vs. $M=4.73, \mathrm{SD}=1.50 ; p=.002$ ), and higher

Figure 1: Mean ratings across certainty conditions. * indicates $p<.05, * *$ indicates $p<.01, * * *$ indicates $p<.001, \dagger$ indicates $.05<p<.1$. Error bars represent standard error.
quality $\left(M=2.16_{\text {control }}, \mathrm{SD}=0.94\right.$ vs. $M=4.20, \mathrm{SD}=1.45 ; p$ $<.001$ ). Predicted patient reactions to Uncertain experts were more positive in the complex condition in that patients were seen as more likely to refer them to friends ( $M=$ $2.67_{\text {control, }} \mathrm{SD}=1.35$ vs. $M=4.16, \mathrm{SD}=1.23 ; p=.002$ ) and less likely to sue $\left(M=5.67_{\text {control }}, \mathrm{SD}=1.35\right.$ vs. $M=4.13$, $\mathrm{SD}=1.89 ; p=.008$ ).

This effect of complexity was reversed in Certain experts. Certain experts were seen in the Complex condition as more indecisive $\left(M=2.28_{\text {control }}\right.$, $\mathrm{SD}=0.99$ vs. $M=3.19$, $\mathrm{SD}=$ $1.35 ; p=.042$ ), marginally less informed ( $M=5.53_{\text {control }}$, SD $=0.96$ vs. $M=4.80, \mathrm{SD}=1.02 ; p=.095$ ), and marginally lower quality $\left(M=5.13_{\text {control }}, \mathrm{SD}=0.098\right.$ vs. $M=4.31$, SD $=0.96 ; p=.058$ ). Predicted patient reactions to Certain experts were less positive in the complex condition in that patients were seen as less likely to refer the expert to friends ( $M=4.93_{\text {control }}, \mathrm{SD}=1.18$ vs. $M=3.89, \mathrm{SD}=1.15 ; p=$ .028 ), and more likely to sue ( $M=3.27_{\text {control }}, \mathrm{SD}=1.33 \mathrm{vs}$. $M=4.53, \mathrm{SD}=1.77 ; p=.028$ ).

Interestingly, complexity of decisions did not alter impressions of Ambivalent experts, with no significant differences obtaining when the diagnosis was described as complex versus not. Ambivalent experts were seen as just as indecisive $\left(M=3.87_{\text {control }}, \mathrm{SD}=1.25\right.$ vs. $M=4.42, \mathrm{SD}=$ $1.00 ; p=.20)$, just as informed ( $M=4.16_{\text {control }}, \mathrm{SD}=1.36$ vs. $M=4.43, \mathrm{SD}=1.15 ; p=.51$ ), and of equal quality $(M=$ $3.27_{\text {control }}, \mathrm{SD}=1.44$ vs. $M=3.57, \mathrm{SD}=1.15 ; p=.46$ ). Predicted patient reactions did not differ across levels of complexity for likelihood to refer the expert ( $M=4.04_{\text {control }}$, $\mathrm{SD}=1.37$ vs. $M=3.57, \mathrm{SD}=1.35 ; p=.29$ ) or likelihood to sue $\left(M=4.80_{\text {control }}, \mathrm{SD}=1.66\right.$ vs. $M=5.29, \mathrm{SD}=1.16 ; p=$ .36).

## General Discussion

Relying on experts to aid in specialized decisions is a core feature of modern human reasoning. As such, it is vitally important to understand how people think about experts and their decision-making process. We have presented one of the first explorations of impressions of ambivalent experts by investigating how people perceive ambivalent versus certain and uncertain experts within the health domain. In two experiments, we present converging evidence that expressed ambivalence is particularly costly for experts (Experiment 1) and this cost holds regardless of the complexity of the task and the determination of a final categorization decision (Experiment 2). These results suggest that when an expert expresses ambivalence about a categorization decision in his or her area of expertise, observers react negatively to this expert regardless of the complexity of the task and whether a decision is eventually made.

Why do people react so negatively to ambivalence in experts? Thinking about our specific examples, the health care experts in our experiments were ambivalent as to how to classify patients into one of two categories. As discussed earlier, the idea that an expert may have difficulty categorizing something in their area of expertise may go
against our fundamental assumptions of how categories function in the world. If an expert expresses ambivalence in categorizing something within their domain, this may challenge the belief that categories are clearly defined and can be recognized with enough knowledge. In this sense, people may feel uncomfortable with ambivalent experts because they undermine assumptions about the nature of categories in the world that fall from essentialism.

If the negative reaction to ambivalent experts stems from implications of essentialism, then this would imply that ambivalent experts should be more acceptable for categories where essences are not inferred. Medical and mental health categories are seen as possessing causal essences that define the features of the category and are necessarily possessed by members of the category (Ahn, Flanagan, Marsh, \& Sanislow, 2006; Cooper \& Marsh, in preparation). If we use a domain that was inherently less essentialized, or not essentialized at all (e.g., artifacts, nominal kinds) we may see a shift in perceptions of experts' decision-making process. For example, if we interacted with an expert who could not categorize a man-made object, we may be more accepting of this expert's ambivalence precisely because there is not a defining causal feature by which to organize the object.

A tension has formed: ambivalence improves decisionmaking (Rees et al., 2013) but is perceived negatively by laypeople when expressed by an expert. This sets up the possible recommendation of telling experts to balance different ideas and be open to feeling ambivalent during decision-making, but under no circumstances express this ambivalence to others. This clearly seems like a less than ideal recommendation given that many experts are expressly charged with communicating their decision-making process to laypeople (e.g., the shared-decision making model of medicine). Further research is needed to understand how experts can convey ambivalence and not upset the laypeople they are tasked to help, as well as to understand for whom (e.g., what types of patients) ambivalence may be more or less palatable.

# Is it Really that Simple? The Complexity of Object Descriptions in Human-Computer Interaction 

Vivien Mast (viv@tzi.de)<br>SFB/TR8 Spatial Cognition, I5-[DiaSpace]<br>University of Bremen<br>Evelyn Bergmann (ebergman@uni-bremen.de)<br>SFB/TR8 Spatial Cognition, I6-[NavTalk]<br>University of Bremen

#### Abstract

In the literature on verbal human-computer interaction there is general consent that humans' preconceptualisations of the machine's capabilities lead to conceptual and syntactic simplifications of the language used. We present a Wizard of $\mathrm{Oz} /$ Confederate study where humans communicate with either a system or an expert in a localization task in a complex building, in a setting which encourages them to give as much information as possible. We analyzed the syntactic complexity of object descriptions. Although we did find differences concerning the complexity of object descriptions on the clausal level, there were no significant structural differences on the subclausal level.

Keywords: human-computer interaction; syntactic variation; complexity; dialogue systems; Wizard of Oz; object descriptions

## Introduction

Imagine you were lost in a building, but a dialogue system offered help if only it could locate you by a description of your surroundings. What kinds of information would you believe to be comprehensible to the system? And how would you shape your language in order to be understood?

According to prior research, humans communicating with artificial agents tend to use language that is both conceptually and syntactically simpler than when talking to other humans (Amalberti, Carbonell, \& Falzon, 1993; Tenbrink, 2005; Moratz, Fischer, \& Tenbrink, 2001). On the other hand, we know that humans adapt to the needs of their communication partners (Clark \& Wilkes-Gibbs, 1986; Clark \& Bangerter, 2004). In interaction with artificial agents, humans often do not know what level of knowledge and competence to expect from their interlocutor, and their expectations are influenced by different sources, such as preconceptualizations, domain, robot appearance, dialogue situation, and the course of the dialogue itself (Fischer, 2011).

When designing a system for user localization in complex buildings, it is central to determine what kinds of utterances should be expected, and whether findings from human-human interaction (HHI) research serve as a good basis for system design. In this paper, we will present a comparative study of human-computer interaction (HCI) vs. HHI in a user localization scenario designed to encourage the assumption of high cognitive and linguistic system capacities. Our analysis focuses on the number and syntactic complexity of object descriptions, as they are a central part of localization dialogues.

Based on the literature we expected participants' language to be more complex when talking to the expert than when talking to the system. Finally, we will discuss the consequences of our findings for research in human-computer interaction and system design.

## Human-Computer Interaction

Amalberti et al. (1993) summarize early Wizard of $O z$ research which found that in HCI participants tend to use fewer dialogue control acts, less structured dialogue, more "standard" forms, and simpler linguistic structures than in HHI. Linguistic simplifications include fewer referring expressions, less variation of syntactic structures, shorter verbal complements and a smaller vocabulary. For example, in a study comparing typed conversations, Kennedy, Wilkes, Elder, and Murray (1988) found that participants in HCI relied on a reduced lexicon, minimized usage of pronominal anaphor, and used shorter utterances, as compared to HHI.

A number of studies also report conceptual simplifications in HCI : when giving route instructions to a system in a mapbased task, speakers mainly rely on turn-by-turn instructions, as opposed to the more complex goal-oriented descriptions usually used by humans (Tenbrink, Ross, Thomas, Dethlefs, \& Andonova, 2010). In an experiment by Moratz et al. (2001), when instructing a robot to interact with objects, users tend to use fine-grained, path-based instructions, micromanaging the robot's movements; unlike known findings in HHI, they also consistenly use the robot's perspective.

## Influences on Expectations and Behaviour

The studies mentioned here seem to give a clear picture, indicating that humans use conceptually and linguistically simpler language when speaking to an artificial agent, as compared to humans. However, linguistic behaviour depends on a number of influencing factors, and the nature of the communication partner (human vs. machine) is only one of them.

When communicating with an artificial agent, humans do not know what degree of linguistic, cognitive, and sensorimotor capacities to expect from their interlocutor, be it a robot or an information-based computer system (Moratz et al., 2001; Fischer, 2011). Therefore, they are bound to form a hypothesis based on the information available. Fischer argues that both conceptual and linguistic behaviour of humans in HCI
depend on the user's conceptualization of the agent's affordances (Fischer, 2011). She shows that this conceptualization can be partially influenced by the physical appearance of the artificial agent, but more strongly so by users' preconceptions and the dialogue flow (Fischer, 2011, 2008).

It has also been widely demonstrated that speakers adapt to their partner during the course of a dialogue (Clark \& WilkesGibbs, 1986; Clark \& Bangerter, 2004; Garrod \& Pickering, 2007). This also holds for HCI. For example, speakers show linguistic adaptation to improve understandability (Oviatt, Bernard, \& Levow, 1998). Concerning the differences between HHI and HCI, while Kennedy et al. (1988) failed to manipulate the language of the user towards a more HHI-like style by more polite machine output, Amalberti et al. (1993) show that differences between HHI and HCI decrease over time, if the interlocutor's behaviour is identical in both conditions. Also, the mode of communication influences discourse behaviour. Generally, in oral communication speakers produce longer utterances than in written communication, and use a less normative style (Chafe, 1985).

In our opinion, crucial factors in influencing user's linguistic style are the domain and dialogue task. Early Wizard of $O z$ studies centered on problems that could be solved by exchanging relevant information in short question-answer pairs, like requiring information about which cells contain which geometrical shapes (Kennedy et al., 1988). Also, it was usually very clear which kind of information would be required in order to succeed in solving the task.

An extreme example of a different domain and dialogue task is $E L I Z A$, an early conversational agent that took the role of a Rogerian psychotherapist and was designed to draw "his patient out by reflecting the patient's statements back to him." (Weizenbaum, 1976). Though mainly intended as a demonstration gimmick, people who conversed with ELIZA became "deeply [...] involved with the computer and [...] unequivocally [...] anthropomorphized it." (Weizenbaum, 1976).

In the following, we present the setup of our study which was aimed at comparing HCI and HHI in a scenario designed to encourage participants to form high expectations of their interaction partner.

## Setup of the Study

In the study presented in this paper, we relied on two strategies to create a dialogue situation that would encourage participants to speak naturally to the system.

Firstly, the setting itself was chosen to be one where the precise nature of the information needed could not be easily guessed. Participants were brought to different positions in a complex building, and engaged in a remote spoken language dialogue with either the so-called "Infocenter expert" or "Infocenter system" whose supposed task it was to locate the participants in the building. No information was given to participants about the kind of information the sytem/expert had or could process, and it is evident that such a task does not provide a clear and easy solution. Any number of objects
and their features or relations to each other could be relevant, and there are numerous ways to describe these. Therefore the task and setting itself encouraged the participants to describe as much as possible so that they could be localised.

Secondly, participants were encouraged to give detailed descriptions by employing feedback methods (see section Dialogue Flow below). This is closer to natural discourse behaviour than just shaping questions more politely, as Kennedy et al. (1988) did.

## Procedure

We conducted the study in GW2, a complex building at the University of Bremen. The building has four floors with different layouts consisting of one or two main areas. Five positions in the building with different spatial layouts ( t intersections, open spaces, and an irregular intersection) were chosen for the experiment, making sure they were sufficiently far apart to make the dialogue situation plausible.

Before the task, participants filled in a questionnaire regarding basic demographic facts, prior knowledge of the building, and the Questionnaire on Spatial Strategies by Münzer and Hölscher (2011). They were then told that they would talk to either the "Infocenter system" (system condition) or the "Infocenter expert" (expert condition) that would try to locate them in the building and ask them questions. They were instructed to answer as well as they could. In order to enable inherently plausible dialogues about the physical environment, participants were told that the use of room numbers was not allowed.

Participants were brought to each point in ascending order. They were instructed to initiate the dialogue at each position with a predefined phrase, Ich bin bereit. (I am ready.). If participants asked the experimenter about the kind of expressions or information they should use, he/she repeated that they could say whatever they wanted, except for room numbers. No further information about the task was given.

## Participants

Overall, we tested 33 participants. One participant had to be excluded from evaluation due to technical problems. Of the remaining 32 participants, 17 interacted with the system, and 15 with the expert. All participants were students at the University of Bremen and reported native or near-native competence of German. There were 26 female ( 13 per condition) and 6 male participants (expert condition: 2, system condition: 4) aged $18-31$ years (mean: 22). Prior knowledge of the building was intermediary: On a 7-point Likert scale, scores ranged from 2 to 5 in both conditions, with means of 3.18 in the system condition $(s d=1.07)$ and 3.6 in the expert condition ( $s d=0.91$ ) There was no significant difference between conditions (two-sample t-test: $t=-1.194, d f=30$, $p=0.2418$ ).

## Technical Setup

Three experimenters took turns as wizard or confederate, each experimenter playing both roles. Great care was taken to

Figure 1: Overview of the dialogue flow for a given position.
provide a technical setup that ensured equivalent behaviour.
In the system condition we used a modified Wizard of Oz setup. The participant interacted with the system via spoken language, using a headset connected to a laptop. The participant's speech was sent via a one-way skype connection to the wizard laptop. The wizard classified the user utterance using an interface implemented for this purpose, whereupon the system response was automatically determined by the interface according to the dialogue flow described below. This ensured that the wizard and confederate behaved equivalently. The system response was sent as text via a socket connection to the user laptop where it was converted to speech using the MARY text-to-speech system (Trouvain \& Schröder, 2003).

In the expert condition a computer-aided confederate setup was created. The confederate used the same interface as the wizard in order to determine the next response. Instead of text-to-speech conversion, a two-way skype connection was used. The response text was shown on the wizard interface, and was then spoken by the confederate. Confederates were instructed to conform as closely to the wording of the response utterance as possible while still maintaining natural speech rather than reading out loud.

## Dialogue Flow

Care was taken to create a dialogue flow where participants felt an expectation to give as much information as possible without rendering the dialogue unnatural. Therefore, system/expert responses were designed to be as open as possible, and to give the general impression that the previous utterance(s) had been understood. In this respect, our dialogue flow was partly inspired by ELIZA. Although our wizard interface did not perform transformations on user utterances, it did use object names users uttered (which were typed in by the wizard/confederate) for generating replies, giving the impression that the user had been understood.

Additionally, in order to increase the naturalness of the dialogue and give the impression of high verbal capacity of the system, we produced a number of variant utterances for each system response type. The response variants were checked by two independent coders for equivalence. Responses that were semantically or pragmatically more constrained than the de-

| Code | Example utterance |

Table 1: Codes and example utterances for the different utterance types of the expert/system.
sired response were discarded.
Before the first position, the participant was greeted by the system/expert, and after the last position, the system/expert thanked them for their participation. As a general rule, the system/expert gave a success or failure message after the user had named at least 5 types of objects. Success and failure were predetermined and did not depend on the performance of the user. Position 2 led to failure, all others to success.

If less than 5 types of objects had been named, the system asked questions to elicit further information, depending on the course of the interaction. The detailed dialogue flow can be seen in Figure 1. Examples for each type of system/expert utterance are given in Table 1; the beginning of a dialogue between the system and a participant is shown in Table 2.

| Sp. | Code | Utterance |
| :--- | :--- | :--- |
| S | WHERE | Wo stehst du gerade? <br> Where are you standing now? |
| U |  | Ich stehe vor einem Gang, der durch eine Glastür geht und links <br> und rechts von mir ist jeweils auch ein Gang. <br> I am standing in front of a corridor that goes through a glass <br> door and left and to my left and right is also a corridor each. |
| S | MORE <br> -INF | Beschreibe mir bitte diesen Gang etwas genauer. <br> Please describe this corridor to me in a bit more detail. |
| U |  | Ahm, der Gang vor mir geht durch, äh, eine Glastür und ist noch <br> sehr lang. Ähm, von dem Gang gehen viele Türen ab. Der Gang <br> rechts von mir ist sehr kurz. Ähm, in diesem Gang befinden sich <br> zwei Säulen und der Gang links von mir ist auch relativ lang, <br> ähm. Geht aber ziemlich bald durch eine Glastür und auch in <br> diesem Gang befinden sich viele weiße Säulen. <br> Erm, the corridor in front of me goes through, erm, a glass door <br> and ist very long. Erm, from the corridor many doors go off. The <br> corridor to my right is very short. Erm, in this corridor there <br> are two pillars and the corridor to my left is also relatively long, <br> erm. But goes also quite soon through a glass door and also in <br> this corridor there are many white pillars. |
| S | ELSE- <br> SEE | Kannst du noch mehr sehen? <br> Can you see anything else? |
| U |  | Hinter mir ist ein Zeichen für einen Feuermelder, verschiedene <br> Informationsplakate. <br> Behind me is a sign for a fire-alarm, different information <br> posters. |

Table 2: Beginning of a dialogue between a user (U) and the system (S).

## Analysis

One major strategy for localization dialogues is a description of the current view, the spatial scene that surrounds the user. When asked where they were standing, participants answered with lists of concrete physical objects and optionally their relative position, but also with higher level descriptions of corridor constellations and region names that were inferred from signs or retrieved from knowledge. Another description strategy was to provide a route description to the current position. In our analysis, we focused on descriptions of objects. However, these could include descriptions of potential actions, as will be explained below.

The structure and complexity of object descriptions has been analyzed mainly from the point of view of how humans establish joint reference (Clark \& Wilkes-Gibbs, 1986; Clark \& Bangerter, 2004) and computational generation of referring expressions (Bohnet \& Dale, 2005). A referring expression has the structure of a more or less complex noun phrase, modified with adjectives of colour or form, or prepositional phrases that indicate parts or spatial location. However, in the scenario presented here, people give descriptions of objects to an interlocutor without knowing the amount and nature of information he/she has available. The goal is to provide information about the scene, therefore the syntactic structures are more complex than those of referring expressions.

On the other hand, people usually rely on two main strategies when describing complex multi-object scenes like a room, a city, or a desktop array. Either the discourse is organized sequentially as a mental tour or the objects are described in lines as a parralel structure (Linde \& Labov, 1975; Ullmer-Ehrich, 1982). Object configurations are referred to sequentially or in clusters, and usually the object's location is specified and not its orientation (Tenbrink, Coventry, \& Andonova, 2011). Although it could be expected in the current task that participants relied on the well-documented strategies for room descriptions, interestingly, they did not. For the purpose of localisation, it seems, the participants did not aim for completeness, hence no systematical discourse organisation.

In our analysis, we used object descriptions as the main unit of analysis, taking into account structures more complex than referring expressions, but below the level of full scene descriptions. Based on transcriptions of the original audio recordings, coders identified all object descriptions. The beginning of an object description was identified as follows: Any object that was introduced by a noun in a main clause in rheme position: Es gibt/ ich sehe/ ich stehe vor einer Treppe. (There is/ I'm looking at/ standing in front of a staircase) or in an elliptic main clause: [5] Und dann noch so ne Treppe. ${ }^{1}$ (and also a staircase), was regarded to be the beginning of an object description, unless the clause in question was the continuation of a prior object description.

Once a new description had been identified, all parts of the utterance that preserved anaphoric reference to the described

[^149]object were considered continuations of the given object description. Clauses containing repetitions or reformulations of the object name were considered continuations of the object descriptions only if they did not introduce a new object in rheme position.

## Categories of Elaborations

To address the complexity of object descriptions as explained above, we analyzed the number of attributes and elaborative features (henceforth elaborations) directly relating to the target object on the subclausal level, and the number and type of clauses of the object description. Elaborations and clauses were classified into 8 categories post-hoc on the basis of the data as described below. Annotations were carried out by 3 independent coders. Intercoder reliability was checked for by independent double coding for a subset of $10 \%$ of the data. Levels of agreement were either good or very good: Krippendorff's alpha computed on each of the 8 categories ranged between 0.785 (Adverbial Attributes) and 0.945 (Pronominal Clauses).

Compound Name: A compound noun was counted, if the initial noun describing the object was modified by a morpheme, but not if it was a simplex noun: [2510] KünstlerBüro (artist's office)

Adjective Attribute: indicates the number of dependent adjective attributes of the object: [5] so 'ne blaue Treppe (such a blue staircase)

Prepositional Attribute: number of dependent prepositional phrase attributes: [2320] eine Treppe mit Glaswänden (stairs with glasswalls)

Genitive Attribute: number of dependent genitive attributes: [2320] im Erdgeschoss, äh, des GW2 (on the first floor of the GW2)

Adverbial Attribute: number of adverbial attributes: [17] draußen im Flur (outside, on the corridor)

Pronominal Clause: number of dependent pronominal clauses: [33] Ähm, links von mir ist wieder so 'n Eingang, wo die Haupttreppe zum Kunstbereich kommt. (On my left is an entrance, where you can enter the art department)

Conjunction Clause: number of elaborating subordinate clauses introduced by conjunctions: [1152] Es ist ein Holzbrett davor, um die Tür aufzumachen. (There is a wooden piece in front of it to open the door)

Main Clause: indicates the number of main clauses which elaborate on the aforementioned object. This includes the primary introductory clause, and further clauses connected via 1) anaphoric pronouns „der, die, das, es, da": [9]Ähm, ich seh hier Zeitungen, Flyers- Die sind rechts von mir (I see magazines, Flyers- They are on my right); 2) they explicitly refer back to an object from the discourse history: Ähm, ich seh hier Zeitungen, Flyers. Die Flyers liegen rechts von mir
(I see magazines, flyers. The Flyers are on my right) 3) or they elaborate on parts of the aforementioned object which appear in theme position. Elaborations via main clauses can also be connected via ,also, und, oder" (thus, and, or). In this case, they are only counted as elaborations if they give further information about the described object, and do not introduce new objects. [1942] Und, ähm, man kann sich das vorstellen wie ein, wie ein Dreieck. Also ich stehe gerade, ich kann quasi geradeaus gehen, nach links oder nach rechts. (This is like a triangle. So, I can walk straight, to the left, or to the right)

## Results

In this section, we present our findings with respect to the number of object descriptions given and the usage of the different types of elaborations and clauses. The mean number of object descriptions produced by participants at each position, and the overall mean number of descriptions per position per speaker are shown in Table 3.

| Position | Expert | System |
| ---: | ---: | ---: |
| 1 | 8.87 | 7.59 |
| 2 | 11.07 | 6.65 |
| 3 | 11.13 | 6.82 |
| 4 | 10.33 | 7.18 |
| 5 | 10.13 | 7.59 |
| overall means | 10.31 | 7.16 |

Table 3: Mean number of object descriptions produced by speakers of both conditions at each position.

For the number of object descriptions given per position, we fitted a linear mixed model to the data, including fixed effects for Condition, Position and their interaction and a random intercept and random slope (with respect to Position) for each participant (Pinheiro \& Bates, 2000). There was a significant main effect of condition (HHI vs. HCI) $(F=5.37$ and $p=0.028$ ), but not for position ( $F=0.29$ and $p>0.05$ ). No interaction effect was found ( $F=1.16$ and $p>0.05$ ). In summary, this indicates that participants gave more object descriptions when talking to an expert than when talking to a system, and that there was no significant change in the number of object descriptions given during the course of the interaction.

## Complexity of Object Descriptions

Table 4 shows the frequency of the different types of elaborations and clauses in the corpus in each condition, and the mean frequency of each feature per object description. As can be seen from this table, all feature types are present in both system and expert condition, indicating that humans in both HHI and HCI use the full range of syntactic possibilities for describing objects. As Table 5 shows, while the relative frequency of subclausal elaborations per object description shows only a small difference between conditions, the relative number of clauses per description shows a larger difference.

For the number of clauses per object description, we fitted a linear mixed model with fixed effects for Condition, Position

| Elaborative Feature | Expert |  |  | System |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | $\begin{aligned} & \hline \text { (in } \\ & 773 \\ & \text { OD) } \\ & \hline \end{aligned}$ | $\begin{aligned} & \text { mean } \\ & \text { per } \\ & \text { OD } \end{aligned}$ | $\begin{array}{ll} \hline \% & \text { of } \\ \mathrm{E} & \end{array}$ | $\begin{aligned} & \text { (in } \\ & 609 \\ & \text { OD) } \\ & \hline \end{aligned}$ | mean per OD | $\begin{array}{ll} \hline \% & \text { of } \\ \mathrm{E} & \end{array}$ |
| Compound Names | 276 | 0.36 | 10.57 | 219 | 0.36 | 12.01 |
| Adjective Attributes | 305 | 0.40 | 11.69 | 199 | 0.33 | 10.91 |
| PP-Attributes | 324 | 0.42 | 12.41 | 277 | 0.46 | 15.19 |
| Genitive Attributes | 7 | 0.01 | 0.27 | 3 | 0.00 | 0.16 |
| Adverbial Attributes | 251 | 0.32 | 9.62 | 173 | 0.28 | 9.48 |
| Main Clauses | 1147 | 1.48 | 43.95 | 816 | 1.34 | 44.74 |
| Promoninal Clauses | 209 | 0.27 | 8.01 | 87 | 0.14 | 4.77 |
| Conjunction Clauses | 91 | 0.12 | 3.49 | 50 | 0.08 | 2.74 |
| Total | 2609 |  | 100.00 | 1824 |  | 100.00 |

Table 4: Frequency of the different elaboration or clause types (E) when speaking to the expert vs. the system. The table shows total frequency in the corpus, and mean frequency per object description (OD).

| Feature Type | Expert |  |  | System |  |  |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: |
|  | total | mean | $\% \mathrm{E}$ | total | mean | $\% \mathrm{E}$ |
| Clausal | 1446 | 1.87 | 55.42 | 953 | 1.56 | 52.25 |
| Subclausal | 1163 | 1.50 | 44.58 | 871 | 1.43 | 47.75 |
| Total | 2609 |  | 100.00 | 1824 |  | 100.00 |

Table 5: Number of clauses and non-clausal elaborating features (E) in each condition. The table shows total frequency in the corpus, and mean frequency per object description (OD).
and their interaction and a random effect of Participant on the intercepts. We found a statistically significant effect of condition $(F=10.55$ and $p=0.003$ ), but no effect for position ( $F=2.17$ and $p>0.05$ ), and no interaction $(F=0.43$ and $p>0.05$ ), indicating that participants speaking to the expert used significantly more clauses per object description than those speaking to the system, regardless of the position. For the number of subclausal elaborations per object description, we fitted a linear mixed model with fixed effects for Condition, Position and their interaction and a random effect of Participant on the intercepts. No effect was found for condition ( $F=0.49$ and $p>0.05$ ), but a significant effect for position ( $F=6.41$ and $p<0.0001$ ), and no interaction ( $F=1.31$ and $p>0.05$ ), showing that on the subclausal level there was no systematic difference between HHI and HCI in our study. Using contrasts to break down the effect of position, a significant linear trend was found ( $t=3.32, p=0.001$ ), indicating a linear increase in subclausal elaborations in the course of the interactions.

## Discussion

In this paper, we have examined the differences between human-human und human-computer interaction in a user localization scenario designed to encourage participants to develop high expectations of the linguistic and cognitive capacities of an artificial communication partner. We have analyzed the number of object descriptions and their complexity as represented by 8 types of elaboration in HHI and HCI. Although the number of object descriptions given overall, and the number of clauses within these descriptions was higher for HHI than for HCI, participants in the HCI scenario showed the
full range of syntactic variability. They used all types of clauses and subclausal elaborations in sufficiently high frequency that they cannot be discarded as exceptions. Particularly, for subclausal elaborations, no significant difference in frequency between HHI and HCI could be found. These findings support our assumption that, given the appropriate scenario, HCI can be fairly natural and more similar to HHI than may be expected. In our opinion, this contradicts strong claims of computer talk as a separate register which is per se distinct from HHI (Zoeppritz, 1985). Rather, HCI shows parallels with intercultural communication where a number of individual and situational factors come together to shape (linguistic) behaviour, mediated by the interactant's conceptualizations (Fischer, 2011, 2007).

With regard to system design, the broad variability of the user's utterances shows that there is no way around developing systems with high verbal skills, which includes grammatical as well as conceptual competence. Future research could focus on further determining the influences and boundaries for shaping humans' linguistic behaviour towards artificial agents. Focusing on system design, this could help answer the question of how to frame human-computer interactions in a way that the users' expectations and the competence of the system are well matched.

## Acknowledgments

This research was supported by the $\mathrm{SFB} / \mathrm{TR} 8$ Spatial Cognition (Deutsche Forschungegemeinschaft, DFG). We would also like to thank the I5-[DiaSpace] and I6-[NavTalk] project groups, and especially Thora Tenbrink for support and insightful discussions, and Daniel Couto Vale and Mohammed Fazleh Elahi for their support with the design, technical setup, and data collection. We also thank our student assistants, Nadine Hagemann, Denise Rathjen, Gesa Schole, Christina Freihorst, Jonathan Burke and Verena Seidel for their reliability and speed with data collection and coding.

# Agency Intuitions in Physical Interactions 

Ralf Mayrhofer (rmayrho@uni-goettingen.de) Michael R. Waldmann (michael.waldmann@bio.uni-goettingen.de)<br>Institute of Psychology, University of Göttingen, Gosslerstraße 14, 37073 Göttingen, Germany

#### Abstract

The question how agent and patient roles are assigned to causal participants has largely been neglected in the psychological literature on force dynamics. Based on the linguistic theory of Dowty (1991), we propose that agency is a prototype concept. We adapted Dowty's theory to account for scenarios showing physical interactions. In the standard Michotte launching scenario the ball entering the scene is usually assigned the agent role, whereas the ball that is being launched is viewed as the patient. We showed in two experiments that agency intuitions were moderated by manipulations of the context prior to the launching event. Altering features such as relative movement, sequence of visibility, and self-propelled motion tended to increase agency attributions to the patient relative to the standard scenario. We suspect that shifts in figure-ground perceptions, and intuitions about characteristics of interventions may be the overarching reason for the efficacy of the tested criteria.

Keywords: force dynamics; causal reasoning; agency; Michotte task; physical causality

## Introduction

Currently there is a debate between two competing frameworks modeling causal reasoning. One prominent class is dependency theories, including covariation theories, counterfactual theories, and causal Bayes nets. The ontology expressed by these theories contains causal variables that either encode the presence or absence of events, facts, and properties, or different values of continuous quantities. These variables are interconnected by causal arrows that represent hidden mechanisms, and whose strength can be numerically expressed by causal strength parameters (see Waldmann \& Hagmayer, in press, for an overview).

A completely different view answers the question why an observed lawfulness holds by focusing on the participants involved in a causal relation, for example Ball A and Ball B in Michotte's task, or Aspirin and a person with headache in a medical scenario. One variant of this view, dispositional theories of causation, would say, for example, that the ingestion of Aspirin relieves headaches because Aspirin has an intrinsic property, a disposition (or capacity or power), to relieve headaches in suitable organisms (see, for example, Gnassounou \& Kistler, 2007; Mumford \& Anjum, 2011).

In psychology force dynamics, an example of a dispositional account, has become increasingly popular in recent years. Pinker (2007) has argued that force dynamics is a major competitor of Bayes net theories because it allows us to model intuitions about the generative processes underlying observed covariations. One attractive feature of dispositional theories and force dynamics in particular is that these
theories are capable of expressing abstract intuitions about mechanisms without requiring elaborate knowledge.

Force dynamics has been initially been developed in linguistics in the context of verb semantics (see Riemer, 2010; Talmy, 1988) but uses concepts that can be traced back to Aristotle (see Gnassounou \& Kistler, 2007). Aristotle explained efficient causation as a consequence of the interaction of two entities, an agent and a patient. An agent is, according to Aristotle, a substance operating on another substance, the patient, which is suffering the process of change. The acting agent who affects the patient therefore has the disposition, capacity or power to act; and the patient has the disposition, capacity or power to undergo the agent's action.

In linguistic theories of verb semantics and argument structure verbs place constraints on the possible participants mentioned in the noun phrases. For example, in "Peter pushes Mary", "push" has two arguments, one describing an agent (Peter), the other the patient (Mary). Typically, agents are assigned the syntactic subject position. Other participant roles (also called thematic or theta roles) have been postulated but there is no agreement in linguistics about the proper list (see Riemer, 2010, for an overview). Another important semantic theory for a theory of causation is Talmy's (1988) theory of force dynamics. He argues that intuitions about the interaction of forces are an important component of our general semantic intuitions.

Using a force dynamics framework, White (e.g., 2006, 2009) demonstrated the difference between intuitive causal representations and physics by studying Michotte type launching events. In Michotte's (1963) famous demonstrations of phenomenal causality, subjects observed moving objects. For example, in a launching scenario Object X, a ball, moves towards Object Y, another ball, and touches it. This stops Object X and sets Object Y into motion at the same or a slightly lesser speed. Observers typically describe this scenario as a case in which the movement of Object Y is caused by Object X (i.e., launching). Although according to Newtonian physics the force on body Y exerted by body X is equal in magnitude but opposite in direction to that on body X exerted by body Y, observers often see Object X as the cause and Object Y as the effect (causal asymmetry). Nobody would describe the scenario as a case of Object Y stopping Object X , although this would be a legitimate description.

The impression of causal asymmetry is also reflected in judgments of force. White (2009) presented participants with different launching events, and asked them to provide estimates of the relevant underlying forces. The results
showed that in such events more force is attributed to Object $X$ than to Object $Y$, and that Object $X$ is viewed as active and exerting a force on Object Y, whereas the initially stationary Object Y is viewed as inactive, exerting resistance to being moved. Thus, causal interactions are perceived as the result of the opposition between forces of agents (e.g., Object X ) and resistance of patients (e.g., Object Y).

A related theory that aims at elucidating our understanding of abstract causal concepts, such as "cause", "prevent", and "enable", is Wolff's (2007) theory of force dynamics (see also Wolff \& Song, 2003; Wolff et al., 2010). As in the theories of White (2009) and Talmy (1988), two entities are distinguished, which Wolff calls affectors and patients (i.e., the entity acted upon by the affector)(Talmy labels them antagonist and agonist). Force theory states that people evaluate configurations of forces attached to affectors and patients, which may vary in direction and degree, with respect to an endstate, that is, the possible result. Forces can be physical, psychological (e.g., intentions) or social (e.g., peer pressure). Causal relations are analyzed in terms of three components, (a) the tendency of a patient for an endstate, (b) the presence or absence of concordance between affector and patient, and (c) the degree to which the endstate is reached. For example, force theory would represent the singular causal fact "Winds caused the boat to heel" in terms of a patient (the boat) that had no tendency to heel (Tendency $=$ No), the affector (the wind) acted against the patient (Concordance $=$ No), and the result (heeling) occurred (Endstate approached = Yes).

Empirical support for the model was provided in a series of experiments in which participants made judgments about 3-D animations of realistically rendered objects (e.g., moving boats on a lake) with trajectories that were wholly determined by the force vectors entered into a physics simulator (see also Beller et al., 2009; Wolff et al., 2010; for further developments).

## The Empirical Basis of Agency Intuitions

In psychological research on force dynamics the main focus has been on how causal intuitions can be predicted on the basis of configurations of forces attached to agents and patients. The assignment of the roles of agent and patient to the causal participants has typically been treated as selfevident. In Wolff's (2007) example "Winds caused the boat to heel" there is no question that the winds should be assigned the agent role because obviously they play the role of actively overcoming the passive tendency of the boat. However, one deficit of current psychological versions of this theory is that no systematic set of empirical criteria has been laid out that unambiguously motivates the assignments of the agent and patient roles.

White's $(2006,2009)$ theory represents progress in this regard because he has pointed out one important criterion in the Michotte tasks, movement. For example, in a typical study White presented situations in which one ball stands still, and the other moves toward this ball launching it to the other side. In this scenario the moving ball is clearly as-
signed the role of the agent. However, when both balls were moving the assignment was less clear, and additional assumptions had to be made for agency assignments (see White, 2012, for an extended variant of White's, 2009, theory to predict pushing vs. pulling intuitions in cases in which both balls leave the scene attached to each other).

Another example of the ambiguity of agency assignments comes from a recent study by Mayrhofer and Waldmann (2013). In this study, the alien mind reader task was used that had been introduced in the literature by Steyvers et al. (2003; see also Mayrhofer, Hagmayer, \& Waldmann, 2010, for details). This scenario describes a set of aliens some of which have the capacity of picking up the thoughts of each other. In our studies the causal dependency relations were kept constant. In general a causal transmission process was described in which the thoughts of one alien (i.e., the cause) were transmitted into the heads of three other aliens (i.e., the effects). What we manipulated were subjects' assumption about the underlying dispositions responsible for the observed causal transmission. In one condition, the cause alien was assigned the role of the agent. Here the instructions stated that the cause alien has the capacity to send out his thoughts, and plant them into the heads of the effect aliens. In the contrasting condition, the effect aliens were described as the agents, being capable of reading the thoughts of the cause alien. We empirically ascertained that subjects shared our intuitions about the different assignments of the agent role. Interestingly, the results were clear-cut in the sender but ambiguous in the reader scenario. In the sender condition it was clear that the cause alien was the agent. However, in the reader scenario the intuitions did not uniquely attribute agency to the reader side, but equally divided agentive responsibility to the two sides, cause and effects. This may be analogous to the intuition that, although radios play an important part in picking up radio waves, the sending station also plays an active role.

What these results show is that it cannot always be a priori determined how the agency role is assigned, and sometimes the complementary participants may be both viewed as equally active. Hence our current goal is to empirically investigate empirical indicators of agency.

We are not the only ones who noticed that occasionally it is difficult to determine who should be assigned the agent role. For example, in the sentence "John hits Mary" John is clearly assigned the agent role. This example might suggest that grammatical subjects encode agent roles. However, in "John admires Mary", both participants play an active role so that a clear assignment is often impossible (similar with other psychological verbs, such as "mind reading")(see Dowty, 1991). Other ambiguous verbs include "buying" and "selling." They both require two active participants, and it is hard to uniquely assign the agent role.

Our experiments represent an initial attempt in a physical domain (launching events) to study factors moderating agency assignments. As a heuristic for criteria we will use Dowty's (1991) linguistic theory of the distinction between (proto-)agents and (proto-)patients. According to Dowty,
agency is a prototype concept that can be assigned on the basis of a number of empirical criteria. None of these criteria is necessary (hence prototype) but the confidence of the assignment should increase the more criteria are present. In Dowty's theory the agent features include (a) volitional involvement in the event or state, (b) sentience (and/or perception), (c) causing an event or change of state in another participant, (d) movement (relative to the position of the other participant), (e) exists (independently of the event named by the verb). The complementary patient features include (a) undergoes change of state, (b) incremental theme, (c) causally affected by another participant, (d) stationary relative to movement of another participant, (e) does not exist (independently of the event named by the verb). According to Dowty, when two participants are involved in a scenario, the relative number of properties from these lists decides about the assignment of roles. If there is an impasse, multiple assignments are possible. Dowty's criteria are developed to capture semantic implications of verbs. In scene perception other cues might additionally be used, including covariation.

How can this theory be applied to launching events? Obviously some of the criteria (e.g., sentience) do not apply. The remaining relevant criteria for agency include volitional involvement, causation, and relative movement. We believe that a unifying principle behind these three criteria is provided by the intervention concept popular in both the dependency account (Woodward, 2003) and force dynamic theories (White, 2006). In fact, White (2006) believes that force dynamic intuitions are grounded in sensomotoric experiences of actors sensing resistance from the objects they are attempting to manipulate.

The prototypic agent is a human confronted with a stationary scenario that either is constant or changes in a predictable way (i.e., the ground)(relative movement). The agent's act, which is considered independent of the target system, creates a change in a variable, which in turn affects other variables (i.e., the figure)(volition; causation). Following developmental evidence (Muentener \& Carey, 2010) we believe that people also make agency attributions when some of the features of the prototype are missing. For example, when no human agent is visible, the object behaving like it was manipulated by a hidden agent plays the role of the agent (e.g., one ball in the Michotte task). Apparently uncaused covariation against an invariant background has features of an intervention, which explains why the entity involved in the covariation will play the role of the agent. White's (2007) finding that the moving participant is assigned the agent role is also captured because a typical explanation of an apparently unmotivated movement is that there may be an invisible force causing it.

This theory, although derived from a force dynamic framework, is reminiscent of theories proposed within the dependency paradigm. The distinction between figure and ground is analogous to Cheng and Novick's (1991) criteria of the distinction between causes and enabling conditions. According to their theory, causal events that remain invari-
ant within a focal set are assigned the enabler role, whereas the event covarying (i.e., changing) with the effect within the focal set is the cause. This theory does not distinguish between agents and patients, however. Another closely related theory is the intervention account of causal Bayes net theory (Woodward, 2003). According to this theory a change of a variable by a free agent qualifies as an intervention. Thus, volitional involvement, movement, and causation are hallmarks of this concept. Note that this theory is not restricted to human agents. Every change of a variable that deterministically sets the variable and has characteristics of statistical independence with respect to the target system can play the formal role of an intervention.

Although there are analogies between force dynamic and dependency theories, there are also differences. The dependency theories mainly focus on covariation and event causation, whereas other criteria we will study, including relative or spontaneous movement, are neglected.

Our main empirical strategy will be to present scenarios involving an event with two participants (e.g., two balls) but manipulate across conditions properties of the participants possibly relevant for the assignment of participant roles (agent, patient). Our aim is to show that intuitions based on the proto-agency theory predict whether a participant in a fixed scenario is assigned the agent or patient role (or both).

## Experiment 1

In our experiments we employed variants of the Michotte task, which has been used as a classic demonstration for the usefulness of force theories. White $(2006,2009)$ has extensively studied this task, and has found a causal asymmetry effect: Agents are typically assigned greater force than patients. Another observation consistent with causal asymmetry is that the agent, for example a Ball X that is moving toward a stationary Ball Y, is typically described as causing the movement, but Ball Y is never described as stopping Ball X. Our goal is to manipulate the Michotte task in a way that either Ball X (the pushing ball) or Ball Y (the pushed ball) are more or less viewed as agents. In line with the proto-agency theory we predict that subjects differentiate between a stationary scenario (the ground) and an event that shares properties with hypothetical interventions. In Michotte's task a stationary scenario either consists of a set of balls at rest, or balls that are constantly moving in a predictable way. Given that no volitional agent (i.e., a human) is visible, other properties of causal agency apply.

As baseline condition (Condition A), we used the standard Michotte launching setup that was also used by White (2006, 2007, 2009): Ball Y is at rest in the middle of the display, Ball X is constantly moving and rolls from the left edge toward Ball Y. After contact, Ball Y moves and Ball X is at rest. In this condition Ball X should clearly be seen as the agent and Ball Y as the patient.

In three further conditions, we manipulated agency indicators for Ball Y while holding the properties of the physical interaction (i.e., the collision event) constant. Thus, in all conditions Ball Y is at rest in the middle of the screen im-
mediately prior to the collision. When Ball X hits Ball Y, then Ball X stops and Ball Y moves (with exactly the same speed and direction as Ball X had prior to the collision) towards and then beyond the edge of the screen.

What we manipulated were the conditions prior to the invariant launching event. In Conditions B and C, we manipulated relative movement. In both conditions Ball Y enters the screen from the bottom, moves towards its position in the middle of the screen, and stops there just before it is hit by Ball X. Thus, we added movement as an agency indicator expecting an increase of agency intuitions regarding Ball Y. We suspected that observing the movement of Ball X toward the middle position might lead some subjects to infer an intention to stop Ball X. Given that this possible intention is not successful (Ball Y will be launched by Ball X), this may not fully overcome the assignment of agency for Ball X, but a difference to the standard condition may be expected.

Furthermore, we manipulated which of the balls was seen first by restricting the section of the scene that is visible to the subject. In Condition B, we hid the left hand side margin of the scene; whereas in Condition C the lower margin was hidden. Thus, in Condition B the movement of Ball Y was seen first (i.e., Ball Y is the ground); in Condition C Ball X was already seen moving when Ball Y enters the scene (i.e., Ball Y is the figure). Our goal motivating the sequence of visibility was to test whether this subtle figure-ground manipulation affects agency attributions despite the fact that the underlying physical events are identical across the two conditions. We predicted that viewing Ball Y first as the figure would increase agency attributions regarding this ball.

In Condition D, Ball Y is at rest outside the trajectory of Ball X in the lower part of the screen. Suddenly, Ball Y starts to move so that it ends up in the same position as in the other conditions. Here the constant movement of X should be viewed as stationary (i.e., ground) with Ball Y behaving like an animate volitional agent. It is well known that spontaneous movement is seen as an indicator of animacy. In this condition the intuition that the self-propelled movement of Ball Y is a result of volition should be strongest, which should lead to the strongest agency intuitions within the set of conditions.

To sum up: From Condition A to Condition D we added more and more agency indicators for Ball Y (relative movement; relative visibility; volition). According to the proto-agency theory, we expect an increasing willingness of participants to judge Ball Y as the agent in the scenarios. Of course, given that Ball Y is always eventually launched by Ball X we did not expect a complete reversal of agency assignments.

## Method

Participants 39 students ( 27 women; mean age 23.4 years) from the University of Göttingen, Germany, participated in this experiment as part of a series of various unrelated com-
puter-based experiments in our computer lab. Participants received either course credit, or were paid $€ 8$ per hour.
Material For each condition, we constructed a flash movie of size $760 \times 760$ pixels that played for 3,000 milliseconds; the first and last 400 milliseconds presented a black screen resulting in an effective movie length of 2,200 milliseconds. Ball X and Ball Y were 120 pixels in diameter; one colored in red, the other in blue. In the standard condition (Condition A), Ball Y rests in the middle of the screen such that the left most point of $Y$ coincides with the center of the scene. After 20 milliseconds Ball X enters the scene from the left side on a horizontal trajectory with constant speed until it reaches the center of the screen (and, therefore, Ball Y) after 1,100 milliseconds. Then Ball X stops moving, and at the same time (no time lag) Ball Y starts moving with the same speed as Ball X towards the right hand side of the screen. Ball Y leaves the screen after 2,180 milliseconds. (Thus, the movie is symmetric in time and space.)

Keeping the movement shown in Condition A constant, we slightly altered the events prior to the launching event in the other conditions. We only manipulated the 800 milliseconds prior to the collision after which the movement pattern of the balls were identical across all conditions. In Conditions B and C, Ball Y entered the scene at the bottom after 20 milliseconds and moved vertically upwards until it reached its final position after 800 milliseconds. In Condition B, we covered 240 pixels of the scene's left hand side with a white panel; in Condition C, 240 pixels of the bottom were covered. Thus, in Condition B Ball X entered the scene after 700 milliseconds (whereas Ball Y was visibly moving the whole time); in Condition C Ball Y entered the scene after 840 milliseconds (whereas Ball X was visibly moving the whole time).

In Condition D, Ball Y was at rest in the lower half of the display (200 pixels above the bottom) and started moving upwards after 900 milliseconds (at the same speed Ball Y moves in Conditions B and C), and stopped at its final position after 800 milliseconds (i.e., movement time of 300 milliseconds). This sudden, apparently self-propelled movement was expected to suggest a volitional intervention into the trajectory of Ball X.

For counterbalancing purposes we additionally generated seven more movies per condition by rotating the scene by $90^{\circ}, 180^{\circ}$, and $270^{\circ}$, respectively, and switching colors of the balls yielding $4 \times 2=8$ movies per condition (i.e., in sum 32 movies).

Procedure We presented each subject with all 32 movies in random order. After seeing a movie (self-paced), we requested participants to select one of four sentences (presented in randomized order) as the best description of the scene:

1. The red ball launched the blue ball.
2. The blue ball stopped the red ball.
3. The blue ball launched the red ball.
4. The red ball stopped the blue ball.

Note that only two of the sentences actually described what was seen in the movie. If a subject selected one of the two nonsensical sentences we coded the answer as an error.

Design and Prediction We recoded subjects' responses according to the color coding as "X launched Y" vs. "Y stopped X " (plus error), and aggregated the eight color/rotation versions to align with a consistent $\mathrm{X} / \mathrm{Y}$ assignment. We expected an increasing selection rate for "Y stopped X " and a decreasing selection rate for " X launched Y", respectively, from Condition A to Condition D. ${ }^{1}$

## Results and Discussion

Fig. 1 shows the average selection rates for the two relevant scene descriptions across the four agency conditions. In line with previous research, Condition A revealed a strong preference in selecting Ball X as the agent ( $94.9 \%$ vs. $3.9 \%$ ). As predicted, selecting Ball X decreased from Condition A to Condition D, $F_{3,114}=24.0, p<.001, \eta^{2}=.39$. The preference for seeing Ball $Y$ as the agent increased analogously, $F_{3,114}=22.9, p<.001, \eta^{2}=.38$. The average error rate was 2.6\% and did not significantly differ across conditions, $F_{3,114}<1$.

Experiment 1 clearly demonstrates that agency intuitions are grounded in empirical indicators of agency, and confirmed the proposed proto-agency theory. However, it could be argued that the forced-choice format forced people to choose one description even when their intuition was in line with the symmetry assumptions of Newtonian mechanics. This argument does not explain why on average the choices did not even out, but we still wanted to replicate the results of Experiment 1 using a more unrestricted response format.

## Experiment 2

The goal of Experiment 2 was to replicate the findings of Experiment 1 with an unrestricted response format that allows subjects to express that they see both alternative sentences as valid descriptions of the scene. To accomplish this goal we presented subjects in Experiment 2 with rating scales that allowed them to judge the appropriateness of the scene descriptions independently.

## Method

Participants A new set of 34 students ( 23 women; mean age 23.4 years) from the University of Göttingen, Germany, participated in this experiment using the same design as in Experiment 1.

Material and Procedure We used the same set of 32 movies and the same procedure as in Experiment 1. Instead of a forced choice decision between scene descriptions, we presented subjects with the two sentences (adapted to the respective color version), and requested them to rate how well the sentences describe the scene using two separate rating

[^150]

Figure 1: Results of Experiment 1. Error bars indicate standard error of the means.
scales ranging from 0 ("not appropriate at all") to 10 ("highly appropriate"). Both sentences and rating scales were presented on a single screen; the order of the sentences was counterbalanced within subjects.

Design and Predictions We aggregated subject-wise across color/rotation conditions, which yielded a 4 (agency condition) x 2 (Ball X vs. Ball Y) within-subjects design with agency ratings as dependent measure. Since we expected decreasing ratings for Ball X and increasing ratings for Ball Y, we predicted an interaction between agency condition and the rated ball (X vs. Y).

## Results and Discussion

Fig. 2 shows the results for Experiment 2. As expected, the ratings for Ball X were higher as for Ball Y in Condition A with a decreasing trend for Ball X and an increasing trend for Ball Y from Condition A to Condition D. This pattern led to a significant interaction, $F_{3,99}=23.7, p<.001, \eta^{2}=.42$. Across conditions, Ball X received higher agency ratings than Ball Y, $F_{1,33}=34.3, p<.001, \eta^{2}=.51$, reflecting the fact

Figure 2: Results of Experiment 2. Error bars indicate standard error of the means.
that the salient end of the scene (Ball Y's leaving) overall dominates agency intuitions.

The results of Experiment 2 resemble the results of Experiment 1 closely. Although the difference between rating Ball X as the agent vs. rating Ball Y as the agent is much smaller in Condition A compared to Experiment 1, the overall pattern (decreasing ratings for Ball X and increasing ratings for Ball Y from Condition A to Condition D) was replicated, and showed that the findings were nor restricted to specific response formats.

## General Discussion

In contrast to dependency theories, force and dispositional theories of causal reasoning incorporate the distinction between agents and patients in causal interactions. The principal focus of research motivated by dispositional accounts was on how force configurations predict causal judgments, whereas the assignment of the agent and patient roles has largely been treated as self-evident. Various studies in both linguistics and psychology have shown, however, that role assignments are not always clear-cut. Occasionally it may even be necessary to assign the agent role to multiple causal participants.

Based on the linguistic theory of Dowty (1991), we proposed that agency is a prototype concept with multiple criteria, none of which necessary for the role assignment. We adapted this theory to account for physical interactions (e.g., Michotte type launching events). In the standard Michotte launching scenario the ball entering the scene (and launching the other ball) is typically assigned the agent role, whereas the ball that is being launched is viewed as the patient. We showed that agency intuitions are moderated by manipulations of the context prior to the launching event. Altering scene features, such as relative movement, sequence of visibility, and self-propelled motion tended to increase agency attributions to the patient relative to the standard scenario.

A unifying principle underlying these criteria may be that they all tend to lift the patient into the foreground (i.e., into the figure role), and appear to suggest some kind of volitional intervention. Intervention seems to be a central concept unifying dependency and force theories, although the criteria for determining agency are different in these two frameworks. We realize that our experiments just represent a first step. Future studies will have to go beyond launching scenarios to arrive at a more complete theory of agent/patient assignments.

## Acknowledgments

We wish to thank Sven Ritter for help in preparing the experiments. This research was supported by a research grant of the Deutsche Forschungsgemeinschaft (WA 621/22-1) that is part of the priority program "New frameworks of rationality" (SPP 1516).

# Reasoning with Inconsistent Causal Beliefs 

John V. McDonnell (john.mcdonnell@nyu.edu) ${ }^{1}$<br>Pedro Tsividis (tsividis@mit.edu) ${ }^{2}$ Bob Rehder (bob.rehder@nyu.edu) ${ }^{1}$

#### Abstract

Causal reasoning is a critical part of everyday cognition. We ask how people reason about causes when faced with inconsistent sources of knowledge. Causal models arise from multiple sources of information regarding their constituent parameters. Knowledge sources may be inconsistent both within parameters (when one source says a variable should appear often and another says it should appear rarely), and between parameters (when dependencies among parameters result in an internally inconsistent causal model). We provide a normative model for resolving both these sources of conflict. An experiment found that our model of belief integration predicted the qualitative pattern of adults causal inferences under uncertainty.

Keywords: Causal Learning; Causal Inference; Probabilistic Modeling

## Introduction

From deciding on investment strategies to predicting others' reactions in social situations, we are constantly making probabilistic judgments about causal systems. However, because we receive information from multiple sources, we are often faced with contradictory beliefs. Consider the problem faced by an epidemiologist trying to understand the causes of chronic hypertension in a particular population. She reads a review paper suggesting that smoking tobacco causes hypertension in $50 \%$ of patients, and that all other potential causes of hypertension can be ruled out. The epidemiologist knows from survey data that $25 \%$ of the population of interest are smokers, and (independently) that $25 \%$ have hypertension. If she assumes her maximum likelihood estimates are true, she is left with an incoherent causal model: If smoking is the only cause of hypertension, and is effective half the time, then there should be half as many people with hypertension as there are smokers. Arriving at coherent causal beliefs will require adjustment. Perhaps hypertension isn't really as prevalent as she thought, or perhaps the smoking always causes hypertension. In this paper, we propose a normative probabilistic model for reasoning with these inconsistencies and explore the implications of that model in an experiment in which participants receive conflicting sources of evidence.

## A Model

We assume that people's causal inferences are based on causal graphical models (CGMs), such as the one in Figure 1 in which $C 1$ and $C 2$ are believed to be independent causes of $E$. For simplicity, throughout the paper

[^151]we will assume that all variables are binary (present or absent) and that all causal links are generative, bringing about their effects through a noisy-or functional form. We allow for the possibility of additional causes of $E$ not shown in the graph by aggregating them into a single background cause that is always present (for a review of graphical models, see Koller \& Friedman, 2009). A fully parameterized CGM is sufficient to answer virtually any question one might want to ask about the variables involved, including questions of conditional or joint probability, counterfactual reasoning, and predicting the effect of interventions (Pearl, 2000). However, complications arise when one recognizes that CGMs are constructed from many individual beliefs held by the reasoner. Since these beliefs may come from multiple sources that vary in their reliability, it is inevitable that they will sometimes contradict one another. We ask: How should one draw causal inferences in light of such inconsistencies?

To answer this question, we first note that inconsistencies can be either between or across parameters, where parameters represent one's beliefs about each constituent of the model. For example, a belief about the probability of a cause being present is one constituent; a belief about the strength of a causal relation is another. In the first section we advance a new proposal for representing uncertainty in CGMs and show how it solves the problem of within-parameter conflicts. We then tackle the more challenging problem of between-parameter conflicts.

## Resolving conflicts within parameters

Consider the problem of representing the base rate of variable $C 1$, represented by parameter $c_{1}$ in Figure 1. We suppose that beliefs about base rates may come from first-hand observations (observing the prevalence of $C 1$ ), explicit, instruction (e.g., hearing that $C 1$ is uncommon), and prior beliefs (e.g., a tendency to believe that events of this type arise rarely). Because probability is bounded to the range $[0,1]$, the information from each of these sources can be encoded as a probability density function in that range. If knowledge is represented as a point estimate of the expected value of the variable combined with a confidence in that point estimate, this information can be encoded as a beta distribution. PDFs of beta distributions representing knowledge sources for $C 1$ are shown at the top of Figure 1. The shape of a beta distribution is controlled by two parameters, $\alpha$ and $\beta$, constrained to be positive (we will refer to such parameters as knowledge parameters, or $k$-parameters, to emphasize that they represent participants' knowledge and to avoid confusion with the constituent parameters).

Figure 1: A simple common-effect causal graphical model. Here $C 1$ and $C 2$ are potential causes of $E$. Variables of boxes indicate the parameters of the model. Our conflict-resolution model assumes participants encode their beliefs about each of these variables as beta distributions, depicted alongside each of the variables. Above, knowledge sources for $c_{1}$ and $m_{2}$ are depicted, also represented as beta distributions.

The expected value of the odds is the ratio of the two k -parameters, while their sum can be interpreted as the confidence in that estimate.

Reconciling different beliefs encoded as beta distributions is simple. Bayes' rule gives the posterior belief as the renormalized product of the prior and likelihood distributions. In the case of beta distributions, this is derived by summing the parameters. This means that for the knowledge sources in Figure 1, if we denote the k -parameters $\alpha_{\text {prior }}, \beta_{\text {prior }}, \alpha_{\text {instruct }}$, $\beta_{\text {instruct }}, \alpha_{\text {exp }}$, and $\beta_{\text {exp }}$, the posterior is simply $\operatorname{Beta}\left(\alpha_{\text {prior }}+\alpha_{\text {instruct }}+\alpha_{\text {prior }}, \beta_{\text {prior }}+\beta_{\text {instruct }}+\beta_{\text {prior }}\right)$. This process is depicted in Figure 1 for $c_{1}$.

A similar treatment can be applied to the strengths of the causal relations in Figure 1, shown in the figure for the case of $m_{2}$. Following Cheng (1997), we assume that each link is represented as a causal power: the propensity of the cause, when present, to bring about the effect. Because they are probabilities, beliefs about causal powers can also be stored as beta distributions.

As depicted in Figure 1, the model consists of six pa-
rameters: the base rates of $C 1$ and $C 2\left(c_{1}\right.$ and $\left.c_{2}\right)$, the strengths of causal relationships $C 1 \rightarrow E$ and $C 2 \rightarrow E$ ( $m_{1}$ and $m_{2}$ ), the strength of the background causes of $E(b)$, and the rate at which $E$ occurs (e). We suppose that belief in the value of each of them is represented as a posterior beta distribution.

## Resolving conflicts between parameters

Computing the posterior beta distribution for each model parameter does not eliminate all potential inconsistencies, however. As illustrated in the introduction, when all the causes of an effect are fully described, the effect variable's rate of occurrence is no longer free to vary. Because the value of $e$ is fixed, random draws from the individual beta posteriors will never return valid causal models (assuming infinite precision). This means we need a way to integrate information about effects into our beliefs over possible causal models without violating the constraints of the model.

Following Figure 1, let $\mathbf{V}$ represent the set of variables in the domain. For each $v \in \mathbf{V}$, belief in the probability of $v$ is characterized by the PDF of a beta distribution, denoted $\pi_{v}$. These correspond to $c_{1}, c_{2}$, and $e$ in the figure. Next, let $\mathbf{L}$ be the set of causal links in a model. For each $l \in \mathbf{L}$, the learner's belief in the causal power of $l$ is characterized by a beta-distributed PDF denoted $\pi_{l}$ ( $m_{1}$ and $m_{2}$ in the figure). Finally, let $\mathbf{E} \subset \mathbf{V}$ be the effects. For each $e \in \mathbf{E}$, the belief in the background causes of $e$ is characterized by a beta-distributed PDF denoted $\pi_{e}$ ( $b$ in the figure).

We now define the posterior over valid causal models. Let $\mathbf{r}, \mathbf{m}$, and $\mathbf{b}$ be vectors describing the base rate of every variable in $\mathbf{V}$, the strength of every link in $\mathbf{L}$, and the strength of the background causes for every effect in $\mathbf{E}$, respectively. Under a noisy-or causal model, all effects are explained by the likelihood of their causes and the strength of those causes. This means the rate of occurrence for an effect $e$ is constrained to be

$$
\begin{equation*}
r_{e}^{\prime}=1-\left(1-b_{e}\right) \prod_{(l \in \mathbf{L}) \wedge\left(l_{e}=e\right)}\left[1-r_{l_{c}} m_{l}\right] \tag{1}
\end{equation*}
$$

where $l_{c}$ and $l_{e}$ are the cause and effect variables associated with causal link $l$. Enforcing this consistency, we can define the joint probability of a fully parameterized model as
$P(\mathbf{r}, \mathbf{m}, \mathbf{b}) \propto\left\{\begin{array}{l}0 \quad \text { if } \exists e \in \mathbf{E}: r_{e} \neq r_{e}^{\prime} \\ \prod_{v \in \mathbf{V}} \pi_{v}\left(r_{v}\right) \prod_{l \in \mathbf{L}} \pi_{l}\left(m_{l}\right) \prod_{e \in \mathbf{E}} \pi_{e}\left(b_{e}\right) \text { otherwise. }\end{array}\right.$
This is equivalent to saying that the posterior over joint model values is defined as the result of sampling from the beta distributions characterizing each of the variables in the model, discarding the inconsistent models. Our central hypothesis is that, when inconsistencies among be-

|  | Rare Causes (25\%) | Common Causes (75\%) |
| :---: | :---: | :---: |
| One Cause (50\%) | Severely Underexplained <br> Implied base rate of effect: 12.5\% | Mildly Underexplained <br> Implied base rate of effect: 38\% |

Figure 2: Design of the experiment.
liefs exist, people draw inferences as if they are reasoning with the maximum a posteriori causal model.

## An Experiment

One important prediction of our model is that when faced with an invalid model, reasoners will make tradeoffs among the parameters to find a valid causal model (Equation 2 above). We tested this hypothesis by querying the adjustments individuals make to their instructed causal model given a variety of inconsistent beliefs.

Each participant learned about four binary variables in one of three domains: economics, meteorology, or sociology. Participants learned about four relevant variables and the beliefs of experts in their domain. In the domain of economics, for example, the four variables were interest rates (moderate/high), trade deficits (moderate/large), retirement savings (moderate/high), and job mobility (moderate/high). Depending on the condition, one or three of those variables (denoted $C_{1}, C_{2}$, and $C_{3}$ ) were been described as generative causes of a fourth $(E)$.

A $2 \times 2$ design (depicted in Figure 2) explored the effect of varying the number of causal links (one vs. three) and the base rates of those causes ("rare" vs. "common"). In all conditions, the effect was "somewhat common," (occurring $44 \%$ of the time), and the causes brought about the effect half the time.

Manipulation of these two parameters should of course result in changes to participants' estimates of the values of those parameters. However, because they also imply between-parameter conflicts, they should also result in compensating changes to other parameters in order to yield a consistent model. For example, consider the condition in which only one rare cause is instructed. Here the participants were told about a cause happening 4 times out of 16 and bringing about its effect $50 \%$ of the time. As indicated in the figure, these facts imply a base rate for the effect of .125 , which conflicts with its instructed base rate of .44. Thus, the effect is underdetermined by the causes in the model. There are many ways in which reasoners could compensate: They could
adjust the likelihood of the effect downward, increase the likelihood of the cause, increase the causal strength of the cause, or increase the likelihood of background causes. Participants must choose a combination of these adjustments to reason with a valid causal model.

Conversely, in the case where participants were instructed about three causes, each common, the implied base rate of the effect is .84 , that is, the effect is now over-determined, and the reverse adjustments are needed to help form a valid model. Note that because we did not explicitly control the confidence subjects should hold in their beliefs about individual parameters, we do not make predictions regarding which variables will be adjusted, but rather only that some subset will be adjusted to attain a consistent model.
To measure the adjustments made by participants, we followed this instruction with a series of questions designed to assess their beliefs about the parameters of the causal model.

## Method

Participants A total of 234 subjects were tested, consisting of 114 New York University undergraduates who received course credit and 120 online subjects who received a small cash incentive. Subjects were randomly assigned to the 1link/rare, 1 -link/common, 3 -link/rare, and 3 -link/common, conditions. Participants whose numerically-coded responses over the course of the experiment had a standard deviation of less than 2 were excluded, leaving $54,52,57$, and 47 participants in each of the conditions, respectively.
Materials Three knowledge domains were tested: Economics, meteorology, or sociology. In each domain, the same four variables were used, so the same variables always played the role of $C_{1}, C_{2}, C_{3}$, and $E$. Subjects in the 3 -link conditions learned three causal links: $C_{1} \rightarrow E, C_{2} \rightarrow E$, and $C_{3} \rightarrow E$. Those in the 1-link conditions learned only $C_{1} \rightarrow E$.
Base rate information was displayed as an instruction screen displaying a pictorial representation of the rates at which each of the variables was observed. Base rates of the causes were described as occurring $25 \%$ of the time ("rare"), or $75 \%$ ("common"). $E$ was always depicted as occurring $44 \%$ of the time ("somewhat common"). The base rates were illustrated using a pictorial graph showing them the values of each variable for 16 random systems from a "survey". For example, $\frac{7}{16}$ of systems were always shown to have the effect.

Causal information was conveyed in writing. For each causal relationship, participants were told that the cause brought about the effect $50 \%$ of the time. They were also given a short description of the mechanism underlying the relation. For example, if told that large trade deficits cause high job mobility, they were also told, "The flood of cheap imports means that many domestic manufacturing jobs are lost and workers must find new employment." Participants were also told that experts believed there were no other causes of the effect.
Procedure After being introduced to the domain, participants were presented with screens presenting experts' beliefs about the base rates of the variables and their causal relationships. After the instructions, online subjects were quizzed on their memory for the instructions. This repeated in a loop until they were able to correctly answer all questions.

Participants were asked four types of test questions presented in blocks. Block order was randomized. For all question types, participants responded with an estimated probability on a scale of $1-11$ by choosing one of 11 radio buttons, with the two extremes labeled "very unlikely" (on the

Figure 3: Causal model parameters derived from the empirical results from the experiment compared across all conditions (without modeling learning or prior belief). (A) The base rates of the causes (parameter $c_{1}$ ). (B) The strength of the causal links (parameter $m$ ). (C) The base rate of the effect (parameter $e$ ). (D) The strength of alternative causes (parameter b). Error bars are standard errors.
left) to "very likely" (on the right). The first questions were joint probability questions. In these questions, subjects were given the states of all four variables in their scenario and asked to rate the likelihood of those variable states being observed. All 16 possible questions formed by varying the state of the three binary variables were asked. A second question type consisted of conditional probability questions. For these questions, subjects were given the state of three of the four variables and asked to rate the likelihood of the fourth. All 8 possible conditional probability judgments formed asking for the probability of $E$ as a function of the presence or absence of the three causes were asked. In addition, eight questions asked for the probability of one of the causes with the effect either present or absent (with the other causes always stipulated to be absent). Finally, the third and fourth question types directly queried the base rates of the four variables and the strengths of the three potential causal links. To avoid the possibility that subjects would forget the initial information about the causal model, a "theory reminder" was presented on the right side of the screen, accompanying each question.

Finally, subjects were given the chance to learn more about their causal system by observing a sample of 32 instances from that domain. The sample was drawn from a model in which the causes had a base rate of .50 , two causal links $\left(C_{1} \rightarrow E\right.$ and $\left.C_{2} \rightarrow E\right)$ of strength .50 , with no alternative causes of $E$. Subjects were asked to "consider how these data might change your beliefs about the causal relationships in this system and the overall likelihoods of the variables involved." Participants were then asked to re-answer all the previous questions. Then they cycled through once more, again observing a sample of 32 instances, and again reanswering the questions. These responses were used in model fitting, but because learning effects appeared to be small the results of these test phases will not be reported here.

## Results

To characterize subjects' judgments of joint and conditional probability, we fit those judgments to a causal model with three causes and one effect, yielding eight parameters: $c_{1}, c_{2}$, and $c_{3}$ (the likelihoods of the causes),
$m_{1}, m_{2}$, and $m_{3}$ (the strengths of the putative causal links), $b$ (the background cause of $e$ ) and $e$, the likelihood of the effect (see the Appendix for details).

Figure 3 summarizes the effects of our two manipulations on the causal model parameters. For purposes of comparison, we only present those parameters that were involved in a causal relationship in all conditions $\left(c_{1}, m_{1}, e\right.$, and $\left.b\right)$. A $2 \times 2$ ANOVA with the causes' base rate and the number of causal links as factors was performed for each panel. A main effect of the base rate manipulation on estimates of base rates of $C_{1}$ (plotted in Figure 3A) confirmed the success of that manipulation $(F(1,206)=35.45, M S E=.034, p<.001)$. Importantly, the manipulation also resulted in an increase in the prevalence of the effect (parameter $e$ in Figure 3C, $F(1,206)=19.00, M S E=.074, p<.001)$ and a decrease in the strength of the background causes (parameter $b$ in Figure 3D $(F(1,206)=10.23, M S E=.058$, $p<.01$ ). That is, to accommodate the more prevalent causes, participants compensated by increasing the base rate of the effect and decreasing the effectiveness of alternative causes, as predicted by our model. There was no effect of the manipulation on causal strengths (parameter $m_{1}$ in Figure 3B).

The manipulation of the number of causal links also had two important effects. First, it reduced the base rate of $C_{1}$ (parameter $c_{1}$ in Figure $3 \mathrm{~A}, F(1,206)=35.45$, $M S E=.073, p<.001)$. Second, it reduced the strength of the $C_{1} \rightarrow E$ causal relationship (parameter $m_{1}$ in Figure $3 \mathrm{~B}, F(1,206)=20.67, M S E=.088, p<.001)$. Apparently, to accommodate two additional causal links, participants compensated by decreasing the effectiveness of the $C_{1} \rightarrow E$ link, reducing both $c_{1}$ and $m_{1}$ as predicted by our model. Changing the number of causal links did not have a significant effect on either the prevalence of the effect (parameter $e$ in Figure 3C, $F<1$ ) or the strength of alternative causes (Figure 3D, $F(1,206)=2.16, M S E=.058, p=.19)$. None of the 2-way interactions approached significance (all $F$ s $<1$ ).

## Discussion

The results of this experiment supported the claim that when people are given inconsistent information, they draw inferences as if they're reasoning with the most likely causal model. Increasing the base rates resulted in participants believing that the effect is more likely and alternative causes are weaker. Increasing the number of causes led participants to adjust their beliefs about the causes, weakening both their efficacy and their base rates. We now assess whether our theoretical model can provide not only a good qualitative account of these data, but an acceptable quantitative one as well.

## Theoretical Modeling

Recall that although our theoretical model of uncertainty and belief integration specifies that reasoners will adjust

Figure 4: Causal parameters derived from the fit of the theoretical model. (A) The base rates of the causes (parameter $c_{1}$ ). (B) The strength of the causal links (parameter $m$ ). (C) The base rate of the effect (parameter $e$ ). (D) The strength of alternative causes (parameter b).
parameters in order to reason with a consistent causal model, it does not specify which parameters will be adjusted in the absence of any information about the confidence with which beliefs about those parameters are held. To assess our model's potential for providing a quantitative account of the experiment, we fit it to those results treating confidence in each constituent parameter as a free parameter (a fifth control condition, not reported here, was also fit in which subjects were instructed on the same model that generated the learning data; see Procedure section). For any constituent parameter of the model $k$ (a variable or causal link), confidence is represented as a beta distribution with k -parameters $\alpha_{k}$ and $\beta_{k}$. We recast those k-parameters into the pair $v_{k}=\frac{\alpha_{k}}{\alpha_{k}+\beta_{k}}$, representing the expected value of the parameter, and $t_{k}=\alpha_{k}+\beta_{k}$, representing the overall confidence with which the expected value is held. We assume that reasoners may have different levels of confidence in the different types of parameters, represented as four free k-parameters: $t_{c}$ (the base rates of the cause), $t_{m}$ (the strength of the causal links), $t_{b}$ (the strength of the alternative causes), and $t_{e}$ (the base rate of the effect). Because we assume that subjects do not perfectly encode the initial numerical information provided about each parameter, those are free parameters as well. Let k-parameters $v_{m}, v_{b}$, and $v_{e}$ represent the instructed values of $m$ (causal link strengths, described to subjects as .5), $b$ (the strength of the alternative causes, described as 0 ), and $e$ (the base rate of the effect, described as .44), respectively. $v_{m 0}$ was the initial strength of the links on which subjects were not instructed. k-parameters $v_{c-r}$, $v_{c-m} v_{c-c}$ represent the initial base rates of the causes in the rare, moderate, and common conditions, respectively
(described as .25, .5, and .75).
This model was fit to the group level causal model parameters fit in the experiment. Eight parameters $\left(c_{1}, c_{2}\right.$, $c_{3}, m_{1}, m_{2}, m_{3}, b$, and $e$ ) were estimated per phase per condition. This included the learning phases as well as a fifth control condition not reported here. This involved fitting $8 \times 3 \times 5=120$ data points with 10 parameters. The parameters that minimized squared error were $t_{c}=106, t_{b}=299, t_{e}=3252, v_{c-r}=.162, v_{c-m}=.351$, $v_{c-c}=.485, v_{m}=.454, v_{m 0}=.069, v_{b}=.122$, and $v_{e}=.7$. The correlation between observed and predicted values was .964. The predictions are depicted in Figure 4, which is analogous to Figure 3. Figure 4 reveals that the model is able to capture the effects of the causal strength manipulation, namely the base rate of $C_{1}$ (parameter $c_{1}$, Figure 4 A ) and the strength of the $C_{1} \rightarrow E$ link (parameter $m_{1}$, Figure 4 B ) both decrease as the number of causal relations increases (compare with Figure 3A and B, respectively). It is also able to reproduce the effects of the base rate manipulation on the strength of the alternative causes (parameter $b$, Figure 4D), namely, that alternative causal strength decreases as the base rates of the causes increase (compare with Figure 3D). Less successfully, it predicts an increase in the base rate of the effect with larger base rates of the causes (parameter $e$, Figure 4C), although the magnitude of that change is much smaller than the one exhibited by subjects (compare with Figure 3C). Note the insensitivity of parameter $e$ to changes in the other causal model parameters is a manifestation of the large confidence the model places on its initial value $\left(t_{e}=3252\right.$, vs. all other $t \mathrm{~s}<300$ ).

## General Discussion

In ecologically valid settings, causal reasoning often takes places with multiple knowledge sources that are potentially inconsistent with one another. To specify how causal inferences should be drawn in such situations, we developed an account of how uncertainty about causal models might be represented and then showed how to derive the most likely causal model that is sensitive to each knowledge source yet resolves inconsistencies between them. Our central hypothesis was that people would draw causal inferences as if they were reasoning with the most likely consistent model.

The qualitative predictions of this model were confirmed in an experiment manipulating two instructed parameters: the base rates of the causes and the number of causal links. Making causes more prevalent resulted in alternative causes becoming weaker and the effect becoming more prevalent. Making causal relations more numerous resulted in the causes becoming rarer and other causal links becoming weaker. We know of no other model that is capable of predicting these sorts of effects.

Our model also yielded moderately good quantitative fits to the data. One result it was unable to reproduce was participants' tendency to adjust the likelihood of the effect ( $e$ ) when the causal base rates were adjusted but not when the number of causes was adjusted. Moreover, we acknowledge that these fits used a large number of parameters, necessitated by the fact that confidence in each instructed model parameter was not specified experimentally and so needed to be free parameters. We are conducting follow-up studies manipulating instructed confidence in the information provided to participants.

Although our representation of uncertainty was sufficient to account for our empirical results, its assumption that the distributions of the causal model parameters are independent is unrealistic in some situations. For example, Lu et al. (2008) have modeled the traditional causal learning experiment as one in which the prior distribution is a two-dimensional density function on the strength of the to-be-learned causal link and the strength of alternative causes. Multivariate representations of uncertainty like this may be common. In addition, one might imagine that reasoners not only have experiential knowledge about the base rates of variables (Figure 1), but also about configurations of variables. Finally, in addition to changing parameters to attain consistency, reasoners might also change the function relating an effect to its causes (e.g., by assuming that the causes combine interactively rather than independently) or even the structure of the model itself (e.g., deleting a causal link, as proposed by Griffiths \& Tenenbaum, 2005).

One facet of the data not discussed above was the distinction between our explicit queries (e.g., directly querying the causal efficacy of $C_{1}$ ) and our implicit ones, such as judgments of conditional and joint probability. Perhaps unsurprisingly, explicit queries more closely resembled the likelihood information participants were given, unadjusted for consistency, suggesting that such questions do not invoke inconsistency resolution processes we have specified here. We also observed (but did not report here) that participants' causal models changed little as a result of observing data. Whether this result reflected a kind of anchoring effect (initial judgments influenced later ones) or participants large confidence in the initial domain theories on which they were initially instructed remain questions for future research.

## Appendix

Participants' causal models were simultaneously fit to participants' judgments of conditional and joint probability. Fitting assumed that participants formed a common-effects model with $C_{1}, C_{2}$, and $C_{3}$ as potential causes of $E$. The joint is defined as the probability that the four variables will take any particular combination of values. From the axioms of probability, we derive

$$
\begin{equation*}
p\left(E, C_{1}, C_{2}, C_{3}\right)=p\left(E \mid C_{1}, C_{2}, C_{3}\right) p\left(C_{1}, C_{2}, C_{3}\right) \tag{3}
\end{equation*}
$$

Because $C_{1}, C_{2}$, and $C_{3}$ are assumed to be independent,

$$
\begin{equation*}
p\left(E, C_{1}, C_{2}, C_{3}\right)=p\left(E \mid C_{1}, C_{2}, C_{3}\right) p\left(C_{1}\right) p\left(C_{2}\right) P\left(C_{3}\right) \tag{4}
\end{equation*}
$$

Assuming that the causes bring about their effects according to a noisy-or rule, the probability that $E$ is present given the status of the causes is given by

$$
\begin{equation*}
p\left(E=1 \mid C_{1}, C_{2}, C_{3}\right)=1-(1-b) \prod_{i \in\{1,2,3\}}\left(1-m_{i} C_{i}\right) \tag{5}
\end{equation*}
$$

where presence or absence is coded as 1 or 0 , respectively.
Equations 4 and 5 are sufficient to specify the probability of any combination of the variables as a function of the parameters $c_{1}, c_{2}, c_{3}, m_{1}, m_{2}, m_{3}$, and $b$.

Separate $c, m$, and $b$ parameters were estimated for each participant for each test phase. To transform responses on the 1-11 scale into probabilities, we applied a nonlinear (power) transformation. This necessitated fitting a power parameter, $\gamma$. Each subject's rankings were predicted as follows:

$$
\begin{align*}
& \text { rating }_{\text {cond }}\left(r_{b, i}\right)=10 p_{k}\left(r_{i} ; c_{b}, m_{b}, B_{b}\right)^{\gamma_{\text {cond }}}+1  \tag{6}\\
& \operatorname{rating}_{\text {joint }}\left(o_{b, i}\right)=10 p_{k}\left(r_{i} ; c_{b}, m_{b}, B_{b}\right)^{\gamma_{\text {joint }}}+1 \tag{7}
\end{align*}
$$

where $r_{b, i}$ and $o_{b, i}$ are the subject's conditional and joint judgments, respectively, on trial $i$ in phase $b . \gamma \mathrm{s}$ were fit within participant and question type, and constrained to the range $[0,5]$. This resulted in $7 \times 3=21$ causal model parameters and the two $\gamma$ parameters (23 in total) used to fit $32 \times 3=96$ responses. Parameters were fit using gradient descent.

The model fits included a control condition in which participants were instructed with a causal model that conformed to the data they observed. The results are not elaborated in this paper due to space constraints.

This model achieved a respectable correlation between its predictions and the empirical data points (.950; . 783 averaged over subjects).

# Naïve Physics - the wrong theory? 

I.P.L. McLaren (i.p.1.mclaren@exeter.ac.uk), K.Wood, \& R.P. McLaren<br>School of Psychology, University of Exeter, UK.

#### Abstract

In this paper we examine the idea of a "naïve physics" in humans solving physics problems. This invokes the idea that people have a theory of motion in their heads that is nonNewtonian, and hence leads to systematic errors on these problems. We are able to show that, by selecting our problems carefully, it is possible to obtain answers that are consistent with this naïve physics and inconsistent with it; suggesting that it is not used to solve these problems but sometimes offered as post-hoc justification for the answers given. We offer evidence that the answers given owe more to past experience than any theory, and that a theory that postulates extrapolation on the basis of associative memory can give a good account of our results.

Keywords: Associative, Memory, Naïve Physics, Theory.

## Introduction

McCloskey, Caramazza and Green (1980) and McCloskey, Washburn and Felch (1983) have proposed that people consistently make particular mistakes when asked to predict the path of an object, given certain initial conditions, because they are applying the wrong theory, an intuitive mechanics or "naïve physics", to this type of problem. Their evidence is that, when given a relatively simple physical situation and asked to extrapolate on the basis of the information supplied, people tend to make certain types of error rather than others, and justify this with verbal reports that indicate a non-Newtonian approach to the problem (even though the instructions encourage that type of approach). One example of such a problem would be for participants to be asked to imagine looking down on the curved tube (which is held horizontally) in Figure 1, while a ball bearing is inserted with some speed, v, as shown. Their task is to draw the path the ball bearing takes on exiting the tube, ignoring such factors as friction between ball bearing and tube, and any wind resistance. The plan view is intended to take gravity out of the picture for the purposes of this problem, and the correct, Newtonian solution, is to draw a straight line as shown in the figure (solid line) as the ball bearing leaves the tube. Instead, many participants draw something approximating the curved dotted line as their answer, and justify this by claiming that the ball bearing has acquired "curvy impetus" as a result of its journey through the tube and this continues to cause its path to curve on exiting the tube. A more sophisticated version of this account will claim that this impetus dissipates with time, and so the curved path will gradually straighten as the ball bearing gets further from the tube (see McCloskey et al, 1980).

Figure 1: The ball bearing and curved tube problem.
Another classic problem studied by McCloskey and colleagues concerns what they call the "straight down belief" (McCloskey, Washburn \& Felch 1983). The idea here is that people tend to predict a straight down trajectory for objects that are dropped whilst being carried, whereas they predict a parabolic path for objects that fall when moving independently. A classic example of this is a cannonball projected off a cliff. If fired horizontally from a cannon with initial velocity, $v$, an "out and down" approximation to the parabolic path is a typical response from participants asked to draw its subsequent path. But if carried (by some overhead conveyor belt arrangement) to the edge of the cliff with velocity, v , and then released, even though this is the identical problem in physical terms, participants are much more likely to describe the cannonball's motion as straight down. The reason they give for this is that, in the first case, the cannonball possesses its own impetus when it leaves the gun. This horizontal impetus takes it out past the cliff edge, but starts to dissipate. At the same time, gravity takes hold, and accelerates it downwards - hence the "out and down" parabolic trajectory. But, in the case of the cannonball being carried by a conveyor belt, participants think it has no impetus of its own, and so, when released, gravity takes hold immediately and it drops straight down.

The research reported in McCloskey et al's paper investigates the basis for this finding. On the one hand, it may be just as it seems and as participants in these experiments claim, i.e. that they have applied a naïve physics (or natural intuition) to the problem which is, in some sense the "wrong" theory as it is non-Newtonian, and it is this that leads to the consistent error in predicting the path of the object. On the other hand, it may be that the
account given by participants of why they drew that particular path is more by way of a post-hoc rationalization of what they did, rather than an account of what caused them to do it. Instead, the causal factor in producing this consistent error could be extrapolation on the basis of experience, by which we mean to imply associativelymediated retrieval of memories based on some surface similarity to the problem just posed. On this account, the reason why a carried object is often portrayed as taking a path straight downwards when released is because that is the perceived experience that we have, and call upon, of this situation in real life. Imagine you are cycling along and you drop a package. To a first approximation at least, the package appears to fall straight down. This is because both the package and the observer on the bicycle share a (moving) frame of reference, and in that frame of reference there is no horizontal motion with respect to one another. But a thrown package, which, in naïve physics terms, is one moving independently, does not have this property and so will follow a curved trajectory.

We realize that proponents of the naïve physics view will argue that it is exactly episodes of this kind that lead to induction of a naïve physics i.e. the incorrect theory is derived from these types of experiences, and it is only by running carefully controlled experiments that allow for friction, wind resistance, and frames of reference that the proper Newtonian theory can be arrived at. But we would differ from this view in arguing that the effect of experience is primary, and that its impact via retrieval from memory is what drives the response, not its impact via some naïve physics induced on the basis of these experiences. This stance makes the prediction that, if we are able to find scenarios where experience would predict that a carried object would follow a curved trajectory, or an object moving independently should take a path straight down, then the result of putting these problems to participants should be quite different to that predicted on the naïve physics account. If participants have a theory that drives their responses, then it should apply across different situations, as long as the particular scenario employed does not change the essential physics of the problem. Equally, if the outcome of experimental investigation of this proposition were to be that the responses made to a problem involving a carried object were to predict a path straight down (independent of considerable variation in the surface features of the scenario), then this would be inconsistent with an account in terms of associative memory (to the extent that different memories would be expected to lead to different predictions.

## Experiment

## Method

## Participants

27 University of Exeter students with ages ranging from 18-35 participated in this experiment. All were
undergraduates studying psychology, but were naïve to the hypotheses under test in this experiment.

## Design

Eight physics problems, featuring falling objects, were devised. These problems all had the same underlying structure, and therefore the same answer (in terms of Newtonian physics), but different surface and contextual features. The problems were of two types: Those in which the object was carried prior to being released, and those where the object had been moving freely (independently) throughout. These two problem types were further divided to give two subsets in which the expected answers were either congruent or incongruent with the predictions of a naïve physics theory.

Four different types of problems were, therefore, presented to the participants in a questionnaire:

Type 1: Carried - Congruent (CC) - Problems in which objects are carried prior to release and where our predicted answer "falls straight down" is in accordance with naïve physics theory.

Type 2: Carried - Incongruent (CI) - Problems in which objects are carried prior to release and where our predicted answer is not in accordance with naïve physics theory.

Type 3: Free - Congruent (FC) - Problems in which objects are moving freely/independently and where our predicted answer "curved forwards/parabolic trajectory" is in accordance with naïve physics theory.

Type 4: Free - Incongruent (FI) - Problems in which objects are moving freely/independently and where our predicted answer is not in accordance with naïve physics theory.

Two imaginary scenarios were devised for each type of problem. These were constructed using MS Powerpoint and Word software on a Macintosh computer as follows:

## Table 1

1. Carried Congruent condition (CC):

Problem 1. Bird in flight dropping ice cream
Problem 5. Plane dropping crate
2. Carried Incongruent condition (CI):

Problem 2. Swinging monkey drops banana
Problem 6. Cricket bowler drops ball at release
3. Free Congruent condition (FC):

Problem 3. Cannonball fired off cliff
Problem 7. Skier approaching a crevasse
4. Free Incongruent condition (FI):

Problem 4. Skateboarder dropping in to a half-pipe Problem 8. Water falling over a cliff

Figure 2. The figure shows one of the scenarios (Problem 1) presented for the CC condition. Participants were asked to select one of the 5 responses to indicate the trajectory of the dropped object (e.g. the ice-cream)

The problems in Table 1 were chosen so that the CC and FC examples, i.e. the congruent problems, were closely modeled on problems that have typically been used in previous experiments on naïve physics. As far as we could tell, there were no associations to events or situations that contradicted the predictions of a naïve physics theory for these examples. The incongruent problems (CI and FI) were chosen so that they conformed to the "Carried" or "Free" designation, but had associations that seemed to us to suggest that a response that was incongruent with a naïve physics theory would be given. Thus, a cricket bowler (e.g. Problem 6) is typically seen as projecting the ball forwards, not dropping it straight down. If you observe someone or something else (e.g. the monkey in Problem 2) in a state of motion carrying an object that they drop, then the typical perceived experience is for that object to continue to follow that state of motion. Because waterfalls (e.g. Problem 8) are typically seen from front-on and below, the modal experience is of them falling nearly straight down; and when

Figure 3. This shows examples of the other three types of scenario presented to our participants. The top panel is an example of a CI (Type 2 problem), the middle a FC (Type 3 problem) and the bottom a FI (Type 4 problem) example. In each case the same five response options were offered, illustrated by mini-drawings to show the path suggested (see Figure 2 for examples).
skateboarders drop in (e.g. Problem 4), they typically appear to take an initial path that is straight down. So, our hope was that these scenarios would predispose our participants to choose paths that were not expected on a naïve physics account.

## Procedure

The eight problems were collated into a nine page A4 sized booklet printed in black and white using size 12 Arial font. The front page consisted of instructions to the participants, a consent form and a question asking for information about their level of physics knowledge. Each of the following eight pages featured one of the physics problems, a pictorial multiple-choice selection showing the available answers and a text box with space for participants to write an explanation of the rationale behind their selection. The presentation of the problems was randomized, with each problem appearing once, and equally likely to appear on any page.

Participants were asked to look at each problem and attempt to predict the path of the object as it fell to the ground. They were then asked to select, by circling the relevant number from the multiple choice answers, which of the five responses: 1. Backwards, 2. Straight Down, 3. Out \& Down, 4. Curved forwards (Parabolic) and 5. Straight Forwards, most closely resembled the path they had thought of. Participants were also asked to write a short rationale for their choice of path to make clear the connection between their answer and their intuition. After completing all problems participants returned the booklet and were thanked for their contribution.

## Results

The data of interest are the frequencies of each response (1-5) provided for a given problem. Table 2 gives these frequencies for each problem. The responses that might be considered consistent with naïve physics (NP) for a given problem are shown in green, those that are not and are better explained by an appeal to associative memory (AM) are shown in red.

## Table 2

| Response |  |  |  |  |  |
| ---: | ---: | ---: | ---: | ---: | ---: |
| Question | 1 | 2 | 3 | 4 | 5 |
| 1 | 7 | 18 | 3 | 3 | 5 |
| 2 | 4 | 12 | 2 | 17 | 1 |
| 3 | 0 | 3 | 11 | 21 | 1 |
| 4 | 0 | 25 | 4 | 5 | 2 |
| 5 | 9 | 21 | 0 | 2 | 4 |
| 6 | 1 | 3 | 3 | 28 | 1 |
| 7 | 0 | 0 | 13 | 21 | 2 |
| 8 | 0 | 5 | 24 | 7 | 0 |

We took the view that for a "Carried" problem (Problems 1, 5, 2 and 6) the NP congruent response would be 2 ("Straight Down") and the AM (or NP Incongruent) response would be 3 ("Out \& Down") or 4 ("Curved Forwards"). For a "Free" problem (Problems 3, 7, 4 and 8) the NP responses we allowed as congruent were either 3 ("Out \& Down") or 4 ("Curved Forwards"). This was done
because, in practice, distinguishing between responses 3 and 4 was difficult. The AM (or Incongruent) equivalent response for these problems was 2 ("Straight Down"). Responses 1 and 5 were relatively rarely used, so when computing Chi-Square values we collapsed responses 1 and 2 together, and responses 3,4 and 5 together. This gave two basic classes of answer, which we can characterise as mostly straight down and certainly not forwards (1 and 2), and mostly curved forwards (3, 4 and 5).

We first of all collapsed over the two problems per condition, and then ran a $\chi^{2}$ as a $4 \times 5$ contingency table ( 4 conditions by 5 responses) to see if there was any effect of condition on responding. The resultant $\chi^{2}=157$, 12df, $\mathrm{p}<.005$ suggests that there is. We then collapsed further so that there were only two response classes as already detailed (to ensure that the expected values in each cell were sufficiently high), and carried out a series of $\chi^{2}$ analyses to investigate the basis of this effect. A $2 \times 2$ contingency table (hence, 1df) analysis of congruency by response gave a $\chi^{2}=0.95, \mathrm{p}=\mathrm{ns}$, indicating no main effect of this factor. Analysis of "Free" vs. "Carried" by response gave a $\chi^{2}=26.13, \mathrm{p}<.001$, showing that this factor exerted a strong influence over choice of response, with, as expected, "Free" problems tending to produce mostly curved forwards responses and "Carried" problems mostly straight down responses. If we break this down further, then the $\chi^{2}=3.06$, $\mathrm{p}=\mathrm{ns}$ for the Incongruent data suggested that there was no significant difference in the distribution of responses caused by this factor in these problems, but the $\chi^{2}=78.06, \mathrm{p}<.001$ for the Congruent data indicates that it is these problems that drove the strong tendency for the two types of problem to lead to different responses.

The data of main interest, however, are how the Congruency factor influences performance on the "Free" and "Carried" problems. Taking the "Free" problems first, a $2 \times 2$ contingency table analysis with congruency as a factor, and collapsed response as the other, produced a $\chi^{2}=28.66, \mathrm{p}<.001$, with Congruent problems favouring a curved forwards response over straight down answers, and Incongruent problems significantly reducing this tendency. The "Carried" data show an even clearer effect, with Congruent problems favouring straight down responses and Incongruent data reversing this effect to show a strong tendency to elicit curved forwards responses, $\chi^{2}=34.09$, $\mathrm{p}<.001$. It seems that we were successful in our attempt to select problems that either favoured the response expected on the basis of naïve physics (Congruent), or were not congruent with this prediction and instead owed more to associative memory (Incongruent). This effect was particularly marked for the "Carried" problems, where there is essentially a pure interaction, with the Congruent problems behaving exactly as naïve physics would predict and the Incongruent problems showing quite the opposite pattern. The results corresponding to these analyses are shown in an easily interpretable form in Figure 4.

Figure 4. This shows the response difference score for each of the four conditions in our experiment. This score is simply the difference between the aggregated responses, $(3+4+5)-(1+2)$, and measures preference for one response class over the other, with a positive score denoting a bias in favor of the curved forwards class over the straight down alternative.

In essence, Figure 4 demonstrates that whilst it is entirely possible to get the pattern of results predicted by a naïve physics model for how people solve this type of problem, it is also possible to choose problems such that the effect is eliminated.

## General Discussion

What are we to conclude from these findings? Perhaps the first, and most obvious conclusion, is that a simple naïve physics theory that predicts the "straight down effect" because carried objects do not have any impetus of their own is not going to be able to explain these results. Either the theory is wrong, or it is not being applied in these situations. And this last is a real possibility. By giving considerable context to the problems, we have definitely biased participants in the way that they approach them, perhaps they do not invoke a naïve physics in these circumstances because the problems are not abstract enough?

Our objection to this analysis would be that naïve physics is exactly that which should be able to deal with these "real world" situations. And furthermore, there is as good qualitative evidence for naïve physics being used in our experiment as there is in other studies that have used this evidence to argue for a naïve physics theory. If we take the CC class of problem first, we have the following quotes that are typical of the approach taken to these problems by our participants.
For Problem 1: "As soon as the seagull lets go there is no forward momentum, so therefore it will drop straight down."
And for Problem 5: "The box dropped straight out of the plane so would not have been affected by the movement of the plane."

Both these problems are Carried Congruent scenarios. The typical response selection was No. 2, "straight down", and the explanation offered is the classic "an object has no impetus of its own if carried" justification given on the basis of a naïve physics. But if we now consider the explanations given for the Carried Incongruent problems we have for Problem 6: "From my experience of ball games, they don't just drop downwards."
Which clearly indicates a reliance on experience that we take to be mediated by associative memory. It might be argued that the memory simply overrides the predictions of the theory in this instance, and of course this is a possible explanation of the forward path typically chosen for this problem. But when we come to Problem 4, one of the Free Incongruent scenarios, then the justification offered for choosing the straight down response (No. 2) is in Problem 4: "That's how skaters do it."
So we would have to argue that once again recall based on experience is overriding the predictions of the theory (which would predict that the path is curved forwards). At this point the reader will notice that in every case the answer chosen is one consistent with generic experience of the world, and this impression is confirmed by our final class of problem, Free Congruent, where the typical response is curved forwards as a naïve physics would predict, and the generic explanation for offering this response is in Problem 7:
"Due to moving at speed."
Which fits nicely with the idea that a freely moving object has impetus. Thus we have two conditions where we have the results and the rationale expected on a naïve physics view, and two conditions where we have the opposite. But in all cases, the responses and rationale seem grounded in experience, and an explanation based on extrapolation from experience is tenable. Surely in these circumstances it is more parsimonious to attribute the answers given to memory-based extrapolation from experience, rather than invoke some abstracted theory that has to be overridden much of the time?

But we do not think that just any memory-based extrapolation from experience will serve to explain our results. Instead, we believe that the memory involved is associative in nature, so that it has captured the basic statistical regularities embedded in experience and retrieves them on the basis of a surface similarity to the problem. As such, we believe that an error-correcting system (e.g. McClelland and Rumelhart, 1985, Rumelhart, Hinton and Williams, 1986, and see McLaren and Dickinson, 1990 for a discussion) is required, as this will be able to extract the necessary structure. A version of such a system that can then function as a model of associative memory would be ideal (e.g. see the model in McLaren, 2011, based on McLaren, 1993, and the most recent version of this in McLaren, Forrest and McLaren, 2012). Finally, the ability to capture structure over time will also be needed, and for this the SRN (Elman, 1990) and it's more sophisticated variant the Augmented SRN (Cleeremans and McClelland, 1991, see
also Yeates, Jones, Wills, McLaren and McLaren, in press, and the APECS variant in Jones and McLaren, 2001) fits the bill.

This more primitive, associative system is only part of the story, however, we also postulate another rule-based system that takes the output of associative memory and then constructs a story about the answer given around it. In doing this we are advocating a dual-process theory of cognition along the lines of that given in McLaren, Green and Mackintosh (1994), and illustrated in Spiegel and McLaren (2003, 2006) and Jones and McLaren (2009). It is this combination of extrapolation based on experience, followed by induction of some heuristic to explain why a particular answer has been given, that we believe has led to the notion of a naïve physics. It results in reliably incorrect answers to physics problems, and a narrative that accompanies these answers. The point of our research, however, is to show that if we frame what is essentially the same problem in a different way, so that we access a different type of experience, then the answer changes and so does the accompanying narrative. Clearly, if a deeper physical analysis of the problems were involved in accessing experience, the answer to all the problems studied here would be the same, a parabolic path forwards. Hence we have to postulate retrieval on the basis of surface similarity for this aspect of our theory to work. We would then argue that actually the inductive inference that suggests a naïve physics is more a matter of an attempt to "make sense" of our participants intuitive response to these scenarios.

## Conclusion

We have arrived at a position where the statements made by participants attempting to solve simple physics problems and taken to support the existence of a naïve physics are seen as post-hoc rationalization for the answer given rather than causally implicated in that answer. We believe that it is extrapolation based on experience, via retrieval from associative memory (that is itself the product of associative learning), which is responsible for the reliably incorrect answers given to the problems studied here. We would go further, and say that our position also applies to the more abstract problems often studied in naïve physics experiments, though clearly here the experiential memories involved must be of a more generic nature. Take as an example the problem shown in Figure 1. How are we to explain that result? What memory could be accessed for that problem? There are not many retrieval cues, just a curved tube and a ball bearing. But this is enough to retrieve memories of water emerging from a garden hose (as these are often curved) - and the path the water takes is typically curved as well. The analogy between hose and problem is, of course, incorrect - but the superficial similarity exists and this is what drives associative processing. The result is an extrapolation to an incorrect, curved path, because it feels right. And then we tell a story about why we gave that answer. The great advantage of this explanation is that it
generalizes to the results reported in this paper. And so we conclude that as a theory of why we seem to have the wrong idea about how objects move, it is to be preferred to the naïve physics point of view.

#### Abstract

In sequential diagnostic reasoning, the goal is to infer the probability of a cause event from sequentially observed effects. Typically, studies investigating such tasks provide subjects with precise quantitative information regarding the strength of the relations between causes and effects. By contrast, we examined people's performance when this information is communicated through qualitative, rather vague verbal terms (e.g., " $X$ occasionally causes symptom $A$ "). We conducted an experiment in which we compared subjects’ judgments with a Bayesian model whose predictions were derived using numeric equivalents of various verbal terms from an unrelated study with different subjects. We found a remarkably close correspondence between subjects' diagnostic judgments based on verbal information and the model's predictions, as well as compared to a matched control condition in which information was presented numerically. Additionally, we observed interindividual differences regarding the temporal weighting of evidence.

Keywords: Sequential diagnostic reasoning; verbal reasoning; causal inference; Bayesian models; recency effects; linguistic probability terms; evidence accumulation

## Introduction

In diagnostic reasoning, the goal is to infer the probability of a cause event from observing its effects. The characteristic feature of sequential diagnostic reasoning is that multiple pieces of evidence are observed at different points in time. For instance, a doctor whose aim is to infer the cause of a patient's symptoms may take a blood sample and order different diagnostic tests. The test results may come in distributed over time, with each result potentially providing evidence for different diseases. Thus, sequential diagnostic reasoning requires keeping track of the evidence and the hypotheses under consideration.

We investigated different aspects of sequential diagnostic reasoning. Theoretically, we considered different ways in which such tasks can be modeled. For instance, standard probability calculus (e.g., Bayes's rule) is not sensitive to the temporal dynamics of evidence accumulation. Yet, there are ways to incorporate temporal weighting of evidence into probabilistic models of diagnostic reasoning and to model its potential influence on people's inferences.

Empirically, we were interested in investigating diagnostic reasoning with verbal information. In many real-world situations, everyday language is used to communicate probability or frequency information (Budescu \& Wallsten,

1995; Teigen \& Brun, 2003). For example, we might find it unusual if a doctor told us that the probability of a particular disease causing some symptom is $66 \%$. By contrast, a statement such as "disease $X$ frequently causes symptom $A$ " may feel more natural, despite the apparent lack of preciseness (Wallsten, Budescu, Zwick, \& Kemp, 1993).

Although using verbal probability terms is common in many real-world situations, they do not easily fit with computational accounts of cognition. As a consequence, in most behavioral studies subjects are provided with precise quantitative information (e.g., Meder, Mayrhofer, \& Waldmann, 2009). By contrast, we investigated reasoning with verbal information by using the numeric equivalents of linguistic terms (Bocklisch, Bocklisch, \& Krems, 2012) to derive model predictions. This allowed us to examine people's capacity to make diagnostic inferences in the absence of quantitative information and to compare their judgments to different accounts, including variants of Bayesian and linear models. To test for the temporal weighting of information, we varied the testing conditions by manipulating whether all evidence obtained so far was directly available when making a judgment or had to be partially retrieved from memory.

## Modeling Sequential Diagnostic Reasoning

The characteristic feature of sequential diagnostic reasoning is that different pieces of evidence are acquired step by step. Consider the causal model shown in Figure 1a. There are two (mutually exclusive) cause events, $X$ and $Y$; each can generate effects $A, B, C$, and $D$. In our experiment the cause variables were two chemical substances and the effects were different symptoms caused by these substances. The symptoms were observed sequentially and the goal was to infer whether $X$ or $Y$ caused them. How can such inferences be formally modeled?

## Standard Model: "Simple" Bayes

Let $S$ denote a set of symptoms $\left\{S_{1}, \ldots, S_{T}\right\}$, and let $X$ and $Y$ denote two mutually exclusive causes that can generate $S$. Since $X$ and $Y$ are mutually exclusive, $P(Y \mid S)=1-P(X \mid S)$. The posterior probability of cause $Y$ given the symptoms, $P(Y \mid S)$, can be computed using Bayes's rule:

$$
\begin{equation*}
P(Y \mid S)=\frac{P(S \mid Y) P(Y)}{P(S \mid Y) P(Y)+P(S \mid X) P(X)} \tag{1}
\end{equation*}
$$

where $P(S \mid Y)$ denotes the likelihood of the symptoms given cause $Y, P(Y)$ is the base rate of cause $Y$, and $P(S \mid X)$ and $P(X)$ denote the corresponding estimates for the alternative cause.

We considered only situations in which $X$ and $Y$ were equally likely a priori, thus $P(X)=\mathrm{P}(Y)=.5$. In this case, Eq. (1) simplifies to

$$
\begin{equation*}
P(Y \mid S)=\frac{P(S \mid Y)}{P(S \mid Y)+P(S \mid X)} \tag{2}
\end{equation*}
$$

Thus, the posterior probability of $Y$ is a function of the likelihood of the set of symptoms $S$ under each of the two hypotheses $X$ and $Y$.

## Temporal Weighting of Evidence: "Memory" Bayes

For the simple Bayes model, the temporal order in which observations are made does not matter: The resulting probabilities are the same regardless of whether beliefs are updated sequentially according to the individual symptoms or conditional on all symptoms at once.

However, we were also interested in modeling the sequential dynamics of evidence accumulation. For instance, diagnostic inferences can be influenced by memory limitations, such as the (partial) neglect of earlier obtained evidence. To model the influence of time, we applied the log odds form of Bayes's rule to the target inference:

$$
\begin{equation*}
\varphi=\log \frac{P(Y \mid S)}{P(X \mid S)}=\log \frac{P(S \mid Y)}{P(S \mid X)}+\log \frac{P(Y)}{P(X)} \tag{3}
\end{equation*}
$$

Assuming both hypotheses are equally likely a priori, we can omit the prior odds from the derivation and expand the likelihood odds by summing over the sequence of symptoms $S_{1}, \ldots, S_{T}$ given their conditional independence:

$$
\begin{equation*}
\varphi=\sum_{t=1}^{T} \log \frac{P\left(S_{t} \mid Y\right)}{P\left(S_{t} \mid X\right)} \tag{4}
\end{equation*}
$$

where $t$ is the current symptom and $T$ is the total number of symptoms observed so far.

The log posterior odds can then be transformed into a conditional probability by an inverse-logit transformation:

$$
\begin{equation*}
P(Y \mid S)=\frac{1}{1+e^{-\varphi}} \tag{5}
\end{equation*}
$$

This equation is mathematically equivalent to the standard form of Bayes's rule for the posterior probability of $Y$ given the set of symptoms $S$ as shown in Eq. (2).

Importantly, the log-odds form allows us to introduce an exponential decay parameter $\delta$ that controls the weighting of symptoms in the course of their presentation (Steyvers, Tenenbaum, Wagenmakers, \& Blum, 2003). Therefore, we replace Eq. (4) by

$$
\begin{equation*}
\varphi=\sum_{t=1}^{T}\left[\log \frac{P\left(S_{t} \mid Y\right)}{P\left(S_{t} \mid X\right)}\right] e^{-\frac{T-t}{\delta}} \tag{6}
\end{equation*}
$$

In the limit, if $\delta=\infty$, there is no decay and Eq. (6) reduces to Eq. (4). In this case, all symptoms are equally weighted and symptom order does not matter (as predicted by the simple Bayes model). The closer $\delta$ is to 0 , the more weight is given to the current symptom. If $\delta=0$, the posterior probability depends on only the most recent symptom, yielding an inference strategy that is completely ignorant of past information (e.g., an agent without memory). Thus, "memory" Bayes can be used to model recency effects (Hogarth \& Einhorn, 1992; Trueblood \& Busemeyer, 2011).

## Mapping Verbal Terms to Numbers

A key question of our research was how accurately people reason with verbal information, absolutely and relative to situations in which quantitative information is available. Answering this requires translating verbal expressions into a numeric representation that can be used to derive precise model predictions for the verbal reasoning task.

We used numeric equivalents of verbal expressions from a study by Bocklisch et al. (2012). They asked subjects to provide numeric estimates for different verbal expressions in a frequency format (e.g., It is frequently necessary to work at a rapid pace means "in $X$ of 100 work tasks/cases"). This mapping of words to numbers provided the basis for our empirical study, in which we used the four verbal expressions "infrequently", "occasionally", "frequently", and "almost always" to convey the strength of the cause-effect relations. ${ }^{1}$ The corresponding numeric mean estimates were $19 \%, 29 \%, 66 \%$, and $88 \%$ (Figure 1b).

These estimates were used to derive posterior probabilities of the causes given the symptoms via Bayes's rule [Eq. (1)], which served as normative benchmarks for evaluating subjects' diagnostic judgments. Note that the numeric equivalents were elicited from a different, unrelated sample from the one used in our study.

[^152]
## Experiment

The main goal of our study was to investigate sequential diagnostic reasoning with verbal information and compare different presentation formats with respect to the temporal weighting of evidence.

The first factor we manipulated was the way in which subjects were informed about the strength of the relations between causes and effects. In the verbal condition the strength of the individual relations was conveyed through four verbal terms ("infrequently", "occasionally", "frequently", "almost always"). In the numeric condition, causal strengths were presented in a percentage format. The two formats were matched using the estimates from Bocklisch et al. (2012). For instance, in the verbal condition subjects learned that $X$ "almost always" causes $A$, whereas in the numeric condition subjects learned that the probability of $X$ causing $A$ is $88 \%$ (see Figure 1b).

With the second manipulation we aimed to investigate possible influences of temporal weighting on diagnostic judgments (i.e., recency effects). In the single-symptom condition, only the current symptom was visible on the computer screen when participants made the diagnostic judgment. In the all-symptoms condition, the full set of symptoms reported so far was visible on the screen when they made a diagnosis. ${ }^{2}$ The rationale behind this manipulation was that there might be a tendency to overweight the currently presented symptom when previously obtained evidence needs to be recalled from memory.

## Method

Participants One hundred fifty-six students (103 women; $M_{\text {age }}=23.4$ years) from the University of Göttingen, Germany, participated in this experiment as part of a series of various unrelated computer-based experiments. Subjects either received course credit or were paid $€ 8$ per hour.

Materials and Procedure We used a hypothetical medical diagnosis scenario in which the subjects' task was to find out which of two fictitious chemical substances was the cause of certain symptoms in patients. The instructions asked subjects to take the role of a doctor being responsible for the workers at two chemical plants. At one plant workers may come in contact with the substance "Altexon"; at the other they may have contact with "Zyroxan". Each of these substances can cause four symptoms: dizziness, fever, headache, and vomiting. The assignment of labels to causes (substances) and effects (symptoms) was randomized.
Subjects were informed that their task would be to diagnose a series of workers who had had contact with either of the two substances. The instructions explicitly stated that accidents were equally likely to happen in each of the plants (i.e., the base rate of each cause was $50 \%$ ). Subjects were

[^153]also told that the patients would report their symptoms sequentially.
The experiment consisted of two phases: a learning phase, in which subjects learned the strengths of the individual causal relations, and a test phase, in which subjects were sequentially presented with symptoms of different patients and had to make a diagnostic judgment after each symptom.

Figure 1b illustrates the strengths of the relations between substances and symptoms according to the two presentation formats. In the learning phase, the subjects' task was to learn the strength of the individual relations in a trial-bytrial fashion. On each trial, subjects were shown a substance along with a symptom and had to estimate how often the substance causes the symptom. In the verbal condition, possible answers were "infrequently", "occasionally", "frequently", and "almost always". In the numeric condition, the corresponding answers were $19 \%, 33 \%, 66 \%$, and $88 \%$. After making an estimate, subjects received feedback regarding the actual relation. The eight relations were presented block-wise, with the order randomized within a block. To proceed to the test phase, subjects needed to answer two consecutive blocks correctly (or pass 12 blocks in total).
In the test phase, the subjects' task was to make diagnostic judgments for different sequences of symptoms, with each symptom sequence referring to a different patient who had come in contact with either $X$ or $Y$. Each test trial consisted of three sequentially presented symptoms (e.g., $A-D-C$ ), with a diagnostic judgment requested after each symptom. In the all-symptoms condition, all symptoms reported so far were present on the screen. In the single-symptom condition, only the current symptom was displayed. All judgments were given on an 11-point scale from 0 to 100 , with the endpoints labeled as "The patient definitely had contact with Altexon" and "The patient definitely had contact with Zyroxan".
Table 1 shows the six symptom sequences together with the posterior probabilities derived using the likelihoods shown in Figure 1b, assuming $P(X)=P(Y)=.5$. Additionally, we presented the six symptom sequences that entailed identical posterior probabilities for $X$ (e.g., $P(Y \mid A-D-$ $C)=P(X \mid D-A-B)$ such that diagnoses were counterbalanced. Thus, each subject saw 12 sequences in total. The corresponding pairs were later recoded and aggregated.
The test trials were administered in random order. After the test phase, we tested subjects again with respect to the strength of the individual substance-symptom relations (as learned in the learning phase) by presenting an additional

Table 1: Test trials with sequentially presented symptoms.

| Posterior | Symptom sequence |  |  |  |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
|  | $A-D-C$ | $D-A-C$ | $B-C-A$ | $C-B-A$ | $A-C-D$ | $C-A-D$ |
|  | .18 | .82 | .31 | .69 | .18 | .69 |
|  | .50 | .50 | .50 | .50 | .33 | .33 |
|  | .69 | .69 | .18 | .18 | .69 | .69 |

Note. Numbers refer to the posterior probability of cause $Y$ given a set of symptoms $S$ according to the simple Bayes model.
block of the learning phase (without feedback). This served as a manipulation check to ensure that subjects still remembered the relations between substances and symptoms.

Design Subjects were randomly assigned to one of the 2 (numeric vs. verbal) $\times 2$ (single vs. all symptoms) betweensubjects conditions. Within each subject, we aggregated over the (recoded) judgments within the counterbalanced pairs of trials, yielding 6 (trials) $\times 3$ (symptoms) withinsubject conditions with judged $P(Y \mid S)$ as dependent measure.

## Results and Discussion

Learning Criterion At the end of the experiment we tested subjects on the eight substance-symptom relations presented in the learning phase. Because the strength of the individual relations is the basis for the diagnostic judgments, we excluded all subjects who could not reproduce at least seven of the eight relations correctly. Accordingly, $28.2 \%$ of the subjects were excluded from the analyses, yielding between 27 and 30 valid subjects per condition (total $N=112$ ).

Overall Fit Figure 2 shows subjects' mean diagnostic judgments for the different symptom sequences along with the posterior probabilities derived from the simple Bayes model. A first inspection of the data indicates that subjects' judgments were remarkably accurate, with estimates being close to the true posteriors. This was the case regardless of whether information was provided in a verbal or numeric format (especially in the all-symptoms condition; see lefthand side of Figure 2). Thus, subjects were capable of making pretty accurate inferences when reasoning with verbal information. This close correspondence is particularly remarkable because the numeric equivalents of the verbal terms were taken from a different sample of subjects who participated in an unrelated study (Bocklisch et al., 2012).

Before conducting the model-based analysis, we ran a mixed analysis of variance with the 2 (numeric vs. verbal) $\times$ 2 (single vs. all symptoms) conditions as between-subjects factors and the 6 (trials) $\times 3$ (symptoms) conditions as with-in-subject factors. The key result of this analysis was that there was no main effect of presentation format, $F(1,108)<1$, a weak effect of the single- vs. all-symptom presentation manipulation, $F(1,108)=3.1, p=.08, \eta_{\mathrm{p}}=.03$, and no interaction $(F<1)$.

To evaluate subjects' overall accuracy we computed the correlation and mean squared error (MSE) between the empirical judgments and the posterior probabilities derived from the simple Bayes model (note that no fitting is involved here). To address if symptoms are weighted differently in sequential reasoning, we fitted the decay parameter $\delta$ of the "memory" Bayes model to the data (separately for each condition, using the MSE as fitting criterion). ${ }^{3}$ The relative size of the decay parameter $\delta$ in the single- vs. allsymptoms condition gives an idea of whether the testing

[^154]

Figure 2: Mean diagnostic judgments ( $\pm 95 \% \mathrm{CI}$ ) and predictions of the simple Bayes model. Rows represent the different trials (see Table 1), separately by testing procedure (all-symptoms vs. single-symptom presentation).
procedure influences people's judgments, in particular whether there is a tendency to neglect previous evidence when only the current symptom is shown when performing a diagnostic judgment. This should result in lower values of the decay parameter $\delta$ for the single-symptom condition relative to the all-symptoms condition. ${ }^{4}$

Table 2: Fits of the "simple" and "memory" Bayes models.

| Format | Symptoms | Simple Bayes |  | Memory Bayes |  |  |
| :--- | :--- | :---: | :---: | :---: | :---: | :---: |
|  |  | $r$ | $M S E$ | $r$ | $M S E$ | $\delta$ |
| Verbal | All | .991 | .0008 | .991 | .0009 | $>$ le +10 |
|  | Single | .952 | .0089 | .983 | .0036 | 2 |
|  | All | .996 | .0004 | .996 | .0004 | 40 |
|  | Single | .971 | .0028 | .988 | .0014 | 4.5 |

Table 2 shows the fits of the two models. Overall, both the (high) correlations and the (low) MSE indicate that the models' predictions fit well with subjects' judgments. In the all-symptoms conditions, the fit for simple Bayes was almost perfect ( $r=.991$ and $r=.996$, respectively), mirroring that for 35 of 36 ( 6 trials $\times 3$ symptoms $\times 2$ formats [verbal vs. numeric]) data points, the model's predictions fell inside the $95 \%$ confidence interval.

The results also indicate some neglect of previous evidence in both single-symptom conditions, in which only the current symptom was displayed on the screen when subjects made a diagnostic judgment (cf. Figure 2). Here, in both the verbal and the numeric condition, lower values for $\delta$ were obtained than in the all-symptoms conditions (see Table 2). Consistent with this finding, for these conditions the memory Bayes model achieved a higher fit than the simple Bayes model, in terms of both the correlation and the MSE. This result indicates that subjects were more likely to overweight the current evidence when previous symptoms had to be recalled from memory.

Model-Based Clustering Temporal weighting of cumulative evidence might not be due to the characteristics of the task or the reasoning context alone but might also result from interindividual differences or strategies. We therefore explored if it is possible to identify homogenous subgroups of subjects differing with respect to their temporal weighting of symptoms (i.e., that differ in the $\delta$ parameter).
To identify such clusters, we adapted the model-based clustering technique introduced by Steyvers et al. (2003), which was inspired by $K$-means clustering. The clustering problem requires solving two problems simultaneously: first, assigning subjects to clusters such that clusters are homogenous with respect to the model predictions, and second, estimating the best-fitting $\delta$ parameter for each cluster. This problem can be approximately solved by a recursive algorithm that starts with a random assignment of subjects to clusters and then iterates over two steps, namely, fitting and re-assignment, until no subject changes cluster. ${ }^{5}$

[^155]Table 3: Results of the model-based clustering.

| Format | Symptoms | Cluster 1 |  |  |  | Cluster 2 |  |  |  |
| :--- | :--- | :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | $\delta$ | $n$ | $r$ | MSE | $\delta$ | $n$ | $r$ | $M S E$ |
| Verbal | All | $\infty$ | 28 | .991 | .0008 | - | - | - | - |
|  | Single | $\infty$ | 15 | .994 | .0014 | 0 | 12 | .993 | .0047 |
| Numeric | All | $\infty$ | 24 | .997 | .0003 | 1.5 | 3 | .969 | .0056 |
|  | Single | 85 | 21 | .993 | .0010 | 0.6 | 9 | .989 | .0017 |

Note. $\delta=\infty$ means that the estimate is greater than $1 \mathrm{e}+10$; in this case there is essentially no difference from the predictions of the simple Bayes model. $\delta=0$ means that the estimate is smaller than $1 \mathrm{e}-10$; in this case there is essentially no difference from the prediction of Bayes's rule taking into account only the currently presented symptom.

We applied this procedure to each of the four conditions; the results are shown in Table 3. The verbal all-symptoms condition yielded only one cluster as a solution, whereas the other three conditions yielded stable two-cluster solutions. Remarkably, in each condition the majority of subjects were assigned to a cluster that is best represented by a very high $\delta$ parameter of the memory Bayes model. Essentially, this means that these subjects are best described by a prediction profile that is almost identical to the predictions of the simple Bayes model. In the single-symptom conditions, however, a substantial proportion of people were best described by a quite low $\delta$ parameter, meaning that their diagnostic judgments were almost exclusively determined by the currently presented symptom. Taken together, the clustering results strengthen the findings we already obtained by the overall fitting of the data.

Linear Models of Diagnostic Judgment In our study, people's diagnostic judgments corresponded strongly to the predictions of Bayes's rule. Can alternative models approximate these predictions? We here consider one alternative class of models, namely, weighted-additive (WADD) approaches. From this view, the cause event is inferred using an average (i.e., linear) combination of symptom weights:

$$
\begin{equation*}
P(Y \mid S)=\frac{1}{T} \sum_{t=1}^{T} w_{S_{t}} \tag{7}
\end{equation*}
$$

where $t$ is the current symptom and $T$ is the total number of symptoms observed so far.

We tested three different linear models that make different assumptions regarding the decision weights. The simplest model, tallying, simply counts symptoms. In our scenario, symptoms $A$ and $B$ are more likely to be generated by $X$, whereas $C$ and $D$ are more likely to be generated by $Y$. Given a set of symptoms, one simply tallies the evidence. For instance, given the sequence $A-C-D$, two of the three symptoms provide evidence for $Y$; accordingly, the resulting

[^156]estimate would be $2 / 3$. Note that this result is very close to the true probability, which is .69 in this case.

The second linear model assumes that the decision weights reflect the strength of the cause-effect relations; we therefore call it likelihood WADD. This model simply sums over the likelihoods and normalizes the result by dividing it by the number of presented symptoms. Given the sequence $A-C-D$, this model would predict that the probability of $Y$ is $.58[(.19+.66+.88) / 3]$, which for this sequence is quite close to the true probability of 69 .

Finally, we examined the predictions of an "optimal" WADD model by fitting the weights to the data, using MSE minimization as a criterion. This model essentially serves as a benchmark, as it provides the best fit given the functional form of the model (linear combination) and the data.

Table 4: Fits of the linear models.

| Format | Symptoms | Tallying |  | $\begin{aligned} & \hline \text { Likelihood } \\ & \text { WADD } \\ & \hline \end{aligned}$ |  | Optimal <br> WADD |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | $r$ | MSE | $r$ | MSE | $r$ | MSE |
| Verbal | All | . 861 | . 0278 | . 901 | . 0093 | . 901 | . 0085 |
|  | Single | . 817 | . 0320 | . 856 | . 0242 | . 857 | . 0197 |
| Numeric | All | . 864 | . 0266 | . 896 | . 0106 | . 898 | . 0094 |
|  | Single | . 848 | . 0285 | . 880 | . 0108 | . 881 | . 0102 |

The results (Table 4) show that all linear models achieved a respectable fit, but none could match the Bayesian models. These results speak against the idea that our subjects used a linear-additive strategy to make judgments.

## General Discussion

Although verbal terms such as "infrequently", "occasionally", and "frequently" are rather vague and imprecise, they are commonly used in many real-world situations. In contrast, researchers interested in human probabilistic thinking and judgment under uncertainty usually provide their subjects with precise numeric information in order to compare their behavior and inferences to the predictions of computational models, which typically also require numeric input.

A key motivation underlying the present work was to investigate subjects' reasoning in situations that more closely resemble real-world situations, in which inferences must often be drawn in the absence of reliable quantitative information. Using a sequential diagnostic reasoning task, we observed that people's inferences were surprisingly accurate when information on cause-effect relations was conveyed merely through linguistic terms. In fact, performance was almost indiscernible from a control condition in which subjects were provided with numeric information. The fact that we took the numeric equivalents from a different study (Bocklisch et al., 2012) supports research showing that the interpretation of linguistic frequency terms is relatively stable across populations (Mosteller \& Youtz, 1990).

Generally, subjects' diagnostic judgments closely resembled the prediction of a simple Bayes model that operates on matched numeric values. This is a promising finding for applying computational models of cognition to verbal reasoning tasks. It is particularly interesting for Bayesian mod-
eling, as this approach is not restricted to numeric point estimates (e.g., mean of an elicited frequency term distributions) but can also operate on full distributions (e.g., fitted Beta distributions).

Furthermore, we investigated the temporal weighting of evidence. We found that symptoms were equally weighted when all relevant symptoms were available during judgment, but we also observed a neglect of previous evidence when only the current symptom was present. Model-based cluster analyses revealed that this was due to a subgroup of subjects who considered only the current symptom, whereas most people took into account all evidence in a normative fashion. Overall, our results contrast with views that consider human probabilistic reasoning as flawed and error prone.

## Acknowledgments

Both authors contributed equally to this research. We thank Franziska Bocklisch, Georg Jahn, Felix Rebitschek, and Michael Waldmann for helpful comments on this project. This research was supported by grants Wa 621/22 and Me 3717/2 from the Deutsche Forschungsgemeinschaft (DFG) as part of the priority program "New Frameworks of Rationality" (SPP 1516).

#### Abstract

Humans can perform several different tasks on the same set of stimuli in rapid alternation. Each task, signaled by a distinct task cue, may require the classification of stimuli using a different stimulus attribute. However, such "task switching" performance comes at a cost, as expressed by weaker performance when switching rather than repeating tasks. This cost is often claimed to be the consequence of a mental reorientation away from the previous task and towards the new task, requiring executive control of behavior. Alternatively, task switching could simply be based on the retrieval of different cue-stimulus-response associations. In this experiment, pigeons learned go-left/go-right discriminations between grating patterns according to either their spatial frequency or their orientation, depending on the color of the pattern (the task cue). When humans solved the same tasks on the basis of verbalizable rules, they responded more slowly and made more errors on trials where they had to switch between tasks than when repeating the same task. Pigeons did not show this "switch cost"; but like humans, their performance was significantly worse when the response (left or right) to a given stimulus varied between tasks than when it stayed the same (the "congruency effect"). Larger effects of both switch costs and congruency were observed in humans learning the tasks by trial and error. We discuss the potential driving factors behind these very different patterns of performance for both humans and pigeons.

Keywords: executive control; associative learning; task switching; humans; pigeons; comparative cognition.

## Introduction

Humans are able to perform two or more different tasks on the same stimulus material when cued to do so (called "task switching"). Typically, each task requires the classification of a set of stimuli according to a different stimulus attribute. The task that is to be performed in a given trial is indicated by a specific task cue (for example, subjects might be asked to judge a grating pattern by its spatial frequency when the color yellow is presented, or to classify the same stimulus according to whether it is vertically or horizontally orientated when the color red appears).

However, it is still a matter of debate which cognitive mechanisms underlie human task-switching ability. Humans may classify the stimuli they see based on rules, and a common phenomenon of task switching, namely longer reaction times and higher error rates after switching tasks compared to repeating the same task ("switch costs"), has been assumed to reflect the executive control processes
associated with this rule use. For example, humans might sort a series of stimuli based on their orientation while ignoring other available stimulus dimensions such as spatial frequency. In this context, switching from one task to the next involves executive control when identifying the current task, retrieving its specific stimulus-response rules into one's working memory (while deleting the rules of the previous task) and adjusting one's response reaction to the new requirements: in short, a mental disengagement from the previous task and preparation for the currently relevant task, known as "task-set reconfiguration" (Vandierendonck, Liefooghe \& Verbruggen, 2010). Switch costs are thought to reflect the need for such reconfiguration in switch trials but not in repeat trials, for which the task-set is already available (Monsell, 2003).

But, if we believe that humans have multiple processes available that support learning (McLaren, Green \& Mackintosh, 1994), task-switching phenomena might be the result of associative learning mechanisms, i.e., the retrieval of cue-stimulus-response associations (Logan \& Bundesen, 2003). Learning to respond correctly in a task-switching paradigm could be accomplished by associating the overall appearance of a stimulus with a certain response (Lea \& Wills, 2008). Each stimulus could be categorized by using its combined dimensions and comparing its similarity to a stimulus to which the correct response is known.

A task-switching phenomenon often observed in addition to switch costs, the effects of stimulus congruency (Monsell, Yeung \& Azuma, 2000), might indeed be better explained by associative learning processes than task-set reconfiguration. As each task makes use of the same set of multidimensional stimuli, stimulus values on individual dimensions can be defined as either congruent or incongruent in relation to the correct response towards them. If a stimulus is congruent, it always requires the same response regardless of the current task; learning to discriminate between different congruent stimuli thus takes the form of a component discrimination, in which the correct response depends on a single element of a multidimensional stimulus. However, when an incongruent stimulus is shown, the correct response varies depending on the current task in the manner of a biconditional discrimination. Given that there is good evidence that such discriminations are difficult to learn (Harris \& Livesey, 2008), it is no surprise that on trials in which a congruent stimulus is shown, reaction time and error rate are distinctly
lower compared to trials with an incongruent stimulus, and humans can exhibit large congruency effects (Monsell, Yeung \& Azuma, 2000). Experiments intended to elicit an associative approach to task switching in humans, either by only providing cue-stimulus-response contingencies instead of full task instructions or by forcing participants to learn how to respond by trial and error, have yielded very large congruency effects and switch costs that were considerably smaller than the effects of congruency (Forrest, Elchlepp, Monsell \& McLaren, 2012).

Humans can communicate the extent to which they refer to certain rules when reacting to a stimulus. It is therefore potentially possible to identify a group of participants who learned the responses based on rules about the stimulus dimensions and those who did not, and compare their performance to that of animals, who might not have the same cognitive mechanisms available.

Stoet and Snyder (2003) were the first to explicitly investigate task-switching effects in nonhuman animals. Their two rhesus macaques behaved very similarly to Forrest et al.'s (2012) humans who were presumed to be learning associatively: while their performance produced a large congruency effect, switch costs were rather small, and in fact absent in one animal. Stoet and Snyder (2003) acknowledged that monkeys might lack at least one of the cognitive control mechanisms necessary to solve taskswitching paradigms in the typical human way, but they did not doubt that their subjects used some form of executive control. However, the possibility remains that both humans and nonhuman animals might solve a task-switching paradigm associatively.

If humans who claim to be unaware of any rules underlying a task-switching paradigm employ an approach similar to that in animals assumedly solving the task by purely associative processes, such as the pigeon (Mackintosh, 1988), their performance would be expected to resemble that of those animals. For this purpose, pigeons might make a more suitable comparison than primates; they can also be tested in larger numbers than monkeys, so more reliable results should be obtained.

To design a paradigm suitable for use with both humans and animals, instead of relying on language-based stimuli or cues, we used varying values of the visual dimensions of color, orientation and spatial frequency to indicate a correct response. Additionally, we used trial-and-error training on cues and stimuli that resembled the conditioning procedures usually employed in animal testing. To investigate whether human performance under these conditions can be compared to that based entirely on associative-learning processes, we trained humans and pigeons on the same paradigm.

## Method

## Subjects

Twenty-four Psychology undergraduate students, in exchange for course credit, and eight pigeons (Columbia livia) participated in this experiment. Pigeons were kept in
an indoor aviary ( $2 \times 1 \times 2.5 \mathrm{~m}$ ) that housed 15 pigeons at the time of the experiment. They were maintained at or above $80 \%$ of their free-feeding weight. Both humans and pigeons were naïve to the testing stimuli, though pigeons had previously been trained to peck at a white observing key presented in the center of a black touch-sensitive display, followed by a peck at a red, blue, green or yellow colored circle appearing in the same position, and finally, to peck at a white reward key randomly presented either to the left or to the right of the display.

## Apparatus

All experiments were carried out inside the Washington Singer Laboratories at the University of Exeter. Pigeons were tested in one of eight identical $71 \times 50.5 \times 43.5 \mathrm{~cm}$ operant chambers. Each pigeon was always tested in the same chamber. One of the long walls of the chamber was fitted with a $31 \times 23.5 \mathrm{~cm}$ (15") touch monitor (Model 1547L 1024x768pxl TFT monitor, CarrollTouch infrared detector, ELO Touchsystems Inc.) mounted 12cm above the grid floor of the chamber. Two 2.8 Watt white houselights were mounted to either side above the screen; below the screen, mounted 4 cm above the chamber floor and directly below each house light, two $6 \times 5 \mathrm{~cm}$ apertures gave access to grain hoppers when solenoids were activated. The food hoppers were illuminated by a 2.8 Watt light when activated and contained a $2: 1$ mixture of hemp seed and conditioner. Also mounted below the screen between the two food hoppers, a 50 Ohm loudspeaker played white noise into the box as well as indicating effective pecks to target areas with an immediate beep. The interior of the box was monitored by a video camera attached to the short wall of the chamber opposite the chamber door. Contingencies were controlled and data collected using a PC computer running the Whisker system (Cardinal \& Aitken, 2010) with client programs written in Visual Basic 6.0. Humans were tested in a small experimental room on an iMac. The program was written in MatLab R2008b ${ }^{\circledR}$ asing the Psychtoolbox (Kleiner, Brainard \& Pelli, 2007) add-on and run using MatLab2011b ${ }^{\circledR}$.

## Procedure

For pigeons, each trial began with the presentation of an observing key (100 pixels in diameter) presented in the center of a black display. Following two pecks at the observing key, it was replaced by one of four task cues, a color-filled circle of 200 pixels in diameter, in the display center. Each of the two tasks was associated with two distinct cues: these were blue or yellow for task A, and red or green for task B. For humans, a trial started immediately with the presentation of the cue; that is, no observing key was presented. Pigeons had to peck the task cue twice, after which the task stimulus appeared, superimposed on the cue, making both the cue and the stimulus visible simultaneously. Humans were asked to mouse-click once on the cue, upon which the stimulus appeared in the same way as for pigeons.

Stimuli, made up as circular Gaussian patches of 200 pixels in diameter, consisted of one of four sinusoidal grating patterns, differing from another in two dimensions: spatial frequency - either low ( 2 cycles per 100 pixels (c/100px) for pigeons and $3 \mathrm{c} / 100 \mathrm{px}$ for humans) or high ( $12 \mathrm{c} / 100 \mathrm{px}$ for pigeons and $10 \mathrm{c} / 100 \mathrm{px}$ for humans) - and line orientation - either horizontal or vertical. All combinations of cue color, spatial frequency and orientation were used, resulting in 16 visually distinct images.

The correct response towards a stimulus depended on the task. For example, for some participants, task A required responding to the spatial frequency of the grating pattern, e.g., if a stimulus, regardless of the orientation of the pattern, had a low spatial frequency, the correct response towards this stimulus was to choose the left reward location, while stimuli with a high spatial frequency afforded choosing the right reward location. Conversely, in task B, stimuli would have to be classified according to the orientation of the grating pattern, regardless of its spatial frequency. That is, if a stimulus showed a horizontal pattern, it required a response to the left reward location, while a vertical pattern indicated a response to the right location as the correct one. Although blue and yellow were always assigned to task A, the stimulus attributes (spatial frequency or orientation) that were important for classification in task A and the reward location that was associated with any cuestimulus combination were counterbalanced across pigeons and across humans. As each stimulus always contained both spatial frequency and orientation information, some stimuli always required the same response, e.g., a horizontal pattern of low spatial frequency might always require a left response regardless of the current task. In addition to these congruent stimuli, responses to incongruent ones depended on the task at hand, for example, a horizontal stimulus with a high spatial frequency pattern might require a response to the left reward location on the orientation task but a response to the right location if the spatial frequency was to be judged.

For pigeons, pecking twice at the composite stimulus in the display center resulted in it being deleted from the center and simultaneously reappearing 200 pixels to the left and to the right of the display center as response keys. Pigeons made a final response by choosing the correct reward location (left or right) by pecking at the stimulus presented on that side. The two response keys were effective between 3 and 6 seconds after the onset of their presentation, after which a single peck at the correct key resulted in the activation of the corresponding food magazine for 2.5 seconds. During training only, if a pigeon developed a position bias, i.e., showed a strong tendency to peck one of the two response keys, responses to the more attended side were made ineffective for one to two (or more if necessary) seconds longer than to the less attended side. The release of the food magazine ended a trial. The inter-trial-interval to the next presentation of the observing key lasted between 15 and 30 seconds. Human participants were asked to mouseclick on the stimulus in the center of the screen, which led to
the appearance of two square, white response keys to the left and right side of the stimulus; the stimulus also remained on display. Participants responded to the stimulus by clicking on the response key that was associated with the present cue-stimulus combination. If the correct response key was chosen, the stimulus and response keys disappeared from the screen and the word "Correct" appeared in white letters next to a golden star for two seconds before the next trial began. If the wrong response key was clicked, the entire display was replaced by the phrase "WRONG!" in white letters. Participants were asked to respond as quickly as possible while making as few mistakes as possible.

Training Both pigeons and human participants received training on each task separately before attempting the taskswitching paradigm. The order in which the tasks were learned was counterbalanced across individuals of each species.

Pigeons received daily training sessions of 3 blocks of 24 trials each, showing each possible combination of the two cues of the task to be trained and the different variations of spatial frequency and orientation three times per block. The first block included a 25th trial (a repeat of the first trial of the session), as that first trial was not included in analyses, resulting in 73 trials per day in total. The order of cuestimuli combinations was randomized within blocks. Discrimination of the stimuli was considered successful if the pigeon responded correctly on at least $80 \%$ of trials within a daily training session, in at least three consecutive sessions. Pigeons thus received a minimum of 3 sessions, or 219 trials, on a task before starting training on the other task. The number of sessions on each task was gradually reduced until pigeons were able to switch between tasks from one day to the next and still perform at or above $80 \%$ correct responses in each session. For humans, training on each separate task was carried out in four blocks of trials. A block was considered successful if subjects reached the criterion of $80 \%$ or more correct responses in the previous trials that included each stimulus at least twice. Thus, the criterion was based on at least eight consecutive trials, two for each of the four different combinations of spatial frequency and orientation. The first training block of a task contained at least 32 trials, then, the second task was trained in at least 32 trials. After this, the first task was repeated for a minimum of another 16 trials until criterion was reached; finally, the second task was repeated for at least 16 trials until the participant reached criterion in this fourth and final training block.

Test Once each task was trained separately to success criterion, subjects entered the task-switching part of the experiment, in which task $A$ and task $B$ trials were intermingled. The task sequence was partially randomized to produce a switch trial in one third of the trials; for nonswitch trials, the two task cues alternated so that the same cue was never shown for two trials in a row. Pigeons received 20 sessions of 73 trials each, or 1460 trials in total; in each block, the four combinations of spatial frequency
and orientation were presented three times per task. Humans completed 24 blocks of 25 trials, a total of 600 trials, in the same manner as described above, with each of the combinations occurring twice on a task-repeat trial and once on a task-switch trial per two blocks. After completion of the task-switching procedure, we determined, via a questionnaire, which approach they used to solve the experiment and assessed their ability to describe the rules that defined a correct response. If a participant was able to correctly identify the contingencies between a task cue and certain stimulus characteristics, he or she was considered to have understood and successfully applied the underlying rule. If participants could not explain any relationship between stimuli, cues and the correct response, this was taken as an indication that they had not used task rules.

## Results

The only basis for comparing the two species was accuracy (errors) when choosing a response key, as it was not possible to obtain an accurate estimation of response latencies for pigeons, although we did record each subject's latency to peck/click on a response key. Restricting pigeons' time to respond would have required differential reinforcement of short response latencies, which could potentially have impaired learning of the cue-stimulusresponse contingencies. Thus, all results reported are for error rates when making a response. We ran four of the birds on ten more sessions with a strongly reduced inter-trial interval after they had completed the main study to assess whether allowing for unrestricted response times potentially decreased any effects, and this yielded similar results to those reported below. Nevertheless, the possibility remains that the particular timing requirements of the task we used may play an important role in producing our results.

For the human data, we calculated participants' error rate when choosing a response key as a percentage for each pair of consecutive blocks, i.e., for 48 trials (the first trial of each block was excluded from analysis, since it was neither a switch nor a repeat trial), resulting in 12 block pairs per participant. Pigeons' performance was calculated for each of the 20 sessions, excluding the first trial of each session.

The different training methods we employed for humans and pigeons resulted in substantially lower error rates for
pigeons. However, while it was necessary to train pigeons to produce error rates below $20 \%$ throughout, we were reluctant to give more training to humans as it would have increased the chances of humans inferring the task rules. As it was, nine of the 24 human participants were able to verbalize the rules for both tasks at the end of the experiment. A further eight reported having discovered one of the two rules or having made up their own solving strategies. Because of the ambiguity as to what mechanisms these participants relied on to solve the tasks, we did not include their data in any further analyses. The remaining seven participants stated that they were not aware of any relationships between the stimuli and the correct response, and it is these participants that most naturally allow comparison with performance by the pigeons on this task.

To investigate the extent to which both humans and pigeons were influenced by switch costs or congruency effects, we conducted a 3-way repeated measure ANOVA using Switch/Repeat Trials, Stimulus Congruency and Block Pair Sequence/Session as within-subject factors. Analyses were carried out separately for humans, according to the number of rules humans could name (No Rule and 2 Rules) and for pigeons. F and p values for the effects mentioned below are reported in Table 1. All results were subjected to Huynh-Feldt correction.

Humans received an average of 137 trials before entering the task-switching stage; pigeons entered the test phase after an average of 109 training sessions. Since the pigeons had received substantially longer training, we conducted all analyses on the the first half of the sessions as well as on the full data set, to rule out potential floor effects. Results were the same for both data sets as the pigeons did not significantly improve their performance over time; accordingly, the results reported are from the full data set of 20 sessions.

Performance of humans was influenced by whether they were able to verbalize the discrimination rules or not; error rates were significantly lower for people who were able to verbalize both tasks ( 2 Rules; $\mathrm{M}=12.1 \%, \mathrm{SD}=2.0$ ) than if No Rule ( $\mathrm{M}=36.1 \%, \mathrm{SD}=2.3$ ) had been inferred $(\mathrm{F}(1,14)=$ $62.20, \mathrm{p}<.001$ ). Pigeons' error rates were low ( $\mathrm{M}=9.1 \%$, $\mathrm{SD}=3.7$ ), due to the amount of they received.

Table 1: Overall F and p values for Switch/Repeat Trials, Stimulus Congruency, Block Pair Sequence/Sessions, and significant interactions between factors for humans depending on the number of rules they named and for pigeons. P values below .05 are marked in bold.

| Switch * Congruency | $14.18(1,8)$ | $\mathbf{0 0 5}$ | $10.69(1,6)$ | $\mathbf{. 0 1 7}$ | $0.55(1,7)$ | .484 |  |

Figure 1: Stimulus congruency effects (difference in error rates between incongruent and congruent stimuli) in trials in which the task repeats and those in which it switches from the previous trial, and across all trials ('Total').

The factor of Stimulus Congruency strongly influenced performance for all groups; human participants and pigeons made more errors when faced with incongruent stimuli than when dealing with congruent ones (Figure 1, 'Total').

Similarly, there was a highly significant effect of the factor Switch/Repeat for humans regardless of the number of rules verbalized: they performed less well on switch trials, which required executing the opposite task to the one on the previous trial, than on repeat trials (Figure 2, 'Total'). However, while the effect was present in both human groups, pigeons demonstrated a noticeable lack of switch costs (Figure 2, 'Total').

All human participants showed significantly higher switch costs on trials with incongruent stimuli than on those trials in which the stimulus was congruent, i.e. there was a significant interaction between the two factors for all three human groups (Figure 2).

The sequence of Block Pairs (or Sessions for pigeons) was reliable for 2-Rules users only, implying that these participants learned to make fewer mistakes as the experiment carried on, while No-Rule users and pigeons maintained their initial level of performance throughout. For those participants who were able to verbalize the two rules, both the effects of Switch/Repeat trials and Stimulus Congruency declined over the course of the experiment, i.e., this group experienced interaction effects of Block Pairs with the two other main factors.
Although not relevant for the species comparisons, it can be noted that, in their reaction times, human showed a similar pattern to what has previously been observed in humans using different learning approaches (Forrest et al., 2012); that is, those who inferred both rules suffered from switch costs much more ( $\mathrm{M}=149.70 \mathrm{~ms}$ ) than from congruency effects ( $\mathrm{M}=94.78 \mathrm{~ms}$ ), whereas humans who did not use any rules were largely affected by congruency effects ( $\mathrm{M}=50.34 \mathrm{~ms}$ ) but barely showed any costs in switching between tasks ( $\mathrm{M}=0.58 \mathrm{~ms}$ ).

Figure 2: Switch cost (difference in error rates between task switch trials and task repeat trials) for congruent and incongruent stimuli, and overall ('Total').

## Discussion

Forrest et al. (2012) showed that humans in the cue-stimulus-response (no rule) condition of their task-switching experiment expressed reduced switch costs and larger congruency effects relative to a Tasks group that were told both of the applicable rules at the start of the experiment. They offer this as a "signature" of associatively-based performance on this type of task. We are not in a position to make a direct comparison with their study, as we did not run an equivalent of their Tasks group. Our 2-Rules participants are perhaps an approximation to this group, but had to induce the rules, and were not instructed to apply them. However, these participants demonstrated significant switch costs and exhibited a congruency effect, similar to the effects usually found when humans are informed of the task rules before engaging in a task-switching paradigm. This group was the only one that significantly decreased their error rates over the course of the experiment; it can be assumed that this was due to participants "figuring out the tasks": during the first few blocks, performance essentially matched that of No-Rule users, but then it dramatically improved to a level similar to the performance of the pigeons, i.e., at error rates of $10 \%$ or less. A third of participants were unable to report any task rules; these might instead be classified as employing an associative approach to task switching. In addition to a generally high error rate, solving the tasks without any knowledge of their underlying rules had considerable impact on the magnitude of typical task-switching phenomena: while a stimulus's congruency only moderately affected performance in those who used both rules, it heavily influenced humans' ability to solve the tasks if they had been unaware of the rules. This comes to no surprise, as it will always be easier, especially in regard to associative learning, to learn the correct response to a given stimulus when it is the same in both tasks - that is, when that stimulus is congruent - than when it varies between tasks, as it does for incongruent stimuli.

Clearly, there is a significant congruency effect in the pigeon data and no cost of switching between tasks. Similar levels - a much bigger congruency effect than switch costs are also observed in the No-Rule humans and in Forrest et
al.'s (2012) study. The typical signature for a task-based approach in humans instructed to use tasks is the reverse, a larger switch cost and a smaller congruency effect. Further research will establish if this true of the tasks used here.

Although we can draw parallels between the performance of pigeons and No-Rule-using humans, there are some very clear discrepancies between the pigeon data and that of either of the human groups. It is especially apparent that in incongruent trials, there is some switch cost in each of the human groups, which was also observed in Forrest et al.'s (2012) results. Even the human participants who were not using any rules exhibited some switch cost for the incongruent stimuli, yet the pigeons show no discernible trace of any such effect but are able to "task switch". Why is this?

The most interesting possibility is that pigeons simply do not suffer from a switch cost in this paradigm. That is, when given a combination of component and biconditional discriminations, they do not exhibit any difficulty in switching from one hypothetical task to another, even in the case of the biconditional discrimination (i.e., the discrimination involving the incongruent stimuli). This result would imply that there is no switch cost in associatively-mediated task switching, and lead to the conclusion that the switch costs in all our human groups were due, in some sense, to contamination by rule use. This would fit rather well with theories that explain switch costs in terms of task-set reconfiguration (Monsell \& Mizon, 2006) but less well with theories that attempt to explain switch costs in associative terms (e.g., Logan \& Bundesen, 2003). A potential way of testing this assumption would be to compare the groups' performance when faced with novel stimuli in a generalization task.

Another possibility would be that pigeons do exhibit switch costs in this paradigm, but that we either lack the power to detect it, or there is another factor masking it. The former possibility cannot be ruled out given that the predicted effect would be small, in any case, but there is simply no evidence of any switch cost to suggest that it would be worth running many more pigeons in an attempt to increase the power. The latter possibility is, however, worth investigating, especially if switch costs are potentially only present for incongruent stimuli while there will be little or no switch costs on congruent trials. A close examination of the paradigm reveals the possibility of an unwanted interaction between the difference between switch and repeat trials and a preference for novelty (e.g. in matching to sample, see Wright \& Delius, 2005). Pigeons might preferentially respond to trials in which there is some change in stimulation (either in the form of a different stimulus or different response) compared to the previous trial, and avoid those in which both the stimulus and the response location are the same as in the preceding trial. The latter, for incongruent stimuli, is only possible on repeat trials, so, other things being equal, performance on those trials should then on average be worse than on switch trials. A disadvantage for repeat trials over switch trials for
incongruent stimuli could potentially cancel out any switch costs in those trials, which by definition compose a disadvantage for switch trials over repeat trials. Whether this is the case or not is a matter for further empirical investigation.

# Relations between Body Motion and Emotion: Analysis based on Laban Movement Analysis 

Junya Morita, Yukari Nagai, Tomoyuki Moritsu<br>j-morita@jaist.ac.jp, ynagai@jaist.ac.jp, moritsu.tom@gmail.com<br>School of Knowledge Science, Japan Advanced Institute of Science and Technology<br>1-1 Asahidai, Nomi, Ishikawa 923-1292, Japan

#### Abstract

This study examined the relationship between human body movements and emotion based on Laban Movement Analysis (LMA). Ten participants participated in the experiment in which they stayed at a small resting room while hearing pleasant or unpleasant sounds. After the stay at the room, the participants rated their subjective emotional states. Participants' body movement were also recorded with four video cameras. The movement analysis based on LMA reveled significant differences in movement features between experimental conditions. In addition, significant correlations between movement features and subjective mood ratings were observed. These results suggest a strong relationship between human body movements and emotion.

Keywords: Emotion; Body motion; LMA

## Introduction

The English word "emotion" comes from the Latin word "emovere," meaning to "move out." This derivation suggests a close relationship between emotion and body movements. In fact, this relationship, which we will refer to as the motion-emotion relationship in this paper, has been repeatedly discussed (Damasio, 1994; Darwin, 1890; James, 1892). Researchers have attempted to reveal causal relationships between emotion and body movements or the evolutionary advantages of emotion. This work has also described how emotion is expressed in body movements. However quantitative relationships between body movements and emotion categories have yet to be fully clarified.

Experimental studies on the motion-emotion relationship have so far, been conducted in the field of emotion perception (Atkinson, Dittrich, Germmell, \& Young, 2004; Dittrich, Troscianko, Lea, \& Morgan, 1996; Field, Hampson, \& Rose, 2005; Kaiser \& Keller, 2011; Pollick, Paterson, Bruderlin, \& Sanford, 2001). For example, in Dittrich et al. (1996) presented participants with stimuli that expressed human body movements, and participants rated their impressions of those movements on basic emotional category scales. The results showed that participants could judge the emotional states even from biological motion produced by pointlight displays.

Pollick et al. (2001) also conducted experiments that followed the paradigm proposed by Dittrich et al. (1996). Unlike the other previous studies, Pollick and colleagues quantified features of body movements as a way to reveal the motionemotion relationship. The results showed that motions with strong velocity tended to be perceived as anger or happiness, while motions with weak velocity tended to be perceived as sadness or tired.

The movement stimuli used in emotion perception studies are usually created from performances of expert dancers or actors. On the basis of this method, several body movement theories have been proposed in the field of drama and dance.

Laban Movement Analysis (LMA) is one of the most famous theories of body expressions in dance (Laban, 1980). This theory assumes two basic opposing forms of body movement: fighting form and indulging form. Fighting form involves active, prominent, brisk body movements, while indulging form is unsteady weak body movements.

LMA assumes that such forms of body movement reflect subjective inner attitudes, refered to as efforts. The theory classifies effort into the following three axes:

- Weight effort that stands for the vigorousness of body movement.
- Space effort that stands for the degree of directional deflection.
- Time effort stands for the hurriedness in the changes of movement.

The terms fighting and indulging refer to opposing or enhancing the characteristics of a type of effort defined in the above three axes. Fighting form has strong weight, space, and time efforts. Indulging form has weak weight, space and time efforts.

LMA does not directly explain the motion-emotion relationship. Instead, this theory was proposed to describe body movements in dance. Laban (1980) did not mention any correspondence between the efforts and emotion categories. However, several researchers have applied LMA to emotion expressions programmed in robots (Hachimura, Takashina, \& Yoshimura, 2005; Masuda \& Kato, 2009; Nakata \& Mori, 2002). For example, Nakata and Mori (2002) defined the three effort axes based on Euclidean vector operations. Here, participants rated impressions of robot motions that manipulated the three efforts based on LMA. The results indicated correlations between emotion ratings and the efforts based on LMA.

Studies using robots are useful in being able to produce precise manipulations of body movement. Researchers can freely create robot's movements, and these movements are easily quantified. However, studies using robots have the same limitations as studies assessing emotion perception. Both fields have only examined intentionally expressed emotion. Ekman and Friesen (1975) pointed out that there are uncontrolled, involuntary, true emotion expressions, as well as
qualified, modulated, or false expressions. Past studies have examined Ekman's second type of emotion expressions. Few studies have challenged the first type of emotion expressions. For a deeper understanding of the motion-emotion relationship, the first type of emotion expressions needed to be examined.

The present study aimed to apply past findings of the motion-emotion relationship from uncontrolled experimental situations (Ekman's first type). To achieve this goal, we quantified involuntarily body movements using LMA. The motion-emotion relationship was explored by calculating correlations between quantitative features of body movements and subjective ratings of emotional states. In addition, this study explored how the environment influences on the motion-emotion relationship. It can be reasonably assumed that the motion-emotion relation will be affected by environment. We prepared two experimental conditions that were expected to arouse different emotional states.

## Methods

## Design

This study utilized audio stimuli that were assumed to arouse participants' emotion. A series of studies have previously examined environmental sounds related to pleasant or unpleasant emotion (Shimai, Tanaka, \& Terasaki, 1990). From this work, we set up an experiment to examine the motionemotion relationship using different environmental sound settings.

A between subjects design was used in the experiment. One group heard a pleasant environmental sound (pleasant sound group), and the other group heard an unpleasant environmental sound (unpleasant sound group).

## Participants

Twenty graduate students from Japan Advanced Institute of Science and Technology participated in the experiment; they were divided into two groups of 10 participants each; all participants were in their 20s and naive to the purpose of the study.

## Apparatus

We did not prepare any specific tasks for the participants because we wanted to examine emotion elicitation and body movement in uncontrolled situations. The participants were just asked to relax in a resting room while hearing the environmental sounds. We prepared the following resting room and environmental sounds:

## - Resting room

The resting room was designed like a Japanese teahouse ( $2 \mathrm{~m} \times 2 \mathrm{~m} \times 2 \mathrm{~m}$ ). The room had two tatami on the floor, and one small window on the wall. The participants' body movements were recorded with four video cameras affixed to the ceiling (Panasonic BB-HCM515).

- Environmental sound

The environmental sounds were prepared using free sound libraries on the web. The pleasant sound was selected from "pdsounds" (http://www.pdsounds.org/). The unpleasant sound was created at "sound 101" (http://www.sound101.org/). Ten sound files were arbitrarily downloaded from these two web sites. Three raters, who were naive to the purpose of the study, assessed the pleasantness of these sounds. The sound that had the highest rating was chosen as the pleasant sound, and the sound that had the lowest rating was selected as the unpleasant sound. The selected pleasant sound was the sound of a brook ( 17 seconds), while the unpleasant sound was composed of several noises, such as sirens, microphone feedback, and scratching noises ( 20 seconds). Each environmental sound was looped during the experiment. The participants heard the sound through wireless headphones (Sony DRBT50). The maximum output sound level was kept below 70 db for both groups.

## Procedure

The procedure for the experiment was composed of the following three steps:

## 1. Instructions

The participants were told that this experiment was conducted to evaluate the resting room with environmental sound. They were asked to rest while hearing the environmental sound. They were not told that their movements would be recorded while in the room.

## 2. Resting room

The participants entered the resting room alone, and took off their shoes. They put on a set of wireless headphones and an orange jump suit. The jump suit was used to analyze body movements with more ease. The participants could not bring any personal items into the room, including their mobile phone. After 30 minutes, the experimenter announced the end of the experiment.
3. Subjective emotional state ratings

Immediately after being in the resting room, the participants rated their emotional states using the POMS (Profile of Mood States) brief test (Pollock, Cho, Reker, \& Volavka, 1979). This test is usually used to assess transient and distinct mood states, which includes 30 questions classified into six factors: tension (anxiety), depression (dejection), anger (hostility), vigor (activity), fatigue (inertia), and confusion (bewilderment). This test outputs standardized scores with an average of 50 points.

The Ethics Committee of Japan Advanced Institute of Science and Technology approved the study.

## Analysis

We analyzed the video data by applying LMA. Although the LMA effort axes were quantified by Nakata and Mori (2002), their method targeted pre-programed movements with parameters such as joint torque or angles of movement. Since our study obtained data in uncontrolled situations, the method from this previous study could not be directly applied. To quantify the efforts of Weight, Space and Time, we used optical flows estimated by image processing.

Weight effort is defined as the following equation.

$$
\begin{equation*}
\text { Weight }=\sum_{n=1}^{t} \sum_{i=1}^{x} \sum_{j=1}^{y} \frac{\left\|v_{n i j}\right\|}{t \times x \times y} \tag{1}
\end{equation*}
$$

where $t, x$, and $y$ indicates the number of frames ( 25 fps ), the width of the frame ( 240 px ), and the height of the frame (320px), respectively. $\left\|v_{n j k}\right\|$ indicates the strength of the optical flow at pixel $i j$ of frame $n$. Weight indicates the time space average of the vector strength. If the participants moved actively, this index would increase.

The following equation defines Space effort.

$$
\begin{equation*}
\text { Space }=\sum_{n=1}^{t} \sum_{i=1}^{x} \sum_{j=1}^{y} \frac{\mu_{n} \cdot v_{n i j}}{t \times x \times y} \tag{2}
\end{equation*}
$$

where $\mu_{n}$ is a mean vector (by-center) of optical flows in frame $n$, which indicates overall direction of body movements in the frame. Space is calculated as the time space average of dot products between a mean vector and individual optical flows. This value would increase when optical flows in the frame had consistent direction. Conversely, the value would decrease if direction of optical flows diverged.

Based on the above two feature quantities, Time (W) and Time ( S ) are defined as hurriedness in the changes of movement.

$$
\begin{gather*}
\operatorname{Time}(W)=\sum_{n=2}^{t} \frac{\left|W_{e i g h t}(n)-W \operatorname{Weight}_{( }(n-1)\right|}{t}  \tag{3}\\
\operatorname{Time}(S)=\sum_{n=2}^{t} \frac{\mu_{n} \cdot \mu_{n-1}}{t} \tag{4}
\end{gather*}
$$

Time (W) and Time (S) represent the difference of Weight and Space between two continuous frames respectively. Time (W) represents the degree of changes of movement strength. Time (S) indicates the degree of changes of movement direction.

These feature quantities were averaged over the four video cameras. Optical flows were determined by Lucas and Kanade (1981)'s gradient method. The frames were preprocessed by gray-scale processing and background differencing technique. For all steps of the above analysis, we used OpenCV that is an open-source library for image processing.

Figure 1: Subjective rating of emotional states after staying in the resting room.

Figure 2: Changes in the features of body movements while in the resting room.

## Results

## Subjective ratings on emotional states

Figure 1 shows the average rating scores on the POMS after staying in the resting room. A 2 (group: pleasant sound vs. unpleasant sound) by 6 (emotion categories: tension, depression, anger, vigor, fatigue, confusion) mixed design Analysis of Variance (ANOVA) revealed a significant interaction between the environmental sounds and the emotion categories $(F(5,90)=3.80, p<.01)$. Simple main effects of the environmental sounds were significant for tension, depression, fatigue, and confusion (tension: $F(1,18)=8.97, p<.01$, depression: $F(1,18)=7.89, p<.05$, anger: $F(1,18)=$ 2.64, n.s., vigor: $F(1,18)=0.01$, n.s., fatigue: $F(1,18)=$ $11.12, p<.01$, confusion: $F(1,18)=5.74, p<.05)$. These results indicate changes in emotional states influenced by the environmental sounds.

Table 1: Correlations between the subjective ratings of emotional states and features of body movements (Overall).

|  | Weight | Space | Time(W) | Time(S) |
| :--- | :---: | :---: | :---: | :---: |
| tension | $0.632^{*}$ | $0.543^{*}$ | $0.655^{*}$ | $0.691^{*}$ |
| depression | 0.436 | 0.275 | 0.405 | $0.560^{*}$ |
| anger | $0.589^{*}$ | 0.372 | $0.560^{*}$ | $0.610^{*}$ |
| vigor | -0.072 | 0.056 | -0.036 | -0.023 |
| fatigue | $0.601^{*}$ | $0.473^{*}$ | $0.601^{*}$ | $0.520^{*}$ |
| confusion | $0.473^{*}$ | 0.327 | 0.435 | $0.468^{*}$ |
| Note $* p<.05$ |  |  |  |  |

## Feature quantities of body movement

Figure 2 shows the feature quantities of body while the participants were in the resting room. Four separete 10 (time: $3-30$ ) by 2 (environmental sounds: pleasant vs. unpleasant) mixed design ANOVAs were conducted for the feature quantities. The analysis did not reveal significant interactions between time and the environmental sounds (Weight: $F(9,162)=0.38$,n.s., Space: $F(9,162)=0.59$, n.s., Time $(\mathrm{W}): F(9,162)=0.49$,n.s., Time(S): $F(9,162)=0.85$, n.s.). We obtained significant main effects of the environmental sounds (Weight: $F(1,18)=12.77, p<.01$. Space: $F(1,18)=11.64, p<.01$. Time(W): $F(1,18)=8.54, p<.01$. Time(S): $F(1,18)=$ 23.92, $p<.01$ ), and significant main effects of time for the four feature quantities (Weight: $F(9,162)=12.17, p<.01$. Space: $F(9,162)=6.22, p<.01$, Time(W): $F(9,162)=$ $12.89, p<.01$. Time(S): $F(9,162)=15.30, p<.01)$.

The main effects of the environmental sounds indicate that the body movements in the unpleasant sound condition were active, directed, and rapid. This suggests that the unpleasant sound changed body movements toward fighting form. On the other hand, the pleasant sound changed the body movement toward indulging form.

The main effects of time indicate that the participants made more movements immediately after entering the resting room. We confirmed qualitative differences in behaviors between the early and latter stages of the experiment. During the first few minutes, several participants observed interiors of the resting room. Next, they tended to lie down on the tatami mats until the end of the experiment.

## Correlations between emotional states and body movement

Table 1 shows correlation coefficients between the rated emotional states and the feature quantities of body movements. In this analysis, we used the feature quantities in the latter 12 minutes to examine body movements that strongly connected to the emotional states.

From the table, we can observe some significant correlations between body motion and the emotion ratings. The emotion categories other than vigor appear to be related to some of the body movements.

However, we cannot exclude the possibility that these correlations were caused by features of the environmental sound

Table 2: Correlations between the subjective ratings of emotional states and features of body movements (pleasant sound condition).

|  | Weight | Space | Time(W) | Time(S) |
| :--- | :---: | :---: | :---: | :---: |
| tension | -0.136 | 0.113 | -0.014 | -0.181 |
| depression | -0.028 | 0.129 | 0.267 | -0.101 |
| anger | -0.531 | -0.405 | -0.355 | $-0.657 *$ |
| vigor | 0.338 | 0.182 | 0.187 | -0.005 |
| fatigue | -0.610 | -0.493 | -0.436 | -0.591 |
| confusion | 0.324 | 0.413 | 0.577 | -0.259 |
| Note. ${ }^{*} p<.05$. |  |  |  |  |

Table 3: Correlations between the subjective ratings of emotional states and features of body movements (unpleasant sound condition).

|  | Weight | Space | Time(W) | Time(S) |
| :--- | :---: | :---: | :---: | :---: |
| tension | -0.616 | 0.389 | 0.580 | $0.798^{*}$ |
| depression | 0.291 | -0.050 | 0.140 | 0.540 |
| anger | $0.731^{*}$ | 0.422 | $0.661^{*}$ | $0.892^{*}$ |
| vigor | -0.232 | 0.039 | -0.123 | -0.020 |
| fatigue | $0.725^{*}$ | 0.451 | 0.621 | $0.719^{*}$ |
| confusion | 0.343 | -0.001 | 0.158 | 0.510 |
| Note. ${ }^{*} p<.05$. |  |  |  |  |

because the participants in the two groups heard different sounds. The body movements might have been influenced by acoustic features such as rhythm or tempo. To exclude this possibility and obtain stronger evidence of the motionemotion relationship, we calculated correlations disaggregated by the environmental sound.

Table 2 and 3 show correlation coefficients between the emotional states and the feature quantities of body movements in the pleasant and the unpleasant sound conditions, respectively. In the pleasant sound condition, anger was negatively correlated with time (S). In the unpleasant sound condition, anger was positively correlated with Weight, Time (W), and Time ( S ). There was a positive correlation between tension and Time ( S ) in the unpleasant sound condition. Fatigue in the unpleasant sound condition was also correlated with Weight and Time (S).

From these results, we confirmed a motion-emotion relationship in a situation where the same environmental sound was presented. However, there were large differences in the pattern of the motion-emotion relationship between the two groups. In the following section, we will try to explain each of the observed correlations.

## Discussion

This study explored the motion-emotion relationship in uncontrolled experimental situations. We prepared two conditions that differed in the environmental sounds presented. The results confirmed that (1) changes in emotional states as a function of environmental sound occured, (2) differences in body movements between different environmental sound
conditions emerged, and (3) correlations between emotional states and body movements in each environmental sound condition were observed. This following section provides an interpretation of these results and discusses implications and limitations of the current findings.

## Changes in emotional states by environmental sound

This study confirmed that environmental sounds changed emotional states as assessed by the POMS test. Although this study does not focus on the relationship between environmental sounds and emotion, we consider this result useful for future experimental studies on emotional arousal. Presentation of environmental sounds is non-invasive and an easy way to manipulate emotional states.

However, Figure 1 also shows limitations of our emotional manipulation. The influence of the environmental sound was limited to specific emotion categories. There were no differences in anger and vigor between the two groups. It is difficult to interpret why these differences occured. To provide a more accurate emotion manipulation, we need to conduct further experiments that explore the mechanisms underlying the relationships between emotion categories in this context.

## Changes in body movements by environmental sound

In addition to the emotional states, the environmental sound influenced body movements. The feature quantities of body movements in the unpleasant sound condition were higher than those in the pleasant sound condition. The participants in the unpleasant sound condition exhibited active, directed, and rapid movement. Such body movements are consistent with fighting form of LMA. In contrast, body movements observed in the pleasant condition are consistent with indulging form. Considering the results of the POMS test, we can assume emotion categories like tension, depression, fatigue and confusion were related to fighting form.

However, this conclusion is not sufficient given that the environmental sounds in the two groups had different physical features. The difference between the two groups might be explained by certain mechanisms, such as sensory-motor coordination (Repp, 2005). This limitation can be addressed by examining correlations disaggregated by the environmental sounds.

## Relationships between emotional states and body movement

Our study observed significant correlations between emotional states and body movements. This was especially the case when we consider that the correlations disaggregated by the environmental sounds are important. We provide an interpretation for the observed correlations in the following section.

Expressions of anger in response to the unpleasant sound In the unpleasant sound condition, anger was correlated with all of the features except Space. From this result, we can con-
sider that anger is expressed as fighting form in LMA. This interpretation is consistent with past studies of emotion perception. As noted in the Introduction, Pollick et al. (2001) observed a correlation between anger perception and velocity of body movements. Masuda and Kato (2009), who analyzed robot motion based on LMA, also observed a strong correlation between anger perception and Time effort. The present study succeeded in extending these findings of emotion perception to an uncontrolled situation.

Expressions of tension in response to the unpleasant sound In the unpleasant sound condition, tension was correlated with Time (S), which quantifies the degree of hurriedness in movement changes. This result is consistent with the classic finding indicating that tension is often accompanied by muscle overactivity (Sainsbury \& Gibson, 1954). Darwin (1890) also classified this action as an involuntary reflex movement. The present study described these relationships using the LMA framework.

Expressions of fatigue in response to the unpleasant sound Weight and Time ( S ) were correlated with fatigue in the unpleasant sound condition. POMS defines fatigue as decrease in motivation or energy. This result is inconsistent with our intuition that fatigue decreases body movements.

However, this result does not necessarily indicate a direct causal relationship between fatigue and these movement features. One possible explanation for this result might be that other emotion categories that covaried with fatigue caused an increase in the movement features.

In the unpleasant sound condition, fatigue was positively correlated with tension ( $r=0.738, p<.05$ ) and anger ( $r=$ $0.698, p<.05$ ), which were also correlated with the movement features (Table 3). From these correlations, we can speculate that fatigue in the unpleasant sound condition was caused by strong and rapid movements accompanying these emotional states. However, our results cannot directly confirm this hypothesis. This possibility needs further study using more sophisticated methods such as path analysis.
Expressions of anger in response to the pleasant sound Compared to the unpleasant sound condition, the pleasant sound condition did not show many correlations between body movements and emotional states. In the pleasant sound condition, anger was negatively correlated with Time (S). This result is incontrast to the positive correlation observed in the unpleasant sound condition.

As in the above case, this contrasting finding might be explained by examining emotion categories that were negatively correlated with anger. In Pollick et al. (2001)'s experiment, both anger and happiness were expressed as active motion. Considering their finding, our negative correlation between anger and Time ( S ) is not too suprising. The increase in happiness might accompany a decrease in anger. However, we cannot confirm with the present results. Future studies that employ emotional ratings including happiness, should be conducted.

## Summary

This study attempted to reveal motion-emotion relationships in uncontrolled situations. As a result, we observed that both motion and emotion were changed by environmental sounds. More importantly, we obtained correlations between emotion and body movements in each environmental sound condition. From these results, we confirmed the motion-emotion relationship from uncontrolled, involuntary emotional expressions.

Our study is characterized by a method of quantifying body movement features based on LMA. This quantitative method is useful for connecting motion and emotion in uncontrolled experimental situations. We consider that our approach can contribute not only to scientific studies of emotion but also to engineering applications. Automatic emotion assessment is applicable to various pragmatic situations, including dance, education and marketing. LMA is a useful tool for systematically describing body movements. Past studies using LMA have not included involuntary motion/emotion in uncontrolled situations. Our study extends the application fields of these past studies.

However, our results also revealed complexities in the motion-emotion relationship. As shown in Table 2 and 3, emotion is expressed differently in different situations. Additionally, there is no one-to-one correspondence between body movements and emotional states. A single emotion category can be connected to several body movements and vice versa. Furthermore, as speculated earlier, emotion categories are intricately intertwined. To reveal the deeper mechanisms of the motion-emotion relationship, studies with larger sample sizes will be needed.

# The missing baselines in arguments for the optimal efficiency of languages 

## Fermín MOSCOSO DEL PRADO (fmoscoso@linguistics.ucsb.edu)

Department of Linguistics<br>University of California, Santa Barbara

Santa Barbara, CA 93106-3100 USA

#### Abstract

I argue that linear correlations between log word frequency, and lexical measures, cannot be taken as evidence for a "Principle of Minimum Effort". The Principle of Maximum Entropy indicates that such relations are in fact the ones most probable to be found. For such claims, one needs to compare the correlations with adequate baselines reflecting what would be expected in a purely random system. I then introduce a way of computing such baselines, and use it to show that the correlations found in a corpus are actually weaker than what one would expect to find by chance. Therefore, if an argument were to be made based on them, it would paradoxically be that language is worse for communication than what one would expect to find in a random system. More appropriately however, what these results reflect is that such correlations are not the best places to look for linguistic optimality.

Keywords: Corpus Study; Lexical Ambiguity; Principle of Maximum Entropy; Zipf's Law of Abbreviation

## Introduction

Arguments about language being optimal for communication have a long tradition within the cognitive sciences, dating at least as far back as Zipf (1935). Zipf observed that, across many texts, there is an inverse correlation between a word's frequency of occurrence and its length in characters, which is now referred to as Zipf's Law of Abbreviation (ZLA). This observation led him to his "Principle of Least Effort" (Zipf, 1949): Humans prefer shorter words to refer to frequent concepts, so that the overall length of utterances will be minimized, and so will the effort required to produce them. In this form, from the speaker's (or writer's) point of view, the optimality of human language would be measured by the amount of effort required by a speaker to produce an utterance. Zipf also realized that, from the comprehender's perspective, optimality would not be so much concerned with the length of an utterance as it would with the ease with which it can be unambiguously decoded. Jointly considering both the perspective of the speaker and that of the comprehender, the structure of language would be subject to a trade-off between utterance length and degree of ambiguity. Zipf was somewhat vague with respect to how such trade-off could be measured, but his general idea is considered valid ever since.

As compelling as Zipf's arguments seem, very early on, researchers in Information Theory and Psychology noticed that they may not be as informative as Zipf thought. Both Mandelbrot (1953) and Miller (1957) realized that the negative correlation between a word's frequency of occurrence and its length in characters (i.e., ZLA) would also arise in randomly generated texts that lack any linguistic structure or communicative value whatsoever; what Mandelbrot dubbed a "typing monkeys" process, and Miller -somewhat less
graphically- called an "intermittent silence" process. The validity and importance of Zipf's original observations on the distribution of word frequencies and word lengths is beyond doubt, as is evidenced for instance in a whole family of power-law distributions and phenomena across many unrelated fields of science being currently named in Zipf's honor (e.g., Zipf's Laws, Zipfian distributions, Zipf-Mandelbrot distribution). However, Zipf's interpretation that such properties reflect the optimization of human language structure is disconfirmed by the fact that those very same properties are also found in systems that are not the result of any optimization process. The properties are therefore not informative about the optimality of the process that generated them. This highlights a problem that is exhibitted by many claims on language properties that reflect some form of optimization: The lack of a non-optimal baseline against which to test whether such inferences are perhaps non sequiturs.

Let us consider a non-linguistic example. Suppose I put forward a theory on the processes governing the outcome obtained when throwing two particular dice. The dice themselves would be beyond my possible observations (e.g., inside a black box), but I would have access to the sum of their outcome. My theory could state that the dice are loaded so that they strongly favor a non-extreme (or optimal) outcome of three or four dots. In order to test my theory, I would collect data from many dice throws (with access only to their summed values). After obtaining a few thousand throws, if I found that the average value of the sum is seven (with some preset degree of precision), which is fully consistent with my theory. As it happens, however, seven would also be the most likely value of the sum, even if the dice were not loaded. Therefore, I could not take the evidence from the average value as support for my theory, as it would also be consistent with the a priori more likely theory that the dice are not loaded. As we will see below, one can objectively say that the unloaded theory is more probable a priori using mere probabilistic arguments (the Principle of Maximum Entropy).

In the example above, the prediction used to test the hypothesized property holds trivially for the most probable outcome. One can of course design situations in which the seven sum property does not hold (e.g., by loading the sixes on dice). Still, even if it is possible to artificially design such a scenario, it is still the case that the most probable outcome, whether or not any optimization is at work, is that the property will hold (i.e., the dice will sum up to seven). However, even if the property were less evident than the one used in this example, testing it also on a few non-optimal baselines would enable us to see that such property does not signal the
presence of optimization.
This discussion is motivated by the recent publication of several papers making claims on the optimality of human language which suffer from the same lack of baseline problem. In what follows, I begin by summarizing four of these recent arguments for language optimality. I then introduce the Principle of Maximum Entropy, and use it to show analytically that the findings presented as evidence for communicative optimality turn out to be trivial predictions that will also be observed in the most probable non-optimized baselines. In the data section, I analyze a corpus of English to assess the strength of the effects used to argue for optimality. The results show that these effects are in fact significantly weaker than what one would expect to find by mere chance. In other words, if one took such correlations as evidence for optimization, one would have to conclude that human languages are actually less optimized than one would expect by chance. I conclude with a discussion of how Information-Theory can be used to make predictions on the optimality of human languages that do indeed survive the non-optimal baselines tests.

## Some Information Theoretical Arguments for Communicative Efficiency

In a recent study, Piantadosi, Tily, and Gibson (2012) extend ZLA to the domain of lexical ambiguity. Following Zipf, they argue that short words require less effort to be produced than longer words would. Therefore, by a similar principle of economy, it would be beneficial to encode as many meanings as possible using the shorter words, and then use the redundancy present in the context to disambiguate them. They support this claim by showing that, in corpora of three languages, there is indeed a negative correlation between word ambiguity and word length when other factors (e.g., frequency) are considered.

A second prediction of Piantadosi et al. (2012) considers the fact that more frequent words have a more accessible lexical representation, as is evidenced by the fact that they elicit shorter reaction times and lower error rates in a broad range of lexical processing experiments (e.g., Oldfield \& Wingfield, 1965). That a word is easy to access makes it a desirable candidate to carry many meanings (or be associated to many uninflected word lemmas) in a system that is optimized to make the production and comprehension of words as effortless as possible. Therefore, they predict a positive correlation between a word's frequency and the number of distinct meanings (or lemmas) associated with it. Their analyses of several corpora indeed find this correlation.

As convincing as these arguments might seem, I will argue below that the findings are but trivial consequences of ZLA, and do not provide support the communicative hypothesis that is put forward. I will further discuss, ZLA is itself a trivial property of most symbolic sequences, irrespective of whether they are optimized.

Piantadosi et al. (2012) also argue that, if one computes the probability of a word according to a triphone (i.e., phoneme
trigram) model, those words with the highest probability correspond to those that provide a more prototypical example of the phonotactics of a language. Those words that conform better to the phonotactic constraints of the language will be easier to pronounce and recognize. Following the "least effort" argument, they predict that words with high phonotactic predictability should be associated with more meanings (or word lemmas) than words with lower phonotactic probability.

## The Principle of Maximum Entropy

Before making any claims that a particular distribution of linguistic probabilities (of words, words lengths, degrees of ambiguity, etc.) constitutes evidence for language being "optimized for human communication", one should check what kind of such distributions one would expect to observe by mere chance, irrespective of the presence any hypothetical optimization process. The relevant properties of the distribution (e.g., ambiguous words being more frequent, etc.) should be found to be significantly more (or less) marked in actual linguistic data than one would expect them to be.

This raises the problem of how to determine, among the infinite possible discrete probability distributions that words could have, which ones are the most probable a priori. The Principle of Maximum Entropy (PME; Jaynes, 1957a, 1957b) states that, among all probability distributions satisfying a set of constraints, the most probable one will be the one that has the highest entropy. The entropy (Shannon, 1948) of a probability distribution defined over a discrete set of words $W=\left\{w_{1}, w_{2}, w_{3}, \ldots\right\}$ is given by

$$
H(W)=-\sum_{w \in W} \mathrm{P}(W=w) \log \mathrm{P}(W=w)
$$

where $P(W=w)$ denotes the probability of encountering word $w$ in a corpus of text (i.e., its relative frequency of occurrence). In what follows, I will use the abbreviated notation $\mathrm{p}_{i}=\mathrm{P}\left(W=w_{i}\right)$. The most probable assignment of values for the $\mathrm{p}_{i}$ is the one leading to the highest value of $H(W)$, with the obvious constraint that the values of the $\mathrm{p}_{i}$ must all sum to one, so that they form an actual probability distribution. ${ }^{1}$

If no additional constraints were present (i.e., any assignment of probabilities could be considered), then, for a finite set $N$ probabilities, the maximum entropy would be the uniform distribution with $p_{i}=1 / N$. Of course, when one considers the probabilities of words, not all probability distributions are valid assignments. Rather, these distributions need to satisfy some basic constraints. These specific constraints can be requirements such as the existence of a mean word length or an average degree of ambiguity. Constraints of this type can be expressed as values of the means of some given functions. For instance, one such function can be the length of a word (measured in either characters, phonemes, or syllables), which maps words into natural numbers ( $\ell: W \mapsto \mathbb{N}$ ),

[^157]and another function can the degree to which words are ambiguous, which maps words into the non-negative real numbers $\left(\mathcal{A}: W \mapsto \mathbb{R}^{+}\right)$. The constraints would then be expressed as the existance of a mean word length $\left(\langle\ell(w)\rangle_{W}=L\right)$ and a mean degree of ambiguity $\left(\langle\mathcal{A}(w)\rangle_{W}=A\right)$.

The most probable distribution that satisfies the constraints would then be the solution to the maximization problem:

$$
\arg \max -\sum_{w_{i} \in W} \mathrm{p}_{i} \log \mathrm{p}_{i}
$$

subject to

$$
\left\{\begin{array}{cll} 
& \sum_{w_{i} \in W} \mathrm{p}_{i} & =1  \tag{1}\\
\langle\ell(w)\rangle_{W}= & \sum_{w \in W} \mathrm{p}_{i} \ell\left(w_{i}\right) & =L \\
\langle\mathcal{A}(w)\rangle_{W}= & \sum_{w \in W} \mathrm{p}_{i} \mathcal{A}\left(w_{i}\right) & =A
\end{array}\right.
$$

Notice that I have added one constraint to indicate that the resulting probability distribution must be normalized. The solution to such a problem is found analitically using the method of Laplace multipliers. It must have the form of a Boltzmann canonical distribution, ${ }^{2}$

$$
\begin{equation*}
\mathrm{p}_{i}=\mathrm{e}^{\lambda_{0}+\lambda_{1} \ell\left(w_{i}\right)+\lambda_{2} \mathcal{A}\left(w_{i}\right)} \tag{2}
\end{equation*}
$$

where the parameters $\lambda_{0}, \lambda_{1}$, and $\lambda_{2}$ are Laplace multipliers whose value is uniquely determined by the individual values of the word lengths $\ell\left(w_{i}\right)$, ambiguities $\mathcal{A}\left(w_{i}\right)$ as well as their average values $L$ and $A$.

## Implications of the PME

Taking logs on both sides of Eq. 2 reveals that a priori assuming the existence of a mean word length $(L)$ and an average degree of ambiguity $(A)-$ the most probable relation between our variables of interest is

$$
\begin{equation*}
\log \mathrm{p}_{i}=\lambda_{0}+\lambda_{1} \ell\left(w_{i}\right)+\lambda_{2} \mathcal{A}\left(w_{i}\right) \tag{3}
\end{equation*}
$$

This equation already makes important predictions. We should expect that -everything else being equal- the log probability of a word (i.e., its $\log$ frequency) should be linearly related to both its length and to its degree of ambiguity. No assumptions about language being optimized for communication are necessary to make this prediction, it just happens to be to most probable type of relation. The signs and values of the Laplace multipliers $\lambda_{1}$ and $\lambda_{2}$ will determine the strength and direction of the correlations. They therefore provide baselines for any effects whose presence is argued to reflect a form of efficiency or optimality. Without any need for efficiency, we should expect to find correlations with the strengths given by $\lambda_{1}$ and $\lambda_{2}$.

A negative value of $\lambda_{1}$ would indicate that ZLA is in fact the most likely relation that one should expect to find between word frequency and word length. Therefore, in order to claim that ZLA provides evidence for communicative efficiency, one should observe that the relation between

[^158]log word frequency and word length is more negative than $\lambda_{1}$. This finding complements the previous arguments of Mandelbrot (1953), Miller (1957), or Ferrer i Cancho and Moscoso del Prado (2011) that random processes also exhibit ZLA. It provides a baseline to assess whether the ZLA observed in a real corpus is stronger than what one would have expected by mere chance.

Similarly, $\lambda_{2}$ indexes the relation between log word frequency and degree of ambiguity. Piantadosi et al. (2012)'s finding of a positive correlation between a word's ambiguity and its frequency of occurrence (i.e., frequent words are more ambiguous) can only be interpreted as evidence for optimality if the regression coefficient found for the degree of ambiguity is more positive than $\lambda_{2}$.

A simple rewrite of Eq. 3 results in

$$
\begin{equation*}
\mathcal{A}\left(w_{i}\right)=\frac{\lambda_{0}-\log \mathrm{p}_{i}+\lambda_{1} \ell\left(w_{i}\right)}{-\lambda_{2}} . \tag{4}
\end{equation*}
$$

This indicates that, when word frequency is kept constant or controlled for, one should also expect to find a linear relationship between a word's length and its degree of ambiguity (with a regression coefficient $-\lambda_{1} / \lambda_{2}$ ), as was documented by Piantadosi et al. (2012). As before, in order to accept Piantadosi and colleagues' interpretation that their finding is indicative of some form of communicative efficiency, one needs to ensure that such relation is less marked than $-\lambda_{1} / \lambda_{2}$.

Although, for reasons of space I do not detail it here, it is easy to show that a word's frequency of occurrence in a corpus is expected to be directly proportional to that word's phonotactic probability as computed from an n-phone (e.g., diphone, triphone, ...) model whose parameters were computed on that same corpus. If we denote a word's triphonebased probability as $T_{i}$, we can therefore say that $k \mathrm{p}_{i} \approx T_{i}$ for some value $0<k \leq 1$ constant across all words. If we substitute on Eq. 3, we obtain

$$
\begin{equation*}
\log T_{i}-\log k \approx \lambda_{0}+\lambda_{1} \ell\left(w_{i}\right)+\lambda_{2} \mathcal{A}\left(w_{i}\right) . \tag{5}
\end{equation*}
$$

Dividing both sides of Eq. 5 by $\ell\left(w_{i}\right)$ with a simple rearrangement results in

$$
\begin{equation*}
\frac{\log T_{i}}{\ell\left(w_{i}\right)} \approx \lambda_{1}+\frac{\log k+\lambda_{0}+\lambda_{2} \mathcal{A}\left(w_{i}\right)}{\ell\left(w_{i}\right)} \tag{6}
\end{equation*}
$$

Therefore, when the degree of ambiguity is controlled for, a word's log triphone (or diphone, ...) probability normalized by its length, is expected to be non-linearly related to word length itself (i.e., linearly related to the reciprocal of word length). One would therefore expect to find the nonlinearities that Piantadosi et al. (2012) found. Hence, such non-linear relation -by itself- cannot be interpreted to be the product of an optimization process, contrary to what was argued by Piantadosi and his colleagues.

In summary, I have shown that the linear relationships between $\log$ word frequency, word length, and word ambiguity -by themselves- do not warrant an interpretation that language is optimized for communicative efficient. In the following section, I will estimate the values of the parameters
$\lambda_{0}, \lambda_{1}$, and $\lambda_{2}$ from corpus data, and I will assess whether or not they provide evidence for (or against) any sort of optimization.

## Corpus Study

In order to test whether the values of the Laplace multipliers $\left(\lambda_{1}, \lambda_{2}\right)$ provide support for the hypothesis that language is optimized for communicative efficiency, I selected the 29,025 most frequent English content words (adjectives, adverbs, nouns, and verbs) present in WordNet (Miller, 1995). ${ }^{3}$ The selection was done using their surface word spoken frequency according the CELEX lexical database (Baayen, Piepenbrock, \& Gulikers, 1995), from where the corresponding word length in phonemes was obtained. ${ }^{4}$ For each word I counted its number of distinct senses (i.e., 'synsets') listed in WordNet (Miller, 1995). The log of the number of senses was taken as the measure of a word's ambiguity $\left(\mathcal{A}\left(w_{i}\right)=\log N_{i}\right.$, where $N_{i}$ is the number of distinct senses of $\left.w_{i}\right) .{ }^{5}$

I normalized the word frequency counts into relative frequencies adding up to one, and estimated the mean word length as the weighted average

$$
L=\left\langle\ell\left(w_{i}\right)\right\rangle_{W}=\sum_{w_{i} \in W} \mathrm{p}_{i} \ell\left(w_{i}\right)
$$

with $\mathrm{p}_{i}$ being the corpus based relative frequency of $w_{i}$. Similarly, the average degree of ambiguity was estimated as

$$
A=\left\langle\mathcal{A}\left(w_{i}\right)\right\rangle_{W}=\sum_{w_{i} \in W} \mathrm{p}_{i} \mathcal{A}\left(w_{i}\right)=\sum_{w_{i} \in W} \mathrm{p}_{i} \log N_{i} .
$$

Using these estimates of $L$ and $A$, and the individual values of $\ell\left(w_{i}\right)$ and $\mathcal{A}\left(w_{i}\right)$, the values of the multipliers $\lambda_{0}, \lambda_{1}$, and $\lambda_{2}$ were estimated by nonlinear maximization (using a Newtontype algorithm) of

$$
H(W)=-\lambda_{0}-\lambda_{1} L-\lambda_{2} A
$$

subject to the constraints of Eq. 1. In order to keep the results comparable to those of Piantadosi and colleagues, additional parameters were added to separate the different grammatical categories.

The values of the Laplace multipliers were estimated to be $\lambda_{0}=-10.37, \lambda_{1}=-.14$, and $\lambda_{2}=1.07$. As I discussed in the previous section, that $\lambda_{1}<0$ indicates that ZLA (a negative correlation between word length and word frequency) is the most likely relationship between these two variables,

[^159]whether or not any optimization is at work. Similarly, $\lambda_{2}>0$ implies that we should expect a priori a positive correlation (all other factors equal) between a word's frequency and its degree of ambiguity. As suspected -by itself- the positive relation between frequency and ambiguity does not warrant the interpretation of optimization, it is rather what one should expect, contrary to Piantadosi et al. (2012).

Figure 1: Non-linear effects of word length (left panels) and degree of ambiguity (right panels) on the lengthnormalized $\log$ triphone probability (top panels) and the length-normalized $\log$ a priori frequency (bottom panels).

To see the actual values of these correlations in the corpus itself, I performed a linear regression predicting a word's log probability from its length and its degree of ambiguity (once more, I also included additional parameters to separate the grammatical categories). As Piantadosi et al. (2012), I found significant effects of both word length and degree of ambiguity (both with $\mathrm{p}<.0001$ ). Interestingly, the estimated coefficient for word length $(\beta=-.05 \pm .003)$ constitutes a much weaker effect than the one we would have expected by chance ( $\lambda_{1}=-.14$ ). This means that the supposed optimization from ZLA is actually weaker than what one should have expected, not supporting any optimization. In a similar vein, the coefficient estimated for the effect of ambiguity $(\beta=.84 \pm .01)$ is also a weaker effect than the chance level $\left(\lambda_{2}=1.07\right)$. Again, it seems that the negative relation between frequency and ambiguity that was claimed by Piantadosi and his colleagues to reflect optimization, is actually significantly weaker than the expected chance level. This illustrates the importance of having meaningful baselines before interpreting lexical statistics.

As discussed in the previous section the ratio $-\lambda_{1} / \lambda_{2}=.13$
indexes the strength of the correlation between word length and word ambiguity (after controlling for word frequency) that we should expect by chance. Indeed, we should therefore expect by chance a positive correlation between a word's length and its degree of ambiguity, irrespective of any optimization process. The strength of this relationship in the data is given by the ratio between the corresponding regression coefficients $\beta[$ length $] / \beta[$ ambiguity $]=.05$, which is once more weaker than what we would have expected by chance.

In order to assess the non-linear effects of a word's phonotactic probability, I trained a triphone model using the Brown corpus of English (Kucera \& Francis, 1967) after transcribing all the words into the phonemic forms using the CMU Pronouncing Dictionary. ${ }^{6}$ I used this triphone model to estimate the phonotactic probability of each word $\left(T_{i}\right)$. For each the length-normalized $\log$ trigram probabilities $\left(\log T_{i} / \ell\left(w_{i}\right)\right)$ and the length-normalized $\log$ a priori probabilities estimated using the $\lambda\left(\log \mathrm{p}_{i} / \ell\left(w_{i}\right)\right)$, I fitted a generalized additive model with a linear predictor for log word frequency (estimated for the corpus or a priori) and penalized spline smoothers terms for word length and degree of ambiguity. Fig. 1 plots the estimated curves. As predicted, the shape and strength of the non-linear relations is basically the shame for the actual triphone probabilities (top-panels), as it is for the word probabilities that would be predicted a priori (bottom panels). Once more, the shape of the relation does not warrant the interpretation of optimization.

The values of the Laplace multipliers can be used with Eq. 3 to compute what should be the a priori distribution of words, considering only their length and degrees of ambiguity. The log relative frequencies predicted by the method exhibit a remarkably strong correlation with the relative $\log$ frequencies actually observed ( $r=.45, t[29004]=86.41, \mathrm{p}<$ .0001 ). This suggest that the frequency distribution of words is not that different from the distribution one would expect to find by chance. In other words, it does not appear to reflect much specific optimization.

It could be argued that, by using the actual values of word length and word ambiguity as estimated from the corpus, I am covertly exploiting the possible correlations that are already present in their distributions, even before considering word frequency. To control for this possible confound, I used a Jackknife technique. New values of word lengths and ambiguity were randomly assigned to each word by randomly sampling (with replacement) from the original distributions. In this way, one obtains distributions of word length and ambiguity which are fully uncorrelated, but retain their original distributional shapes. I repeated this process two hundred times, re-estimating the values of the Laplace multipliers in each case. Fig. 2 compares the original $\lambda$ estimates (blue dots), the distribution of $\lambda$ values obtained in the resampling (box and whiskers plots), and the $\beta$ parameters of the regressions on the actual corpus (red crosses). As it can be seen, even after fully decoupling word length and ambiguity, the

[^160]expected effects are much stronger than those observed in the corpus. In short, the effects that allegedly reflect optimization of language for communicative efficiency are actually much weaker than we should have expected them to be.

## Conclusion

These results do not question either ZLA or Piantadosi et al. (2012)'s effects, rather the effects themselves are indeed replicated here. What is questioned is the interpretation of such effects as evidence for optimization. I have shown that by themselves- the linear relationships between log word frequency, word length, and degree of ambiguity, do not warrant the interpretation that language is optimized for communicative efficiency. The shape and direction of the effects reported in Piantadosi et al. (2012), as well as ZLA, are precisely what one would expect to obtain by chance (i.e., by a random assignment of probabilities). Furthermore, if anything, I find that the effects present in a corpus are actually weaker than what one would obtain by chance. Following the classical "Principle of Least Effort" interpretation is therefore not warranted by this type of correlations.

These findings complement previous studies showing that mere random typing processes (e.g., Mandelbrot, 1953; Miller, 1957; Ferrer i Cancho \& Moscoso del Prado, 2011) also exhibit ZLA. More generally, the most likely observation is that a word's log probability of occurrence is linearly related with any property of the word for which a mean value exists. Therefore, in order to claim that observations of this kind are indicative of any type of process (optimization or otherwise) giving rise to the word frequency measures are not warranted, unless the effects are explicitly found to be significantly the stronger than the effects one should find by chance. In other words, such effects are meaningless unless compared to random baselines.

Notice that the same conclusions would be reached if, instead of unigram word frequencies, I had considered the $a$ priori distribution of word bigrams or trigrams. It would merely be a question of applying the PME to the whole matrix of $n$-grams and we would expect to obtain the same type of linear relations between $\log n$-gram frequencies and lexical measures. Thus, similar arguments as those expressed in Piantadosi, Tily, and Gibson (2011), would suffer from exactly the same problems I discussed above.

By this I do not intend to claim that language is not optimized for human communication. Rather the opposite, I am strongly convinced that this is indeed the case. However, pure correlational values between lexical measures (or for that matter $n$-gram measures) are not sufficient evidence to support such claims. Of course, there is a certain commonsensical aspect to the claim that human language is optimal for communication: It would be difficult to find a cognitive scientist who disagrees with such a statement. However, claims on optimization of human language should rely on specific mechanisms by which the optimization takes place, together with explicit mathematical (e.g., variational) de-

Figure 2: Estimated relations between log word frequency, word length, and degree of ambiguity. The red crosses indicate the magnitude of the effects observed in the corpora. The blue dots plot the magnitude that we should expect to observe $a$ priori. The box and whisker plots plot the distribution of the a priori predictions once word length and ambiguity have been decoupled using Jackknife. The leftmost and middle panels respectively plot the effects of word length and ambiguity of log word frequency. The rightmost panel plots the direct relation between word length and word ambiguity. Notice the different vertical scales between the panels.
scriptions of how such an optimization proceeds, as exemplified by some recent studies (e.g., Ferrer i Cancho \& Solé, 2003; Ferrer i Cancho \& Díaz-Guilera, 2007).

# Social Roles and Category Use: A Study of Creativity Assessment 

Jennifer S. Mueller (jmueller@sandiego.edu)<br>University of San Diego, 5998 Alcalá Park<br>San Diego, CA 92110 USA<br>Jeffrey Loewenstein (jloew@illinois.edu)<br>University of Illinois, Urbana-Champaign, 1206 South Sixth Street MC-707<br>Champaign, IL 61820 USA<br>Shimul Melwani (shimul_melwani@kenan-flagler.unc.edu)<br>University of North Carolina, Chapel Hill, 4725 McColl CB 3490<br>Chapel Hill, NC 27599 USA

#### Abstract

We show that social roles alter creativity assessments. Specifically, the two main roles in the innovation process generator roles for producing new ideas and implementer roles for selecting ideas to pursue - invoke different lay theories about what is creative. Study 1 showed that implementers rated a low novelty version of an idea as more creative than a high novelty version, but generators did the opposite. Study 2 showed that generators rated a low usefulness idea as more creative than a high usefulness idea, but implementers did the opposite. Thus, complementary roles prompted competing perspectives. These findings underscore a new challenge for the social distribution of knowledge-intensive work.

Keywords: Social Roles; creativity; categories; lay theories.

## Introduction

Editor's response to Sylvia Plath: There certainly isn't enough genuine talent for us to take notice.

Editor's response to Rudyard Kipling: I'm sorry Mr. Kipling, but you just don't know how to use the English language.

Many creative ideas are rejected and not necessarily more kindly than Plath's and Kipling's were. Thus, it is not enough to produce creative ideas. For cultural and scientific advancement, others need to recognize that the ideas are creative. One longstanding view is de gustibus non est disputandum-assessments are idiosyncratic. In contrast, current creativity theory and research claims that assessments are guided by domain knowledge. People within a community develop lay theories surrounding the category of creativity-causal and relational knowledge about what counts as creative and what is a more and less central member of the category. With expertise in the area (Amabile, 1982; Csikszentmihalyi, 1988), or even just moderate exposure to the area (Hennessey, Amabile, \& Mueller, 2010; Sawyer, 2012), individuals appear to converge with others in their assessments of creativity. However, given how complex the causal and relational
knowledge is that underpins judgments about creativity, we suggest that individuals' assessments of creativity are guided by more than just their domain knowledge. We suggest that they are also guided by their social roles.

We explore the possibility that the editors failed to recognize Plath and Kipling's creative ideas not because of lack of knowledge or idiosyncratic taste but because of their roles as editors. Specifically, we examine two key roles studied by organizational psychologists examining organizational innovation (Elsbach \& Kramer, 2003; Klein \& Knight, 2005; Klein \& Sorra, 1996): implementers, such as a book editor, and idea generators, such as a book author. We propose that adopting an implementer role leads to a different view of what is creative than adopting a generator role. The argument we make is parallel to one made about roles and person perception: different roles can produce different expectancies (Biddle, 1986), which then lead individuals in those roles to form different assessments of the same focal person (e.g., Winquist, Mohr, \& Kenny, 1998). Accordingly, it is not just that expectancies can highlight some aspects of the causal and relational structure underpinning a complex category and so alter judgments about that category, but also that those expectancies are systematically tied to particular social roles.

Social roles could shape assessments of creativity by shifting the lay or implicit theories (Paletz \& Peng, 2008; Sternberg, 1985) people use to evaluate ideas for creativity. This would resolve a puzzle in the creativity literature, which provides evidence of multiple, potentially conflicting lay theories about creativity. While there is widespread agreement that creative ideas combine novelty and usefulness (George, 2007), one lay theory is that novelty is the dominant characteristic in creativity assessments (Amabile, Barsade, Mueller, \& Staw, 2005), whereas another lay theory highlights that usefulness is the essential component of creativity assessments (Cooper, 2006). Which concern, novelty or usefulness, is deemed most causally central might be critical, as there is now evidence that people's assessments of novelty and usefulness are negatively related (Rietzschel, Nijstad, \& Stroebe, 2009). One reason why is a lay theory that highly novel ideas are not very useful, as they are likely to fail to solve problems
on time and within budget (Elsbach et al., 2003), and to fail in the marketplace (Fleming, 2001), rendering them less creative (Mueller, Melwani, \& Goncalo, 2012). Another reason why is a lay theory within scientific communities that high levels of usefulness can indicate that an idea is not very novel, as usefulness indicates taking on a smaller challenge and making a smaller change from current practice (Drazin, Glynn, \& Kazanjian, 1999). We suggest that people's social roles guide which lay theories they use, and so which causal factor underlying their model of creativity is central and shaping their creativity assessments.

We focus on two social roles that are fundamental to the social division of labor in the innovation process, generator and implementer roles (Elsbach et al., 2003). The innovation literature notes that these roles are complimentary, and their coordination is key to the process of innovation (Krishnan \& Ulrich, 2001): generators create new ideas, products and processes that implementers then assess, select and pursue. For example, scientists generate articles that editors vet, entrepreneurs generate business ideas that venture capitalists fund, and researchers generate product ideas that managers implement.

The two roles generate different expectancies. Generator roles include expectations around generating new ideas and overcoming challenges to solve problems in novel ways (Drazin et al., 1999). Hence, generator roles may activate lay theories about novelty being key to creativity and about highly useful ideas being less creative due to less opportunity for overcoming novel challenges. Implementer roles include expectations around maximizing efficiency by meeting timelines as well as budgetary and resource constraints (Drazin et al., 1999). Accordingly, implementer roles may activate lay theories about creative ideas being distinguished by usefulness and about highly novel ideas being less creative due to challenges of implementation.

If these predictions hold, then it will provide support for the importance of social roles and expectancies in assessing creativity. Managers may want creativity, but as implementers, they may adopt perspectives that lead them to reject the ideas that creators find most compelling. Thus, our account provides an explanation for the phenomenon of managers saying they want creativity but nonetheless end up rejecting creative ideas, a phenomenon that is widely noted in the popular press (e.g., Bussey, 2012; Hindo, 2007) and in the innovation research literature (DeFillippi, Grabher, \& Jones, 2007; Smith \& Lewis, 2011; Staw, 1995). The broader theoretical implication is that two complementary roles, such as implementer and generator roles in the innovation process, may bring with them complementary knowledge, but they may also bring with them competing causal models of the same categories that may thwart their ability to coordinate, communicate, and perform together.

## Experiment 1

This study examined how individuals in generator and implementer roles assessed a high and a low novelty idea.

We expected generators to assess the high novelty idea as more creative than the low novelty idea, because of their lay theory that novelty is the distinguishing characteristic of creative ideas. The key prediction though is that we expected implementers to rate the high novelty idea as less creative than the low novelty idea, because of a lay theory that highly novel ideas are less useful and so less creative. Critically, we examine these predictions about role effects by ensuring there were no systematic differences in domain knowledge (an effect that may otherwise accompany roles) by randomly assigning people to roles (as classically done in Anderson \& Pichert, 1978, among other work).

## Method

Participants and Design We recruited 176 people from Amazon's Mechanical Turk ( $62 \%$ male, $M=28.41$ years, $S D=9.43)$. Participants averaged $8.09(S D=8.94)$ years of work experience. Participants were randomly assigned to one of four conditions of a 2 (role: generator, implementer) X 2 (idea novelty: high, low) between-subjects design. Each cell contained more than 34 cases.

Procedure and Materials In Part one, participants were assigned to either a generator or an implementer role at a "large innovative product development firm" that "develops high performance outdoor gear." Generators were responsible for "generating new ideas, brainstorming technologies, and developing products and processes." Implementers were responsible for "cost savings, profitability, decreased time to market, meeting deadlines and product functionality." These descriptions were from prior research outlining generator and implementer role expectations (Drazin et al., 1999). Participants then wrote about the "important things that help you perform this role." In a pilot study $(\mathrm{N}=152)$, three coders (average coder-pair agreement was $94 \%$ ) rated whether participants described resources for novelty (e.g., "good team to help bounce ideas off of," "inspiring workspace") and for usefulness (e.g., "efficient staff," "computer with accounting programs"). Implementers $(96 \%)$ mentioned usefulness more than generators ( $36 \%, \chi^{2}(1)=61.46, p<.01$ ). Generators ( $80 \%$ ) mentioned novelty more than implementers ( $13 \%, \chi^{2}$ $(1)=70.01, p<.01)$. Thus, this manipulation led participants to adopt the intended roles and associated concerns.

In Part two, participants rated an idea for a "waterproof fleece," which "uses a soft, breathable and waterproof fabric using bio-mimicry to replicate the properties of a leaf in the Amazon rain forest that repels water yet is also very soft and pliable to the touch." The high novelty idea was described as a "completely new technology not currently available in the marketplace," while the low novelty idea was described as "an existing technology currently available in the marketplace." In a pilot study $(\mathrm{N}=54)$, participants (not put in any role) rated the high or low novelty idea as: new and original (assessing novelty, $\alpha=.86$ ), useful and valuable (assessing usefulness, $\alpha=.73$ ), and creative and
innovative (assessing creativity, $\alpha=.83$ ). Participants rated the low novelty idea $(\mathrm{M}=4.70)$ as less novel than the high novelty idea $(M=5.83, t(53)=3.53, p<.01)$, but comparably useful $(M=6.00)$ to the high novelty idea ( $\mathrm{M}=$ $5.89, t(53)=-.45, \mathrm{~ns})$. In addition, participants rated the low novelty idea ( $\mathrm{M}=5.22$ ) as less creative than the high novelty idea $(\mathrm{M}=5.70, t(53)=2.68, p<.05)$. Thus, the level of novelty was noticeable and produced a shift in perceived creativity. Participants in the main study rated the ideas using the same creativity, usefulness and novelty scales (all alphas above .70).

## Results

A multivariate ANOVA identified interactions between role (generator or implementer) and idea type (high or low novelty) when predicting creativity ratings $(F(1,172)=$ $\left.38.38, p<.01, \eta^{2}=.15\right)$, novelty ratings $(F(1,172)=9.00$, $\left.p<.05, \eta^{2}=.03\right)$ and usefulness ratings $(F(1,172)=$ 7.75, $p<.05, \eta^{2}=.05$ ). Planned comparisons revealed a crossover interaction such that generators rated the high novelty idea as significantly more creative $(M=6.04)$ than implementers $\left(M=5.43, t(86)=3.48, p<.01, \eta^{2}=.19\right.$; Figure 1). Generators rated the low novelty idea as significantly less creative $(M=4.62)$ than implementers ( $M$ $\left.=5.91, t(86)=-4.40, p<.01, \eta^{2}=.02\right)$. The critical finding was that implementers saw the low novelty idea as more creative than the high novelty idea $(t(71)=-2.06, p<$ $.05, \eta^{2}=.14$ ), whereas generators saw the low novelty idea as less creative than the high novelty idea $(t(101)=6.08, p$ $<.01, \eta^{2}=.04$ ).

Regarding novelty, generators saw the low novelty idea as less novel $(M=4.57)$ than implementers $(M=5.30, t(86)=$ $\left.-2.31, p<.05, \eta^{2}=.04\right)$, but generators $(M=5.47)$ and implementers $(M=5.29)$ had comparable ratings of the high novelty idea $\left(t(86)=.81, \mathrm{p}=\mathrm{ns}\right.$; see Figure $\left.2, \eta^{2}=.003\right)$. Generators rated the high novelty idea as more novel than the low novelty idea $\left(t(101)=3.48, p<.01, \eta^{2}=.07\right)$, whereas implementers did not show a detectable difference $\left(t(71)=-.06, n s, \eta^{2}=.00\right)$.

Regarding usefulness, implementers saw the high novelty idea as less useful $(M=5.36)$ than generators $(M=5.79$, $t(86)=1.99, p<.05$; see Figure 3, $\left.\eta^{2}=.03\right)$. Implementers also saw the low novelty idea as more useful $(M=5.95)$ than generators $(M=5.53, t(73)=-.2 .14, p<$ $.05, \eta^{2}=.02$ ). While generators saw no difference in the extent to which high $(M=5.79)$ and low $(M=5.53)$ novelty ideas were useful $\left(t(101)=1.49, \mathrm{p}=\mathrm{ns}, \eta^{2}=.01\right)$, implementers viewed the low novelty idea as more useful than the high novelty idea $\left(t(71)=-2.41, p<.05, \eta^{2}=\right.$ .04).

To further examine the relationship between roles, novelty and usefulness, and assessments of creativity, we conducted two parallel mediation analyses, one for each role, in which both novelty and usefulness were entered as possible mediators of creativity assessments (using the approach in Preacher, Rucker \& Hayes, 2007). We found that for generators, there was an indirect effect of high and
low novelty ideas on creativity assessments through novelty (mean effect estimate $=.57, \mathrm{SE}=.205 ; 95 \%$ CI 1.025 to .225 , i.e., does not include 0 ), but there was no indirect effect through usefulness (mean effect estimate $=.05, \mathrm{SE}=$ $.04 ; 95 \%$ CI -.0061 to .166 , i.e., includes 0). For implementers, we found the opposite pattern. There was evidence of an indirect effect of high and low novelty ideas on creativity assessments through usefulness (mean effect estimate $=.098, \mathrm{SE}=.064,95 \% \mathrm{CI} .0024$ to .2598 ), but not through novelty (mean effect estimate $=.0084, \mathrm{SE}=.145$; $95 \%$ CI -.287 to .289 ). Accordingly, generators' ratings of creativity seemed driven by novelty and implementers' ratings of creativity seemed driven by usefulness.

Figure 1. Means and $95 \%$ confidence intervals of creativity ratings by role (implementer, generator) and idea type (high novelty, low novelty), Experiment 1.

## Discussion

Adopting generator and implementer roles can lead people to form different assessments of creativity. Generators perceived a high novelty idea as more novel and creative but no more useful than a low novelty idea. This is consistent with the generator role evoking a lay theory that emphasizes novelty when assessing creativity. However, separating an effect of role-based expectancies from task demands driven by role instructions (we told generators to focus on novelty, and so they did) is challenging. We will present a better test of the generator role in Study 2.

The more striking pattern came from implementers, who assessed a high novelty idea as less useful and creative, but not more novel, than a low novelty idea. These data do not suffer from the same concern as the generator role data. Implementers were told to focus on usefulness, but they were not told to ignore novelty, and the ideas that they rated provided no direct information about usefulness. Thus, it is noteworthy that the implementers evaluated the high novelty idea as less useful than the low novelty idea, because it suggests that they were employing the lay theory that highly novel ideas are likely untested and risky and so lower in usefulness and lower in creativity.

## Experiment 2

Study 2 tested high and low usefulness ideas. The key prediction is that generators should assess a high usefulness idea as less novel and creative than a low usefulness idea, due to a lay theory that an idea high in usefulness indicates less novelty and so less creativity. Our account also predicts that implementers should assess the high usefulness idea as more useful and more creative than the low usefulness idea.

## Method

Participants and Design We recruited 161 participants from Amazon's Mechanical Turk ( $64 \%$ male, $M=30.42$ years, $S D=12.17$ ). Participants had an average of 9.75 (SD $=10.62$ ) years of work experience. Participants were randomly assigned to one of four conditions of a 2 (role: generator, implementer) X 2 (idea usefulness: high, low) between-subjects design. Each cell contained more than 29 cases.
Procedure and Materials The only difference with Study 1 was the idea being rated. We used the high novelty idea from Study 1, so everyone rated an idea that was explicitly marked as being highly novel. We added that the idea was "cheap and easy to make" (in the high usefulness condition) or "costly and difficult to make" (in the low usefulness condition).

## Results

A multivariate ANOVA identified interactions between role (generator or implementer) and idea type (high or low usefulness) when predicting creativity ratings $(F(1,157)=$ 20.06, $p<.01, \eta^{2}=.11$ ) and novelty ratings $(F(1,157)=$ $8.51, p<.01, \eta^{2}=.05$ ), but only a marginally significant trend for usefulness ratings $\left(F(1,157)=3.10, \mathrm{p}=.08, \eta^{2}=\right.$ .01 ). Planned comparisons revealed a crossover interaction for creativity ratings (Figure 2). Generators rated the high usefulness idea as less creative $(M=5.14)$ than implementers $\left(\mathrm{M}=6.07, t(76)=-3.95, p<.01, \eta^{2}=.10\right.$; see Figure 4). Generators also rated the low usefulness idea as more creative $(M=5.88)$ than implementers $(M=5.46$, $\left.t(81)=2.19, p<.05, \eta^{2}=.03\right)$. Implementers saw the high usefulness idea as more creative than the low usefulness idea $\left(t(88)=3.36, p<.05, \eta^{2}=.06\right)$, whereas generators recognized the low usefulness idea as more creative than the high novelty idea ( $t(69)=-2.96, p<.05, \eta^{2}=.06$ ).

Regarding novelty and usefulness, generators saw the high usefulness idea as less novel $(\mathrm{M}=4.97)$ than implementers $\left(M=5.81, t(76)=-3.11, p<.05, \eta^{2}=.06\right)$, but generators $(M=5.61)$ and implementers $(M=5.41)$ gave comparable novelty ratings to the low usefulness idea $\left(t(81)=.83, \mathrm{p}=\mathrm{ns}, \eta^{2}=.004\right.$; see Figure 5). Generators rated the low usefulness idea as more novel than the high usefulness idea $\left(t(69)=-2.33, p<.05, \eta^{2}=.04\right)$, whereas implementers saw no difference $\left(t(88)=1.72, n s, \eta^{2}=.02\right)$. Also as expected, implementers viewed the high usefulness idea $(M=6.04)$ as more useful than the low usefulness idea $\left(\mathrm{M}=5.41, t(88)=2.63, p<.05, \eta^{2}=.04\right.$; see Figure 6). Generators did not rate the high $(\mathrm{M}=5.52)$ and low $(\mathrm{M}=$
5.51) usefulness ideas reliably differently in usefulness $\left(t(69)=.01, \mathrm{p}=\mathrm{ns}, \eta^{2}=.00\right)$.

For generators, we found evidence of an indirect effect of high and low usefulness ideas on creativity assessments through novelty (mean effect estimate $=.35, \mathrm{SE}=.176$; $95 \%$ CI .06 to .76 ), but there was no indirect effect through usefulness (mean effect estimate $=-.002, \mathrm{SE}=.09 ; 95 \% \mathrm{CI}$ -.129 to .218 ). For implementers, there was evidence of an indirect effect of high and low usefulness ideas on creativity assessments through usefulness (mean effect estimate $=.12$, $\mathrm{SE}=.063,95 \% \mathrm{CI} .028$ to .282 ), but not through novelty (mean effect estimate $=-.193, \mathrm{SE}=.111 ; 95 \% \mathrm{CI}-.423$ to .009 ). Once again, generators' ratings of creativity seemed linked to novelty and implementers' ratings of creativity seemed linked to usefulness.

Figure 2. Means and 95\% confidence intervals of creativity ratings by role (implementer, generator) and idea type (high usefulness, low usefulness), Experiment 2.

## Discussion

Study 2 found the complementary pattern to Study 1. Unsurprisingly, adopting the implementer role led people to rate the high usefulness idea as more useful and more creative than the low usefulness idea, although separating out role-based expectancies from task demand based on the role instructions is challenging. What is more clearly compelling though is that adopting the generator role led people to rate the high usefulness idea as less novel and less creative than the low usefulness idea. This occurred despite both ideas being described as completely new, which was the primary concern of the generator role. That high usefulness meant lower novelty for generators is consistent with our proposal that generator roles evoke a lay theory that high usefulness indicates a lesser challenge and deviation in practice and so a lower degree of creativity.

## General Discussion

The social roles used to distribute the process of innovation appear to lead to different assessments of creativity, the very issue on which people in those roles need to coordinate. The
generator role seemed to invoke lay theories that novelty is key to an idea being creative, and that highly useful ideas lack novelty. The implementer role seemed to invoke lay theories that usefulness is key to an idea being creative, and that highly novel ideas lack creativity because they are less useful.

A strength of the approach in these studies was that we ensured that there were no systematic knowledge differences by randomly assigning roles, as in practice role differences are likely confounded with knowledge differences. Knowledge differences could also, in addition to role-driven expectancies or other sets of goals, guide perceptions of novelty and usefulness, and alter creativity assessments. In additional exploratory data analyses, we also examined the possibility that work experience could have influenced responses. However, we found no signs of effects of years of work experience, nor did we find any signs of effects of whether or not participants had prior work experience in generator roles (about $30 \%$ did) or implementer roles (about 20\% did). Thus, we have evidence that assigning individuals to roles led them to adopt the goals and perspective of those roles, and that individuals with and without actual work experience in the roles produced comparable assessments.

One theoretical possibility highlighted by these studies is that at least for complex categories, such as creativity, meanings may vary systematically in multiple ways. There are already good reasons to believe that category meanings are not fixed for speakers of the natural language but rather vary across cultural communities (Clark, 1996; Keller \& Loewenstein, 2011). If the studies here generalize, then there may be further social fractionation in category meanings driven by roles. Of interest, just as individuals can code switch from one cultural vocabulary to another, they can also change roles. Thus, individuals' understandings and use of categories might shift systematically as they adopt different roles and identify with different communities. There are not just context effects but social context effects that draw on histories of experience and social interaction. Just because individuals generate their own understandings of categories does not imply that their understandings are constant, internally consistent, or driven by one goal or causal logic.

The effects of social roles on creativity also emphasizes the need for a more comprehensive theoretical account of social context on creativity assessments. This would go alongside work on the effects of social context on creative production (Amabile, 1983; Kim, Vincent, \& Goncalo, 2012). Future work could examine whether situational factors apart from roles also guide creativity assessments. For example, situational uncertainty (Whitson \& Galinsky, 2008) might activate the lay theory that highly novel ideas are not creative because they have uncertain use (cf., Mueller et al., 2012), and so guide creativity assessments.

The generator-implementer difference in creativity assessments that we found suggests a practical problem, because effective coordination hinges on mutual
understanding (Okhuysen \& Bechky, 2009). If implementers and generators do not agree about which ideas are creative, this should lead to conflict, frustration and rejection. Apparently, the division of labor in the innovation process brings with it a division of cognitive labor that is not just about who knows what (Keil, Stein, Webb, Billings, \& Rozenblit, 2010), but is also about perspectives and perhaps attitudes. Indeed, editors may select articles they view as "creative" but that researchers view as "same old, same old," whereas editors view that researchers often pursue "pie-in-the-sky" ideas without grounding them in existing methods. Governments may fund research projects that scientists think perpetuate existing paradigms rather than testing new ones, while grant decision-makers might view many scientists pursuing ideas with little practical value to society. Managers may view that designers generating new products focus on extremely cutting edge ideas that are too costly and expensive to produce at a profit, while the designers view that managers implement old and tired ideas to "make a buck." The result may well be a stubborn coordination challenge on the core task of generating and implementing creative ideas. Or, perhaps at different points in the innovation process, generators and implementers might consider adopting the perspective of the alternative role. Because the true paradox of this paper is that, ironically, both roles may be right.

# Simultaneous Contradictory Belief and the Two-System Hypothesis 

Joshua Mugg (joshuamugg@gmail.com)<br>Department of Philosophy, 4700 Keele St. Toronto, ON M3J 1P3 Canada

#### Abstract

The two-system hypothesis states that there are two kinds of reasoning systems, the first of which is evolutionarily old, heuristically (or associatively) based, automatic, fast, and is a collection of independent systems. The second is evolutionarily new, perhaps peculiar to humans, is rule-based, controlled, slow, and is a single token system. Advocates of the two-system hypothesis generally support their claim by an inference to the best explanation: two systems are needed to explain experimental data from the reasoning, heuristics, and biases literature. The best evidence for this claim comes from simultaneous contradictory belief (henceforth SCB) (Sloman 1996, 2002). I argue that Sloman has not provided us with cases of SCB. In each of his examples there is no evidence that the beliefs are held simultaneously. I then offer the outline for an experimental setup that would offer compelling evidence for the existence of SCB and thereby support the two-system hypothesis.

Keywords: Dual-process; two-system hypothesis; simultaneous contradictory belief.

## Introduction

The two-system hypothesis states there are two reasoning systems (or at least two kinds of reasoning systems), the first of which (System 1 or 'S1') is evolutionarily old, heuristically (or associatively) based, automatic, fast, and is a collection of independent systems. The second (System 2 or 'S2') is evolutionarily new, perhaps peculiar to humans, is rule-based, controlled, and slow. ${ }^{1}$ The advocate of the two-system hypothesis must demonstrate that the two systems are distinct (what I call the distinctness claim), that the two systems are of different kinds (what I call the kind claim), and that S2 is a single system. Advocates of the twosystem hypothesis (I have in mind Evans (2004); Evans \& Over (1996); Sloman (1993, 1996); Stanovich (1999, 2004); Carruthers (2009); and Frankish (2004, 2009)) generally support their claim by an inference to the best explanation: two systems are needed to explain experimental data from the reasoning, heuristics, and biases literature. The best evidence for this claim comes from simultaneous contradictory belief (henceforth SCB) (Sloman 1996, 2002).
However, their inference to the best explanation only supports, if successful, the distinctness claim. While

[^161]criticism of the two-system hypothesis has focused on the kind claim (Samuels 2009; Evans 2011), I argue that Sloman has not provided us with cases of SCB. I then offer an experimental setup that would strongly support the existence of SBC.

## Why SCB?

Before examining Sloman's cases of SCB we need to understand why SCB is good evidence for the two-system hypothesis, and we need to understand what counts as evidence for SCB. Sloman seems to have a rival explanation in mind to account for human reasoning: there is just one reasoning system (call this the one-system hypothesis). The one-system hypothesis can and should allow that this system operates differently under different circumstances. It should, for example, sometimes operate deductively and other times inductively. The two-system theorist allows for a single system to operate inductively and deductive on different occasions, since S1 and S2 engage in both forms of reasoning. What, we should ask, would be the empirical difference between there being one reasoning system that operates differently under different stimuli and there being multiple systems? One reasoning system cannot have contradictory outputs for one input (Here I am in agreement with Sloman $(1996,2002)$ ). So the one-system hypothesis is committed to the following claim: for any question demanding reasoning and for which a reasoning system will produce only one answer, subjects will only offer one answer at any given time.
Sloman understands 'belief' broadly to mean "a propensity, feeling, or conviction that a response is appropriate even if it is not strong enough to be acted on" (384). This definition is not uncontroversial, but (for the sake of argument) I will grant it for the purpose of this paper. From Sloman's definition it follows that there are at least two ways in which subjects might offer more than one response at any given time. The first is behavioral. While people might explicitly say that they believe that $p$, they may exhibit behavior demonstrating that they believe not-p. This would be evidence that there is more than one system involved in reasoning. They believe (explicitly) that p but believe (dispositionally, tacitly, or implicitly) not-p. Second, a subject might feel a tension between $p$ and not-p. This is phenomenological evidence for SCB.
As an example of a task where subjects give simultaneous contradictory responses which indicates the existence of distinct systems, consider the Muller-Lyer illusion. Subjects believe that the two lines are equal, but cannot help but see them as different lengths, even after they have measured the
two lines. Subjects perceive the lines as different lengths, but believe that they are the same length. So the MullerLyer illusion supports the claim that perception and reasoning are governed by distinct systems. Because there are two systems operating simultaneously the tension between believing that the lines are the same length and seeing them as them as different lengths persists.
While in his (1996) Sloman seems to indicate that the Muller-Lyer supports the two-system hypothesis about reasoning, in his (2002) he mere takes it to indicate that perception and knowledge are governed by distinct systems-a conclusion he (2002) recognizes is consistent with the one-system hypothesis. He explains that "the conclusion that two independent systems are at work depends critically on the fact that the perception and the knowledge are maintained simultaneously" (385, emphasis added). So the Muller-Lyer supports the existence of two distinct systems, but not two distinct reasoning systems.
The preceding two paragraphs help elucidate what counts as evidence for SCB. It would be too stringent to require that subjects verbally claim $p$ and not-p at the same time. Alternatively, a subject might quickly alter her reposes (they might say 'it is valid...Wait, no it's not. Wait, yes it is...'). Call this a response toggle. A response toggle is neither necessary nor sufficient for there being SCB, though it might count in its favor. The two contradicting answers might come from an uncertainty in a step of a single system process (e.g. being asked whether an argument is sound, and the argument is valid but the subject is unsure about the truth of a premise). The uncertainty in that case reflects the uncertainty of one or more premises rather than two competing beliefs. So response toggle might count in favour of SCB, but there are cases in which a subject will response toggle without there being any SCB. ${ }^{2}$

While the existence of SCB would be good evidence for the existence of two reasoning systems, it is possible that there are two systems and that no SCB ever occurs. Indeed, it is possible that two systems exist and that they make (almost) no causal difference. I have two lungs, but (when both function properly) they operate in essentially the same way that one large lung would. So it is not the case that if there are two systems then those two systems will differ. That is, the existence of SCB is not necessary for the establishment of the two-system hypothesis, but if there is no SCB the case for the two-system hypothesis will be much weaker. If we can explain all the data using one system, then there is no need to posit a second system. Furthermore, if both the one-system and two-systems hypotheses offer equally plausible explanations then Ockham's Razor favours the one-system hypothesis since it posits the least kinds (and number) of entities.
One might object that SCB does is not sufficient for the establishment of the two-system hypothesis. One might reason as follows: if the two-systems hypothesis is true and

[^162]the two systems can deliver different solutions to the same problem, then there may be cases in which subjects have SCB. But then the existence of SCB supports a necessary condition (rather than sufficient) for the two-system hypothesis. Actually, the argument from SCB to the twosystem hypothesis is different. The reasoning is as follows:

1. There are cases of SCB.
2. If the one-system hypothesis is true, then there will be no cases of SCB.
3. So the one-system hypothesis is false.
4. If the one-system hypothesis is false, then there must be more than one reasoning system.
5. So there is more than one reasoning system.

It is true that this does not establish that there are only two reasoning systems, but if we need to posit more than one reasoning system a good place to start is with two reasoning systems. I now turn to the Sloman's examples of SCB.

## Sloman's cases of SCB

The first example of SCB to consider is Sloman's (1998) experiment in which subjects "tended to project properties from a superordinate category to a subordinate category only to the extent that the categories were similar" (2002, 387). He supports this claim through argument strength. Subjects were asked, assuming the first statement was true, to determine the strength of the following argument:

## Argument 1

Fact: Every individual piece of electronic equipment exhibits magnetic picofluctuation.
Conclusion: Every individual piece of audio equipment exhibits magnetic picofluctuation.

The mean of the subjects who affirmed the conclusion was .89, but of course if all audio equipment is electronic, then (given that the 'fact' above is true) a rational subject would give the conclusion a probability of 1 . Sloman points out that when the category in the conclusion was atypical of the category in the premise, the judgments were even lower. For the following argument (Argument 2) the mean probability judgment was .76 (among those who claimed that all kitchen appliances where electronic).

## Argument 2

Fact: Every individual piece of electronic equipment exhibits magnetic picofluctuation.
Conclusion: Every individual kitchen appliance exhibits magnetic picofluctuation.

During debriefing interviews, subjects agreed that there was good reason to assign this argument the maximum probability because of the category inclusion. However, subjects also thought that their lower probability assessments were also sensible, though "they inevitably failed to express why" $(2002,387)$. Sloman concludes that
after being shown the correct answer they had an associative S1 answer (a probability less than 1 ) and a rule-based S2 answer (a probability of 1 ).
There is a good alternative explanation to Sloman's claim that subjects had two answers in mind. There is an enthymeme in both arguments crucial to the argument going through. In Argument 1 it is "every individual piece of audio equipment is a piece of electronic equipment" and in Argument 2 it is "every individual kitchen appliance is a piece of electronic equipment." While both of these propositions seem plausible we should consider just how certain they are. Would a microphone stand count as part of the sound equipment? Does my wine opener or manual egg beater count as a kitchen appliance? Even if we answer negatively, the questions give us pause. So the enthymeme in the two arguments are not certain, and the level of each enthymeme is gauged by association. I am more inclined to exclude the microphone stand from audio equipment than I am a manual egg beater from kitchen appliances, which would explain why Argument 2 was deemed less certain than Argument 1. I propose that the subjects' responses reflect this uncertainty about the truth of the enthymeme, since subjects were not told to assume the enthymeme.

Sloman might respond that in debriefing interviews subjects admitted that there was good reason to assign each argument a probability of 1 . When researchers pointed out to subjects that they ought to have assigned each argument maximal probability, I suggest that subjects then took the enthymeme to be true. They were then considering a more complete argument in the debriefing interview. However, subjects can claim that their answers were reasonable, and rightly so. Their answers simply reflected the probability that the enthymeme was true, which is identical to the probability of the conclusion given the fact. I conclude that Sloman's (1998) study does not give us a case of SCB.
Next, Sloman cites Osherson, Smith, Wilkie, Lopez, and Shafir (1990) as a case of SCB. In this study subjects were asked to compare the strength of two arguments:

## Argument 3

Robins have an ulnar artery.
Therefore, birds have an ulnar artery.

## Argument 4

Robins have an ulnar artery.
Therefore, ostriches have an ulnar artery.
Most subjects claimed that Argument 3 was stronger than Argument 4. Sloman thinks that subjects believe the correct answer-that Argument 4 is at least as strong as Argument 3. However they associate robins with birds more easily than robins and ostriches, and so they claim that Argument 3 is stronger. Even assuming that subjects' mistake is not due to the ambiguity in quantification (which I suspect it is), Sloman gives us no reason to think that subjects hold the beliefs simultaneously. All that Sloman offers in support of his claim that these beliefs are held simultaneously is the
following: "this is a striking example in which a compelling logical argument fails to erase an even more compelling intuition: How much evidence can a fact about robins provide for an animal as dissimilar as an ostrich?" (2002, 388). So it is the intuition that is supposed to persist even after subjects realize that Argument 4 is at least as strong as Argument 3, but this is not a case of contradictory belief. Our intuitions (inductive reasoning) tell us that Argument 4 cannot be very strong, but deductive reasoning might then recognize that this implies that Argument 3 cannot be very strong either. The competing answers might be held at different times. First one thinks (wrongly) that Argument 3 is stronger than Argument 4. Then (after it being pointed out that ostriches are a kind of bird) Argument 4 looks at least as strong as Argument 3. There is no need for the two beliefs to be held simultaneously.
Sloman offers an example from Revlin, Leirer, Yopp, and Yopp (1980) as a case of SCB in syllogistic reasoning. Subjects were asked which of the following five possible conclusions followed from the premises:

## Argument 5

No members of the ad-hoc committee are women.
Some U.S. senators are members of the ad-hoc committee.
Therefore:
a. All U.S. senators are women.
b. No U.S. senators are women.
c. Some U.S. senators are women.
d. Some U.S. senators are not women.
e. None of the above is proven.

## Argument 6

No U.S. governors are members of the Harem Club. Some Arabian sheiks are members of the Harem Club. Therefore:
a. All Arabian sheiks are U.S. governors.
b. No Arabian sheiks are U.S. governors.
c. Some Arabian sheiks are U.S. governors.
d. Some Arabian sheiks are not U.S. governors.
e. None of the above is proven.

83\% responded correctly for Argument 5 (d. Some U.S. senators are not women) while only $67 \%$ of participants responded correctly to Argument 6 (d. Some Arabian sheiks are not U.S. governors). In Argument 5 the right conclusion accords with our standing beliefs while in Argument 6 our standing beliefs tell us that the stronger answer (b No Arabian sheiks are U.S. governors) is true. Sloman concludes from this example that "empirical belief obtained fairly directly through associative memory can inhibit the response generated by psycho-logic" (2002, 389). Again, Sloman has given us no reason to think that subjects simultaneously believe that, in Argument 6, b and d both follow and that only d follows. Do we currently have behavioral evidence that subjects simultaneously believe b
and only d? I think not. We only have evidence that more subjects chose wrongly in Argument 6, and perhaps they do so because when subjects lacks training in logic they fall back on their standing knowledge.

A final (well-known) example is Linda the feminist bank teller, which was devised by Tversky and Kahneman (1983). Subjects were given the following information: "Linda is 31 years old, single, outspoken and very bright. She majored in philosophy. As a student, she was deeply concerned with issues of discrimination and social justice, and also participated in anti-nuclear demonstrations" (297). Subjects were then asked which of the two following is more likely: "A: Linda is a bank-teller. B: Linda is a bankteller and is active in the feminist movement" (297). In some experimental trials more than $80 \%$ of subjects said statement B was more likely than the statement A, but of course a conjunction can never be more likely than one of its conjuncts.

Sloman claims that he "can trace through the probability argument and concede its validity, while sensing that a state of affairs that [he] can imagine much more easily has a greater chance of obtaining" $(1996,12)$. He offers the phenomenological experience of another psychologist as well: "I know that the [conjunction] is least probable, yet a little homunculus in my head continues to jump up and down, shouting at me-'but she can't just be a bank teller: read the description'" (Gould, 469).
Sloman pointed out the difference in temporal relation between the responses in the Muller-Lyer illusion and the Necker cube illusion to five of his department colleagues. Namely, in the Muller-Lyer case the illusion that the two lines are different lengths persists even after one knows they are the same length, while in the Necker cube illusion one is only able to recognize one square as the front face at any given time. Sloman then asked his colleagues whether their experience in the Linda case was analogous to the MullerLyer or Necker cube case. All five agreed that it was like the Muller-Lyer illusion. Sloman then asked his colleagues whether the 'Monty Hall' case ${ }^{3}$ was analogous to the Muller-Lyer or Necker cube illusion. All of them (as well as Sloman) thought it was analogous to the Necker cube illusion. Sloman concludes that in the Monty Hall case the contradictory beliefs are not held simultaneously, whereas for the Linda case they are.

We should not put much weight on the phenomenology of the theorists. They are not naïve subjects and their phenomenological reports are suspect. Behavioral evidence of SCB from the subjects would be better. Sloman might

[^163]object citing that his definition of belief is such that it is not necessary that subject act upon their beliefs, and a belief might not even make a behavioral difference. Although a subject might not act upon his or her beliefs, if there is a propensity, feeling, or conviction that a given proposition is true then surely it will make some difference to the cognitive processes or behavior of that subject. To be is to have causal powers (Alexander's Dictum). So if there is a belief that p then that mental state has causal powers. Furthermore our mental states do not constitute a totally separate causal web from our behavior. That is, our behavior and mental states are causally connected. Therefore, if a subject believes that $p$ then that subject's behavior will be different than if they did not believe that $p$, even if that belief is too weak to deliberately act upon.

## Experiment to test for SCB

According to the two-system hypothesis there are two systems operating and the reason that subjects answer incorrectly in the examples above is S 2 is not given a chance to make a computation or S2's response is overwhelmed by S 1 . Since the two systems operate in parallel ${ }^{4}$ a subject who offers an incorrect answer and then is told what the correct (S2) answer is will keep her S1 answer at the S1 level. ${ }^{5}$ Take the Linda case for example. If the two-system hypothesis is right then subjects continue to believe (in some sense) that it is more likely that Linda is a feminist bank-teller than a mere bank-teller even after they admit that it is at least as likely that she is merely a bankteller. A subject must suppress her S1 systems if she is to maintain the correct answer while believing a contradictory claim at the S1 level. ${ }^{6}$ This kind of suppression requires the use of cognitive resources, thus temporarily depleting the subject's cognitive resources. So subjects who come to believe the correct answer after the test expend more cognitive energy than those who continue to believe (wrongly) that Linda is more likely a feminist and bankteller than just a bank-teller. Let me offer a rough sketch of an experimental setup (based on experiments performed by Richeson \& Shelton (2007)) to determine if this is right. A similar test could be run for other cases that Sloman and others think are instances of SBC.
In step one subjects are given a reasoning task that might involve SCB (e.g the Linda case). Subjects who offer the correct response should be dismissed. Those who offer the incorrect response should then be divided into two groups. The individuals are interviewed concerning the test that they just underwent. The first group will be made aware of their error during this interview. The experimenters will explain the conjunction fallacy and apply it to the Linda case. The

[^164]second group will not be made aware of their error. In the interviews with members of group two experimenters will explain some unrelated fallacy that is supposed to be similar in phenomenology to the Necker cube (say, the Monty Hall example) (this is step two). Immediately following this interaction members of both groups will be asked to complete a Stroop Test, a typical measurement of executive functioning and cognitive depletion ${ }^{7}$ (step three). If the twosystem hypothesis is right then we should expect that the first group will have slower response times or less accurate responses for the Stroop Test than the second because they will have had to use their executive functioning to suppress their S1 belief that it is more likely that Linda is a bankteller and feminist than she is a mere bank-teller.

It is important that those in group two have a conversation that is cognitively depleting. Otherwise the cognitive depletion in group one but not group two could be attributed to subjects in group one's having a conversation concerning logic beforehand (which depleted their cognitive resources) while the subjects in group two did not. Also, it will be important that subjects in the second group do not come to realize their mistake in the Linda case on their own. Experimenters may want to check at the end of the interview that subjects' in group two have not changed their responses. Alternatively, experimenters could ask subjects if they have changed their response to the initial case after completion of the Stroop Test.

## Conclusion

Sloman has put forth the most explicit reasons for the twosystem hypothesis: at least some of the experiments in the reasoning literature involve SCB, the explanation of which requires at least two reasoning systems. I have argued that the evidence thus far presented does not demonstrate that the beliefs are held simultaneously. However this does not imply a stalemate for advocates and skeptics of the twosystem hypothesis. I have offered the outline for an experiment that would demonstrate the existence of SCB and so give good evidence that humans have two distinct reasoning systems.

#### Abstract

We demonstrate that an ideal observer model bounded by known limitations of the human visual system can explain empirical evidence concerning two effects of distractor ratios on visual search-effects that have previously been explained with salience-based models. The model makes optimal state estimations based on Bayesian estimates of stimuli localization and optimal control decisions of where to fixate in order to maximize task performance. Analysis of the model's behavior under different task strategies and different constraints on the visual system reveal which aspects of the model are responsible for the effects: the distractor-ratio effects on number of fixations is a signature of optimal state estimation in the face of noisy spatial information, and the saccadic-bias effect is a signature of both optimal control and estimation under these same bounds.

Keywords: optimal state estimation, optimal control, ideal observer models, visual salience, distractor ratios

## Introduction

Visual search is so ubiquitous that we probably hardly notice ourselves doing it. We search for our car keys on a cluttered desk, for our family at the market, or for a reference in text. The current paper addresses how one adapts during visual search by determining what information to visually inspect. We address each of these questions through the development of a model based on the optimal integration of perceived information given a set of known constraints on the human visual system.

In a review of the literature on eye movements, Kowler (2011) describes two general approaches to modeling visual search processes. First are map-based approaches, such as salience maps (Itti, 2006; Itti \& Koch, 2000) and activation maps (Pomplun, 2003; Wolfe, 2007), where information is accumulated and processed to produce a topogrpahical map. Peaks in the map represent areas/items that differ from their surround, that contain attributes of the target, or both. Map peaks are used to guide search through the display using some peak selection routine, such as a greedy heuristic (Pomplun, 2003) or winner-take-all algorithm (Itti \& Koch, 2000). In general, the map-based approach assumes that saccades are programmed to move the fovea to an area of a stimulus that
stand out from its surroundings or that is similar in some way to a search goal.

Alternatively, visibility models (Kowler, 2011) such as ideal observer/searcher models (Geisler, 2011; Myers, Gray, \& Sims, 2011; Najemnik \& Geisler, 2008; Baron \& Kleinman, 1969), assume that saccades are programmed to direct foveated vision to areas of impoverished acuity in order to maximize information gained in service of task performance. Najemnik and Geisler (2005) found that the number, and spatial distribution, of saccades to find a target could be predicted by a model in which each saccade was directed to the ideal location (i.e., the highest probability of finding the target). Their model was sensitive to known human constraints on vision (e.g., decreasing contrast sensitivity with increasing eccentricity). Hence, saccadic selectivity could be considered a process that maximizes search performance by considering the effect of the eyes' subsequent fixation location.

In the current paper we build on the ideal observer approach by deriving a boundedly optimal adaptive visibility model capable of capturing empirical phenomena that demonstrate adaptation to changes in the proportion of available environmental features. More specifically, we use the model to explain phenomena associated with the distractor ratio paradigm (Bacon \& Egeth, 1997; Shen, Reingold, \& Pomplun, 2000; Zohary \& Hochstein, 1989)—phenomena that have previously been given interpretations in terms of salience maps. Key to this explanation is the incorporation of constraints on the representation of spatial information in the periphery into an ideal observer analysis .

The adaptive visibility model has a simple structure that decomposes visual search into optimal state estimation (the integration of perceptual evidence into a task-relevant representation of the external stimulus) and optimal control (the choice of overt task responses and information gathering actions; Stengel, 1994). The model incorporates a small number of constraints intended to abstractly characterize important properties of a noisy, foveated vision system (Tanner, 1961). Bayesian state estimation is used to optimally integrate the noisy percepts across fixations in service of two control deci-
sions: 1) where to next fixate and 2) when to issue a task response. Both the estimation and control processes are adapted to the simultaneous constraints of the vision system and the task at hand.

The structure of this model affords the formulation and exploration of a number of interesting theoretical questions concerning visual search phenomena. In this paper, we use modeling to determine whether distractor ratio effects are signatures of optimal state estimation, optimal control, (or both), and to identify the constraints of the visual system that are necessary for the effect to arise. To foreshadow the two key results, the model demonstrates (1) that distractor ratio effects may be understood as adaptation to changes in proportions of task-relevant environment features, and that these effects are signatures of optimal state estimation (not control) in the face of spatial uncertainty in the parafovea; and (2) that saccadic bias may be understood as a signature of both optimal control and optimal state estimation in the face of spatial uncertainty.

In the following sections we first discuss efficient visual search in the distractor ratio paradigm and introduce the boundedly optimal adaptive visibility model. We next discuss model results and their implications.

## Distractor Ratio Paradigm

The distractor ratio is the ratio between distractor sets that share features with a target for a fixed number of items on a display. For example, the distractor ratio when searching for a conjunction of a color and a shape (e.g., red O ) in a display of 48 items is the number of distractors that are the same color relative to the number of distractors that are of the same shape-same-color:same-shape. Hence, the distractor ratio for Figure 1(A) is 3:45, (B) is $24: 24$, and (C) is $46: 2$. Subjects are typically instructed to respond appropriately if they determine that a target is present or absent for each trial.

The distractor ratio paradigm has been used to distinguish between endogenous and exogenous influences on saccadic selectivity processes (Bacon \& Egeth, 1997; Zohary \& Hochstein, 1989). Exogenous influences are hypothesized to arise from the statistical properties of the visual environment, such as salience (Itti, 2006; Itti \& Koch, 2000), whereas endogenous influences are those that stem from knowledge brought to bear on the task through instructions (Yarbus, 1967) or learned during performance (Myers et al., 2011). Regardless of the endogenous/exogenous process distinction, results from distractor ratio experiments demonstrate adaptation to the changing structure of the search environment. Specifically, subjects prefer to actively search through the minority set of distractors that share a common feature with the target. Using eye-tracking, Shen et al. (2000) showed that subjects searching for a target (e.g., red O) preferred the same-color distractors (red X's in Figure 1A), yet adaptively shift this preference to same-shape distractors (i.e., green O) when presented with a distractor ratio where shape was the minority feature (e.g., Figure 1C). Importantly, this adaptation reduced response times and the number of fixations to

Figure 1: Distractor ratio stimuli when searching for a red O, and results from Shen et al. (2000). Panel (A) is a stimulus containing three distractors that share the same color feature as the target. Panel (B) has equal number of like-color and like-shape distractors. Panel (C) has two like shape distractors. Panel (D) demonstrates a $\cap$-shaped curve associated with an increasing number of same-color distractors for target absent (open circles) and target present (filled circles) trials, and represents the distractor-ratio effect.
locate the target (see Figure 1D), improving search efficiency (Bacon \& Egeth, 1997; Zohary \& Hochstein, 1989).

Saccadic selectivity in the distractor ratio paradigm demonstrates rational adaptation from the standpoint that subjects minimize their time to locate a target (c.f. Gray, Sims, Fu, \& Schoelles, 2006). Hence, response times and the number of fixations are minimal when a search stimulus has a minority feature (e.g., color or shape; see Figure 1A) relative to when the distractor ratio is equal to one (see Figure 1B) for target-present and target-absent trials (see Figure 1D). Interestingly, Shen et al. (2000) report that saccadic selectivity favoring the minority feature occurred as early as the very first saccade in a trial.

One potential explanation for the distractor ratio effect is that saccadic selectivity is exogenously influenced through stimulus salience (Theeuwes, 1993). In Figure 1A, the red X distractors stand out from the surrounding green O distractors. The reverse is true for Figure 1C. Hence, the salience approach predicts saccadic selectivity favoring the red X's in Figure 1A and the green O's in Figure 1B. Importantly, the inclusion of some inhibition of return mechanism (IOR; Klein,
2000) is a required addition to salience-based models in order to eliminate endlessly fixating the most salient areas of the display, which are not guaranteed to contain the target. Importantly, the IOR and salience mechanisms would be capable of not only reproducing an important hallmark of adaptive search in the distractor ratio paradigm (the $\cap$-shaped curves depicted in Figure 1D), but also another hallmark: saccadic bias in favor of the minority distractor set.

While the salience + IOR approach provides a potential explanation of adaptive search in the distractor ratio paradigm, we sought an explanation where the observed effects are a consequence of ideal adaptation to noisy encoding processes in the fovea and parafovea. In the following section we describe a reduced complexity version of the distractor ratio paradigm for testing our model.

## Horizontal Array Distractor-Ratio Paradigm

We reduced the task environment complexity from a two dimensional array (see Figure 1A, B, \& C) to a one-dimensional array. This reduction in complexity facilitated the running of a large number of model trials while maintaining the critical components of the distractor ratio paradigm. The reduced complexity version used for testing the model was a set of seven objects arranged horizontally, with $8.3^{\circ}$ of visual angle between adjacent items. The model searched through both target-present and target-absent trials for the same target throughout. Distractors were a conjunction of the same color as the target and a different shape, or vice versa. The model was tested over seven different distractor ratios (6:0, 5:1, 4:2, 3:3, 2:4, 1:5, 0:6; see Figure 2).

Figure 2: Three trials from the horizontal distractor-ratio paradigm. The target is a red O . Trial $5: 1$ corresponds with Figure 1A, $3: 3$ corresponds with Figure 1B, and 1:5 with Figure 1 C .

This one-dimensional version of the distractor-ratio paradigm facilitated computationally tractable Monte-Carlo evaluation of the model, while retaining the relevant features of the paradigm. In the following section we describe the model in detail and present results from the model evaluated on the one-dimensional version of the task.

## Adaptive Visibility Model

The goal of this modeling endeavor is to explain the phenomena associated with strategic adaptation observed in the distractor ratio paradigm, (i.e., the $\cap$-shaped curve and saccadic bias in favor of minority features) as adaptation to perceptual
noise. To achieve this goal we differentiate between state estimation and control (Stengel, 1994). The model we present optimally estimates the state of the visual environment given noisy input, and controls responses based on the optimal state estimation.

The process of active, effortful visual search can be decomposed into two key control decisions: 1) determining if the target is in the stimulus (i.e., the stopping rule), and 2 ) determining where next in the stimulus to inspect (i.e., saccadic selectivity). All search models must contain a stopping rule and a saccade location selection process.

Toward this end we first identified physiological constraints on the visual search process. Next, we assumed that subjects in distractor ratio experiments intended to minimize the time to complete a trial. This assumption has been used in other models as a subjective utility function when an objective utility function is not provided to subjects (Gray et al., 2006; Myers et al., 2011). Third, we determined a set of strategies that could be performed in the task environment. Finally, we used Monte Carlo simulations of the model to determine if the bounded optimal model could explain the distractor-ratio hallmarks of adaptive search. Further, we investigate which model constraints were critical to adaptive visual search observed in humans when performing distractor ratio tasks. We cover each of these steps in more detail in the following sections, and provide a walkthrough of the model process before presenting the model results.

## Constraints on Visual Search

The model begins a trial with a representation of whether the shape and color feature at each of the seven stimulus locations contains the same feature as the target. The model adopts a simple feature-vector coding of the display in which each of the seven locations is represented by 2 real-valued features (one for color, one for shape), where the value 1 is arbitrarily chosen as the target value for each dimension, and 0 as the non-target value. Thus, the true state of the display can be represented as a 14 -element vector of 1 s and 0 s .

There are two constraints on the model, each of which limit the accuracy of the perceived information for each fixation. First, visual acuity decreases with increasing eccentricity from the fovea; we capture this constraint in the model with feature noise. Second, information located in the parafovea is subject to localization error (Levi, 2008; Neri \& Levi, 2006), such that objects encoded in the parafovea may erroneously combine features from different objects at different locations (illusory conjunctions; Põder \& Wagemans, 2007). Each percept obtained by the model is simply the true 14 -element vector representing the display, corrupted by these two noise sources: feature noise and location noise.

The feature noise added to each true percept is a 14 element vector of values sampled from independent normal distributions with mean zero and standard deviations that increase as a step-function based on distance from the fovea. Standard deviations for determining feature noise within the fovea were set to 0.1 and 10 for outside the fovea (the qual-
itative results presented below do not depend on the precise shape of this acuity function). Localization noise was added to the model's percept by allowing the feature value for each position to be sampled from nearby positions with some probability. This probability was set to a low value for the fovea (representing an assumption of good feature binding in the focus of attention) and higher values for parafoveal positions (again, the qualitative results presented below do not depend on the precise values). The result from introducing these constraints was a model with a foveated visual system susceptible to illusory conjunctions. For each location, we sample all objects and obtain noisy feature information from these objects. For the fixation position this will very often be the true object but features will intrude for other positions in the periphery.

## Optimal State Estimation \& Control

The model uses Bayes' rule to optimally estimate the state of the display by integrating noisy perceptual information derived from each fixation. For each given noisy perceptual sample, the model computes the likelihood that the sample was generated from each of the possible target-absent and target-present displays and features at locations within those displays. This is accomplished as follows. First, the likelihoods of observing the perceptual sample at the feature level are computed (using the feature noise model). Second, the likelihoods that a sampled object at a particular location in the display has a specific feature value for each of the possible displays is computed (using the spatial noise model). Third, the probability that the percept was sampled for each display type is computed. Finally, the posterior probability over all the display types is computed using Bayes' rule.

## Search Strategies

There are four potential strategies for locating the target in the distractor ratio paradigm. First, one could choose to make no eye movements at all during a trial, continuing to stare straight ahead. We rule out the use of this strategy as its utility in a search environment such as the distractor-ratio paradigm is very low. The remaining strategies were random search, sequential search and the maximum a posterior (MAP) searcher of Najemnik and Geisler (2008), which we label here the look-for-targets strategy, which simply looks at the location most likely to contain the target.

The random search strategy was implemented by uniformly sampling a location with replacement from all the possible locations in the reduced complexity paradigm until a response was made. Consequently, the model could choose to re-fixate a location it just acquired a percept from. The sequential search strategy was implemented by starting in the middle location and searching from right to left, and back around until a response was made.

The MAP strategy took advantage of the posterior probabilities after each fixation. The model chose the next fixation location based on the posterior likelihood of containing a target. In the next sections we provide a walkthrough of
the model's process for completing a trial followed by results from each of the three strategies just described.

## Model Walkthrough

The model begins each trial with all possible displays being equally likely; consequently, the initial values for the targetpresent and target-absent decision variables equal 0.5 . Once a trial is presented to the model, it begins by fixating a location, obtaining a noisy percept from the fixated location, optimally integrating the noisy percept with previously acquired information from the trial, and calculating decision variables (i.e., target-absent and target-present) based on the optimally integrated percept. If neither of the decision variables reaches a decision threshold (arbitrarily set to 0.85 in the simulations, but which could be optimized to maximize utility in the face of imposed speed-accuracy tradeoffs), then the model selects a new location to fixate. If one of the decision variables is greater-than the threshold, then the model responds appropriately. A maximum number of fixations was set to 30 to prevent the model from infinitely fixating locations in the trial. To be clear, the model is not learning across trials, but is adapting to each trial, independently.

## Model Results

The model was run for 20,000 trials for each of the random, sequential, and look-for-targets strategies. Each trial completed by the model was randomly selected with replacement from all possible trials. Surprisingly, all strategies produced the $\cap$-shaped curve for target-absent and target-present trials, indicating that the distract-ratio effect may arise from optimal state estimation in the face of noisy perception, independent of the saccadic control strategy. We investigate this finding in more detail below.

Less surprisingly, the random strategy required, on average, more fixations to respond $\left(M_{\text {Target-Present }}=\right.$ 4.54; $M_{\text {Target-Absent }}=5.13$ ) than the sequential strategy $\left(M_{\text {Target-Present }}=3.84 ; M_{\text {Target-Absent }}=4.53\right)$, which in turn took more fixations to respond than the look-for-targets strategy $\left(M_{\text {Target-Present }}=2.94 ; M_{\text {Target-Absent }}=3.77\right)$.

The frequency of saccades directed toward objects containing a minority feature in a trial was evaluated to determine if it differed from what would be expected by chance (i.e., saccadic bias in right column of Figure 3; Shen et al., 2000). The analysis revealed that the look-for-targets strategy produced saccadic bias for target-present and target-absent trials whereas the random and sequential strategies did not. The results from the search efficiency and saccadic bias analyses demonstrate that the look-for-targets strategy produces both hallmarks of adaptive search within the distractor ratio paradigm.

To determine which perceptual constraint was required to yield the effects, we ran another round of simulations without location noise (one of two constraints in our ideal observer model). To make this determination we ran two sets of simulations: 20,000 trials for no-location-noise/high-feature-noise and 20,000 trials for no-location-noise/low feature-noise. The

Figure 3: Hallmarks of adaptive search in the distractor ratio paradigm for the random (top), sequential (middle), and look-for-targets strategies (bottom). The left column demonstrate search efficiency in the paradigm and correspond to the human data in Figure 1D. The right column demonstrates saccadic bias in the look-for-targets strategy and the absence of the bias in the other strategies.
removal of location noise eliminated the presence of the $\cap$ shaped curve, whereas high feature noise only contributed to greater fixations to respond relative to low feature noise (see Figure 4). Consequently, we argue that the $\cap$-shaped curve observed in distractor ratio tasks results from the potential for illusory conjunctions in the parafovea.

## Discussion \& Conclusions

The preliminary analysis presented above contrasted a wellknown salience based theory and a novel ideal observer based theory of distractor ratio phenomena. Despite the fact that the salience theory is widely accepted and that there is no previous ideal observer analysis of distractor ratio phenomena, we found that it offered a comprehensive explanation of the available empirical findings. Importantly, the different behaviors seen in people as a consequence of varying the statistical structure of the task environment emerge from a model that computes optimal state estimation and makes optimal control decisions given the constraints imposed by the human visual

Figure 4: Search efficiency results without location noise when feature noise was low (left) and when feature noise was high (right) for the look-for-targets strategy.

## system.

These preliminary findings are promising because the ideal observer, by virtue of the combination of optimal state estimation and control, offers the potential of a deeper explanation than the mechanistic salience model. The ideal observer combines a theory of the information processing mechanisms with an analysis of optimal state estimation and control. Furthermore, the estimation and control decomposition permits the exploration of specific hypotheses concerning the locus of the explanation for a given search phenomenon. Here, we determined that distractor ratio effects are signatures of optimal state estimation in the face of spatial noise in the periphery, while the saccadic bias effects are signatures of both optimal estimation and control.

Although these findings are encouraging, the model requires a number of important revisions before we can be fully confident that it provides a rigorous demonstration of the implications of the hypothesized visual processing constraints for behavior. In particular, we did not explore the full strategy space for directing saccades; although the look-fortargets (MAP) strategy may be close to optimal in this task, we must derive the optimal strategy in the full space and confirm that its predictions are consistent with those of the simple look-for-targets strategy.

Furthermore, we must conduct new human experiments that systematically test predictions of the ideal observer that differ from those of the salience model. We envisage that the new data will be collected using a utility maximization paradigm similar to those used by Trommershäuser and colleagues (Stritzke, Trommershäuser, \& Gegenfurtner, 2009; Trommershäuser, Maloney, \& Landy, 2003) in the explorations of perceptual motor control, and Lewis, Shvartsman, and Singh (to appear) in the exploration of eye-movements in linguistic tasks. Bounded optimal control models naturally predict differences in performance that arise when the payoff is changed but the task and stimuli are otherwise identical,
while salience-based models do not naturally predict such differences. A key advantage of these explicit-payoff paradigms is that assumptions regarding what subjects are maximizing during the experiment are grounded in the external payoffs, which are then used as the subjective utility functions in the optimal control models.

# Is action-guiding vision cognitively impenetrable? 

Bence Nanay (bence.nanay@ua.ac.be or bn206@cam.ac.uk)<br>Centre for Philosophical Psychology, D 413, Grote Kauwenberg 18, Antwerp, 2000 Belgium<br>and<br>Peterhouse, Cambridge University, Cambridge, CB2 1RD, UK

#### Abstract

The aim of this paper is to argue that action-guiding vision is not cognitively impenetrable and arguments that suggest otherwise rely on an unjustified identification between actionguiding vision and dorsal vision - a functional and an anatomical way of describing the mind. The examination of these arguments show the importance of making a distinction between the functional and the anatomical level when addressing the problem of cognitive penetrability.

Keywords: Cognitive impenetrability; dorsal vision; actionguiding vision; perception and action; multimodal perception; top-down influences on perception

## The impenetrability of conscious versus unconscious perception

There are notorious ambiguities in the formulation of the cognitive penetrability debate. Some of these has been acknowledged and (more or less) resolved, like the one about the various senses in which a mental process could be considered to be cognitively penetrable (Fodor 1983). A seemingly simpler but often unacknowledged ambiguity is not about the predicate of the claim that perception is cognitively impenetrable, but its subject.

It seems that when philosophers and psychologists talk about the cognitive penetrability or impenetrability of perception, they mean very different things by 'perception'. Some (mostly philosophers) mean conscious perceptual experience (Lyons 2011, Siegel 2011), some others (mostly psychologists) mean perceptual processes in general, conscious or unconscious. As perception can be conscious or unconscious, even if it is true that conscious perceptual experience is cognitively penetrable (or impenetrable), this should not be generalized to unconscious perception and, as a result, to perception in general.

This distinction is especially important if we consider the following possibility. Many philosophers and psychologists now assume some version of the claim that conscious experiences are cognitively penetrable. But this leaves open the question whether unconscious perceptual states are cognitively penetrable. More specifically, this leaves open whether the most compelling cases for unconscious perceptual processes, namely, the ones that guide our goaldirected actions, are cognitively impenetrable.

According to a more and more influential view, the unconscious perceptual, or, more precisely, visual, processes that guide our goal-directed actions, which we can call 'action-guiding vision' is cognitively impenetrable (Milner 2008, Goodale \& Wolf 2009, Raftopoulos 2001, 2005, Norman 2002, Goodale 2011, Jacob \& Jeannerod 2003, Jeannerod \& Jacob 2005, Jacob 2005, Milner \&

Goodale 1995, 2008, Goodale \& Milner 2004, Rizzolatti \& Matelli 2003). For many philosophers and psychologists, the last refuge of the cognitive impenetrability thesis is unconscious action-guiding vision.

My aim is to argue that action-guiding vision is not cognitively impenetrable and arguments that suggest otherwise rely on an unjustified identification between action-guiding vision and dorsal vision - a functional and an anatomical way of describing the mind. The examination of these arguments show the importance of making a distinction between the functional and the anatomical level when addressing the problem of cognitive penetrability.

## Action-guiding vision

I call 'action-guiding vision' those, mainly unconscious, processes in visual perception that help us to perform the goal-directed movements of our actions. But why should we assume that there is such processes? And why should we think that they are unconscious?

The main reason for thinking that there is such a thing as unconscious action-guiding vision is that in certain circumstances, our conscious visual experiences represent the world differently from the way the perceptual processes that help us to perform goal-directed actions do (see, e.g., Loach et al. 2008, Xu et al. 2012). The most important examples for this comes from the study of optical illusions.

A number of optical illusions mislead our perceptual experience but not (or much less) our action-guiding vision. One such example is the three dimensional Ebbinghaus illusion. The two dimensional Ebbinghaus illusion is a simple optical illusion. A circle that is surrounded by smaller circles looks larger than a circle of the same size that is surrounded by larger circles. The three dimensional Ebbinghaus illusion reproduces this illusion in space: a poker-chip surrounded by smaller poker-chips appears to be larger than a poker-chip of the same diameter surrounded by larger ones. The surprising finding is that although our perceptual experience is incorrect - we experience the first chip to be larger than the second one -, if we are asked to pick up one of the chips, our grip-size is hardly influenced by the illusion (Aglioti et al. 1995, see also Milner \& Goodale 1995, ch. 6 and Goodale \& Milner 2004). Similar results can be reproduced in the case of other optical illusions, like the Müller-Lyer illusion (Goodale \& Humphrey 1998, Gentilucci et al. 1996, Daprati \& Gentilucci 1997, Bruno 2001), the 'Kanizsa compression illusion' (Bruno \& Bernardis 2002), the dot-in-frame illusion (Bridgeman et al., 1997), the Ponzo illusion
(Jackson \& Shaw 2000, Gonzalez et al. 2008) and the 'hollow face illusion' (Króliczak et al. 2006). ${ }^{1}$

What makes it possible for us to reach for the chip with the (more or less) appropriate grip size is action-guiding vision - the visual processes that help us to perform goaldirected actions. Our conscious experience represents the size-property of the chip one way (incorrectly) and our action-guiding vision represents it a different way (more or less correctly). Hence, action-guiding vision is different from our conscious perceptual experience. We cannot explain this behavior without postulating action-guiding vision. And as action-guiding vision represents the sizeproperty of the chip differently from the way conscious perception does, it must do so unconsciously.

I call the representations of action-guiding perceptual processes 'action-oriented representations' (Nanay 2012, Clark 1997, Mandik 2005). In the 3D Ebbinghaus case, it is the action-oriented representation that guides our action: it attributes, unconsciously, the (more or less) correct sizeproperty to the poker-chip - in spite of our very misleading conscious experience.

This focus on action-oriented representations as the mental states that mediates between perception and action provide a more and more popular third alternative to both classic computationalism/propositionalism and antirepresentationalism/enactivism. The mind is to be understood in terms of representations, but these representations are not all propositional, linguistically structured or uniquely human. Some are better compared to the mental representations of the predator that make it possible for it to catch its prey. These representations are simple, supposedly non-propositional, and maybe perceptual, representations and they are also inherently action-oriented (Norman 2002, Hummel et al. 2001, Grush 2004, Gendler 2008, Jeannerod 1997, Millikan 1995, 2004, Pacherie 2011, Jeannerod \& Jacob 2004, Clark 1997, Mandik 2005, Nanay 2011, 2012, 2013, in press).

It is not universally agreed upon that action-oriented representations can be considered to be perceptual states although there are some arguments for this conclusion (Bach 1978, Nanay 2011, 2012, 2013). But those accounts of action-guiding vision this paper is about, the ones that consider action-guiding vision to be cognitively impenetrable, invariably do consider representations that mediate between perception and action to be perceptual

[^166]states (Jeannerod \& Jacob 2003, Jacob \& Jeannerod 2005, Jacob 2005, Jeannerod 1997, Milner \& Goodale 1995, 2008, Goodale \& Milner 2004, Norman 2002).

So far, I treated action-guiding vision as a genuinely philosophical or theoretical category. But this philosophical way of raising the question may puzzle neuroscientists. They have long been studying the link between perception and action and we have a lot of empirical evidence about the nature of the processes that mediate between perception and action. And this body of evidence points to the dorsal visual subsystem. The dorsal visual subsystem is a genuine part of the perceptual system of mammals and its function is widely acknowledged to be the guiding of goal-directed actions.

In the light of the similarities between the dorsal visual subsystem and action-guiding vision, a very tempting suggestion would be to say that action-oriented representations must be the representations of the dorsal visual subsystem (see, e.g., Jacob \& Jeannerod 2003, Jacob 2005, Norman 2002, see also Matthen 2005 for a more cautious claim). The dorsal system guides action and represents the world in such a way that would help us perform actions - this sounds exactly like what actionguiding vision is supposed to do.

I will argue that we should resist this temptation to equate 'action-guiding vision' with 'dorsal vision'. And, more specifically, we should not identify action-oriented representations, the representations, posited on the functional level, with the representations of the dorsal stream. The dorsal stream plays an important role in the implementation of action-guiding vision, but it is unlikely that it plays the only role. We should be careful not to conflate the functional and the neural level.

## Dorsal vision

Humans (and other mammals) have two visual subsystems that use different regions of the central nervous system, the ventral and dorsal streams. To put it simply, the ventral stream is responsible for identification and recognition, whereas the function of the dorsal stream is the visual control of our motor actions. In normal circumstances, these two systems work together, but if one of them is removed or malfunctions, the other can still function relatively well (see Milner \& Goodale 1995, Goodale \& Milner 2004).

If the dorsal stream is malfunctioning, the agent can recognize the objects in front of her, but she is incapable of manipulating them or even localizing them in her egocentric space (especially if the perceived object falls outside the agent's fovea). This is called optic ataxia. If the ventral stream is malfunctioning, a condition called visual agnosia, the agent can perform actions with objects in front of her relatively well, but she is incapable of even guessing what these objects are.

The three dimensional Ebbinghaus illusion I mentioned above is normally explained as a nice demonstration of the dissociation between the dorsal and ventral visual subsystems in healthy human adults: the ventral subsystem is fooled by the illusion, but the dorsal is not. The other
examples in which optical illusions deceive the eye, but not the hand (Ponzo, Müller-Lyer, Kanizsa-compression, hollow face, etc) are analyzed in the same way. Sometimes our ventral visual subsystem attributes a different property to an object from the one the dorsal subsystem does.

The most important characteristics of the dorsal stream from the point of view of this paper is that it is taken to be informationally encapsulated from the rest of the brain. The original picture (in Milner \& Goodale 1995) was that dorsal processing is quick, automatic and insensitive not only to higher order mental processes, but also to processing in the ventral stream. While it has been very much debated whether the dorsal stream is insensitive to processing in the ventral stream (see below), the claim about the insensitivity of dorsal processing to higher order mental processes remains more or less uncontroversial even in the works of those who argue for various interactions between the dorsal and the ventral streams (see, e.g., Jeannerod and Jacob 2005, Rizzolatti \& Matelli 2003, Kravitz et al. 2011, Rossetti \& Pisella 2002).

Back to action-guiding vision. A very tempting suggestion would be to say that action-guiding vision is just dorsal vision and action-guiding representations are the representations of the dorsal visual subsystem. The dorsal system guides action, just like action-guiding vision. The dorsal system represents the world in such a way that would help us perform actions and so do action-oriented representations. Shouldn't we then just say that it is the dorsal stream that mediates between perception and action? If we were to accept this claim, it would follow that actionguiding vision is cognitively impenetrable. In fact, the proponents of the idea of the cognitive impenetrability of action-guiding vision take the informational encapsulation of the dorsal stream to be the main evidence for their claim (see esp. Goodale \& Wolf 2009, see also Jeannerod \& Jacob 2003, Norman 2002, Milner \& Goodale 1995, 2008, Raftopoulos 2001, 2005).

My aim is to carefully detach claims about action-guiding vision from claims about the dorsal stream. Action-guiding vision is not the same as dorsal vision. Whatever the neural implementation of action-guiding vision is, it surely includes the dorsal visual subsystem. But it cannot be restricted to the dorsal visual subsystem, for the following three reasons.

## Interactions between the dorsal and the ventral subsystems

First, the anatomical distinction between the dorsal and the ventral visual subsystems is not as neat and clear-cut as it was originally thought. It seems that there are interactions between the two streams at various point of perceptual processing (see, e.g., Jeannerod 1997, Franz \& Gegenfurtner 2008, Franz et al. 2000, Schenk \& McIntosh 2010, Rosetti \& Pisella 2002).

Further, to make things even more complicated, it has been argued that instead of two visual subsystems, we need to talk about three: the ventral, the ventrodorsal and the
dorsodorsal. To simplify matters considerably, what has been taken to be one single dorsal subsystem should be divided into two: one responsible for manipulating objects (dorsodorsal) and one responsible for localizing in egocentric space (ventrodorsal) (Rizzolatti \& Matelli 2003).

Even more recently it has been suggested that what was originally taken to be the dorsal stream is in fact the ensemble of three different visual subsystems (Kravitz et al. 2011). To talk about the dorsal stream as an independent chunk of the brain and to talk about action-oriented representations as the representations of this unified and independent bit of mental processing would be misleading to say the least.

## Is dorsal vision necessarily unconscious?

Second, there is a major debate both in vision science and in philosophy of cognitive science about whether dorsal vision is necessarily unconscious. The original proposal was that ventral visual processing may be conscious or unconscious, but dorsal processing is always unconscious. (see esp. Milner \& Goodale 1995, Goodale \& Milner 2004). But this view has been criticized both on empirical and on conceptual grounds (see Dehaene et al, 1998, Jeannerod 1997, Jacob \& Jeannerod 2003).

This debate does not seem to go away (see Brogaard 2011, Briscoe 2008, Milner \& Goodale 2008, Jeannerod \& Jacob 2004, Goodale 2011, Clark 2009, Kravitz et al. 2011). As action-oriented representations can be conscious or unconscious (although they are typically unconscious), if we were to equate action-oriented representations with dorsal perceptual processing, we would have to take sides in this grand debate, which proponents of the action-oriented representation approach would be well advised to avoid.

## Multimodality

The third reason why action-oriented representation is not to be identified with the representation of dorsal perception is the multimodality of perception. There is a lot of recent evidence that multimodal perception is the norm and not the exception - our sense modalities interact in a variety of ways (see Spence \& Driver 2004, Vroomen et al. 2001, Bertelson \& de Gelder 2004, O’Callaghan 2008). Information in one sense modality can influence the information processing in another sense modality at a very early stage of perceptual processing (often in the primary visual cortex in the case of vision (e.g., Watkins et al. 2006).

A simple example is ventriloquism, which is an illusory auditory experience caused by something visible (Bertelson 1999, O’Callaghan 2008). The auditory sense modality identifies the ventriloquist as the source of the voices, while the visual sense modality identifies the dummy. And the visual sense modality modifies the way we auditorily experience the scene. But there are more surprising examples: if there is a flash in your visual scene and you hear two beeps while the flash lasts, you experience it as two flashes (Shams et al. 2000).

Now, action-oriented representations are not necessarily visual: they can occur in any sense modality. But the dissociation between the dorsal and ventral subsystem is a distinction in the visual sense modality. Some have suggested a similar dissociation for speech perception (see, e..g, Hickock \& Poeppel 2007) and for touch (Reed et al. 2005), but the evidence for dissociations similar to the one in the case of vision is far from clear in audition, olfaction and the other sense modalities. Tying action-oriented representations to the dorsal visual subsystem would make it difficult to talk about action-oriented representations in sense modalities other than vision.

Further, the literature on the multimodality of perception clearly shows that our perceptual states in one sense modality are influenced by the information we receive in other sense modalities. And there are some recent behavioral experiments supporting the multimodality of action-oriented representations (see esp. Stein et al. 2004, Gentilucci et al., 1995). How about the dorsal stream? Although it seems clear that the dorsal stream is also multimodal (see, e.g., Battaglia-Mayer \& Caminiti 2002), but the exact extent of the crossmodal influences on dorsal processing has been debated (see, e.g., Lewis \& Van Essen 2000, Rozzi 2008). Again, it seems that the neural correlate of action-oriented representation has a lot to do with the dorsal stream, but the current empirical evidence on multimodal perception does not quite support the claim that it is identical to, or fully exhausted by, the dorsal stream.

To sum up, these findings all point in the direction of a theoretical framework where it is clear that the dorsal stream plays an important role in the implementation of actionguiding vision, but it is unlikely that it plays the only role. Whatever the neural implementation of action-guiding vision is, it surely includes the dorsal visual subsystem. But we have strong reasons to doubt that it is restricted to the dorsal visual subsystem.

## Is action-guiding vision cognitively impenetrable?

We are finally in the position to assess the claims about the cognitive impenetrability of action-guiding vision. The proponents of the idea of the cognitive impenetrability of action-guiding vision take the informational encapsulation of the dorsal stream to be the main evidence for their claim (see esp. Goodale and Wolf 2009, see also Jeannerod \& Jacob 2003, Norman 2002, Milner \& Goodale 1995, 2008, Raftopoulos 2001, 2005). But as I argued, action-guiding vision and dorsal vision should not be conflated. As a result, the argument from the informational encapsulation of the dorsal stream will bear no direct implications for the cognitive impenetrability of action-guiding vision.

But we have even stronger reasons to mistrust the suggestion that action-guiding vision is cognitively impenetrable. We have some positive evidence that actionguiding vision is sensitive to various top-down factors, like the subject's affective life (Morgado et al. 2011), her language skills (Pulvermuller et al. 2005) and her
expectations or knowledge. The example I will be focusing on is the following: two very widely used brand of matches in the UK are 'Swan Vestas' and 'Scottish Bluebell'. The box of Swan Vestas is $25 \%$ larger than that of Scottish Bluebells. And it turns out that the brand of the match boxes influences our grip size when grasping them (McIntosh \& Lashleya 2008). When the subjects were grasping the 1.25scale replica of the Scottish Bluebell box, their grip size was smaller than it was when grasping the normal Swan Vestas of the same size. And when they were grasping the 0.8 -scale replica of Swan Vestas box, their grip size was larger than it was when grasping the normal Scottish Bluebell box. Hence, the brand of the match boxes (but at the very least, the recognition thereof) influences grip size: it influences our action-guiding vision.

Dorsal vision may or may not be informationally encapsulated. But action-guiding vision, as the McIntosh and Lashleya experiment shows, is cognitively penetrable. Then this finding can be used as an independent evidence for the claim that dorsal vision and action-guiding vision are different and they should not be confused. ${ }^{2}$

But there is a more general lesson to be learned from the controversy about the cognitive impenetrability of actionguiding vision. Dorsal vision is an anatomical concept - it is identified by means of anatomical criteria. Action-guiding vision is a functional concept - it is identified by means of functional criteria. To confuse the two is to confuse the functional and the anatomical ways of describing the mind.

And this confusion is especially dangerous when it comes to the cognitive impenetrability debate. The proponents and opponents of the cognitive impenetrability of perception agree that whatever is meant by perception in this debate, for example, whether it is conscious experience or some unconscious perceptual process, it is to be identified by means of functional criteria. But then we should be suspicious of using anatomical data in support of, or against, the cognitive impenetrability claim.

If we are to keep the functional and the anatomical levels of describing the mind separate, then using anatomical data to bear directly on the cognitive impenetrability debate is a methodological mistake. The example of using the anatomical data of the dorsal stream to argue for the cognitive impenetrability of action-guiding vision is a good case study of this.

# Finding hidden types: Inductive inference in long-tailed environments 

Daniel J. Navarro (daniel.navarro@adelaide.edu.au)<br>School of Psychology, University of Adelaide, SA 5005, Australia

#### Abstract

Making inference in everyday life often requires people to make inferences about low frequency events. In the most extreme case, some types of object or event may have never been previously observed. An experiment is presented in which participants needed to infer the existence and number of unobserved event types, based solely on the frequency distribution of a set of observed events. Results indicate people's inferences are sensitive to the shape of the distribution over the observed events, even when the number of observed events and event types is held constant, and that people are able to infer abstract rules that describe entire classes of event distributions. Human inferences are shown to be similar to those made by a hierarchical Bayesian model.

Keywords: inductive inference, Bayesian cognition, frequency effects, concept learning

Imagine you are walking through the bushlands in a foreign land. You are accompanied by a local guide, who comments on the plant life around you. So far she has described 20 plants as alba, 20 plants as glabra and another 20 as eburnia. On this basis it is tempting to think that albas, glabras and eburnias are the only types of plants around, or at least the only plant types that your guide is intending to label for you. You could not be certain that this is the correct inference of course, but it seems sensible.

Contrast this with a slightly different scenario, in which your guide refers to 58 of the plants as albas, points to one example of a glabra and one example of an eburnia. Again, it is impossible to be sure what to believe, but it seems much less reasonable to conclude that these are the only three plant labels that your guide is ever going to use. Both scenarios involve 60 plants and 3 category labels, yet they do not feel equivalent.

The logic behind this intuition is relatively straightforward. In the second example, you have evidence of the existence of low-frequency types, whereas in the first example you do not. The fact that some types are relatively rare suggests that there may be other rare types that you have not yet seen. In other words, the shape of the frequency distribution plays a powerful role in shaping our inductive inferences in this problem. This is illustrated in Figure 1.

In essence, this is a category learning problem: the learner has encountered a new kind of object (the foreign plants) and is attempting to learn the extension of the category with respect to a particular feature (the labels). Viewed as a category learning problem, the different inferences drawn in the two cases are an example of a frequency effect, though of a
rather different character than the usual exemplar frequency effects. The key difference is that the effect does not pertain to a specific exemplar, but instead is an effect that pertains to the overall frequency distribution. In the first case, the learner has evidence that the frequency distribution is homogeneous: the observed exemplars have equal frequency. In the second case, the evidence implies that the frequency distribution is long-tailed, meaning that there are a small number of items that are very common, but most observations are quite rare.

## Frequency effects in categorization and choice

Exemplar frequency effects are well-established in the categorization literature: for instance, high-frequency exemplars are classified more accurately, and are judged to be more typical of the category than are low-frequency items (Nosofsky, 1988). However, although the role of item frequency is wellstudied (Nosofsky, 1988; Barsalou, 1985; Barsalou, Huttenlocher, \& Lamberts, 1998), the inductive inference described earlier is rather different to exemplar frequency effects as they are traditionally conceived. In both examples the $o b$ served frequency of blue, purple, white or any other color flower is zero, yet they differ in terms of the expected subjective frequency. That is, changing the distribution of the same set of three types (albas, glabras, eburnias) alters the expectations about the probabilities associated with as-yetunobserved types.

Frequency effects of a different kind arise in the judgment and decision making literature. In this literature the focus is on how much weight people place on low-frequency outcomes when evaluating possible options, whereas the concept learning literature tends to focus on the role of high-frequency items. Although much of the early evidence (Kahneman \& Tversky, 1979; Tversky \& Fox, 1995) suggested that people tend to overweight low-frequency events, there is some evidence indicating that this applies primarily to described frequencies, and not to experienced ones (e.g. Barron \& Erev, 2003; Hertwig, Barron, Weber, \& Erev, 2004), though much of this difference can be attributed to the different information and feedback available to participants (e.g. Rakow, Demes, \& Newell, 2008; Camilleri \& Newell, 2011). As with the category learning literature, these studies have focused on events whose observed frequency is at least one, rather than looking at the inferences people make about never-observed events.

Figure 1: Illustration of why the shape of the type-token distribution matters. Suppose you had observed several observations of types A, B, and C, all of which are equally frequent (panel a). In order to believe that there are more hidden types $\mathrm{D}, \mathrm{E}$ and F , one is required to postulate that the true distribution looks like panel b . If, however, the empirical frequencies observed were asymmetric (panel c), then in order to believe in hidden types $\mathrm{D}, \mathrm{E}$ and F , one is required only to postulate a rank-frequency distribution like the one in panel d. To the extent that the distribution in panel $b$ feels less natural than those in panels $a$, c and d, people should be expected to draw different inferences about unobserved types when presented with uniform data than when they are presented with asymmetric data.

## Learning kinds of feature distribution

A recent topic of interest in the concept learning literature is how people learn abstract rules ${ }^{1}$ that guide inductive inference in new situations (e.g. Kemp, Goodman, \& Tenenbaum, 2010; Perfors \& Tenenbaum, 2009). Applied to the current context, the idea would be that people do not merely learn that a single category shows a skewed frequency distribution over object types. Instead, people can learn that "skewness" is a property that is possessed by multiple categories. For example, if we know that the distributions of flood and fire severity are long-tailed (two categories of natural disaster for which a reasonable of data are available to people), we might also guess that the distribution of asteroid strikes (a category of natural disaster largely unknown to people) has a similar shape. One goal of the current work is to see whether people are willing to draw abstract inferences about distributional shape, and use these inferences to alter their guesses about unobserved event types.

## Overview

The goal of this paper is to investigate how people infer the existence of unobserved event types, and whether people are

[^168]

Figure 2: Sample stimulus in the pencil-and-paper version of the task. This was the first trial in the skewed condition (lower left panel in Figure 3). There are 10 tokens of the $\Im$ type, 1 token of the $\sqrt{ }$ type, and 1 token of the $\varnothing$ type. The computerized task was the same, but types were differentiated by color as well as by symbol, and the assignment of symbols was randomized.
sensitive to distributional form when doing so. The structure of this paper is as follows. An experiment is described in which participants were asked to guess how many types of marbles exist in a bag that is only partially observed, where the distribution of observations is manipulated. Human responses in this task are compared to the predictions of a hierarchical Bayesian model that learns both the number of types and the shape of the distribution over types. The implications of the results for the black swan problem that motivated the experiment are discussed.

## Experiment

## Method

Participants 101 participants ( $68 \%$ female) were recruited from the University of Adelaide community: 33 were undergraduates participating for course credit, 57 were recruited through a paid participant list, and 11 were graduate students. The 57 paid participants did a computerized version of the task, while the other 44 participants completed a pencil and paper version.
Materials \& Procedure The task took the form of a guessing game involving 7 trials. On each trial participants were shown 6,12 or 18 marbles, and told these had been drawn from a bag containing 100 marbles in total. Each marble belonged to one of several types, indicated by a symbol displayed on the marbles surface, and the participant was asked to guess how many types were represented in the full set of 100 marbles. No feedback was given as to the true number of types. Figure 2 illustrates how a set of 12 marbles belonging to 3 types was displayed.

Participants were randomly assigned into one of two conditions, referred to as the "uniform data" condition and the "skewed data" condition. The number of marbles observed and the number of types they belonged to was identical across conditions. For example, the first trial always showed 12 marbles (tokens) belonging to 3 types, and the second trial always showed 18 tokens that represented 4 types of marble regardless of condition. The conditions differed only in the frequency distribution over types. In the uniform condition, the tokens were evenly divided among types: on trial 1 , for instance, there were 4 marbles of each of the 3 types (i.e., a 4-4-4 split). In the skewed condition, the split was highly uneven, with most marbles belonging to a single type: on trial 1 , the split was $10-1-1$. The complete set of frequency dis-

Figure 3: Experimental design. Each panel shows a rank-frequency plot of the marbles on a single trial. The top row shows the type-token distribution for all 7 bags in the uniform condition. The bottom row shows the corresponding distributions for the skewed condition.

Table 1: Descriptive statistics. On the left is a summary of the observations shown to participants on each trial. The middle columns show the $5 \%$ trimmed mean response broken down by bag number and condition. The right columns show the proportion of "extrapolative" responses, namely the proportion of responses that imply the existence of at least one unobserved type.

|  |  |  | Mean |  | Extrapolation |  |
| ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| Bag | Tokens | Types | Unif. | Skew. | Unif. | Skew. |
| 1 | 12 | 3 | 4.35 | 6.38 | 0.34 | 0.47 |
| 2 | 18 | 4 | 4.40 | 7.64 | 0.18 | 0.47 |
| 3 | 18 | 5 | 5.75 | 10.54 | 0.34 | 0.63 |
| 4 | 6 | 3 | 4.58 | 8.64 | 0.45 | 0.70 |
| 5 | 18 | 2 | 2.42 | 2.79 | 0.14 | 0.30 |
| 6 | 6 | 2 | 3.02 | 4.13 | 0.43 | 0.49 |
| 7 | 6 | 1 | 1.32 | 1.77 | 0.25 | 0.47 |

tributions used in the experiment is shown in Figure 3. Note that the final trial was identical in both conditions.
Exclusions Data from 7 participants were excluded either because they gave impossibly large or impossibly small responses, indicating that they did not understand the task. An 8th participant was excluded for omitting responses. An additional 6 participants gave sensible but qualitatively different responses ${ }^{2}$ to the remaining 87 . As such, the data from these two groups should not be aggregated, but the minority group is too small to analyze separately.

## Results

Table 1 presents an overview of the data. For all seven trials, the average number of types estimated by participants was larger in the skewed distribution condition than in the uniform distribution condition. Moreover, if we classify re-

[^169]sponses into two categories - those "extrapolative" responses in which participants inferred the existence of at least one hidden type, and responses in which they did not - we observe the same pattern. Participants were more likely to infer the existence of hidden types when the observed frequency distribution was skewed. ${ }^{3}$

To determine if the tendency to estimate more types in the skewed condition represents a significant effect, it is convenient to code the responses in terms of the number of unobserved types the participant predicted, rather than the total number of types estimated for the bag. When coded in this fashion, a response of " 3 types" on the first trial is treated the same as a " 1 type" response on the last one, because in each case the participant has indicated that he or she does not believe there are any hidden types. This has the advantage that a "0 hidden types" response always represents "no extrapolation", and all other responses represent "the extent of the extrapolation" from the sample shown to the participant.

Once the data are coded in this fashion, they can be analyzed using linear mixed effects models, which are wellsuited for describing data with a repeated measures structure. In addition to including a fixed effect of condition, the model includes a random effect of bag for each participant in order to capture individual differences in responding. ${ }^{4}$ Moreover, because the responses are skewed due to the presence of a floor effect (i.e., "zero" hidden types is a natural lower bound on responses), a Poisson error distribution was used instead of assuming normality. ${ }^{5}$ The key result is that the Wald test for the

[^170]

Figure 4: Two different biases that the model can learn, for bags containing $k=6$ types. In panel (a), the type frequencies are highly uniform ( $\alpha=100$ ), and the expected rank-frequency plot is quite flat (it becomes perfectly flat as $\alpha \rightarrow \infty$ ). In panel (b), the type frequencies are highly variable ( $\alpha=.5$ ) and the expected rankfrequency plot is very skewed.
main effect of condition was significant ( $z=3.11, p=.002$ ): participants did in fact guess that more unobserved types existed in the skewed condition than in the uniform condition.

The previous analysis demonstrated that participants in the skewed condition tended to estimate more hidden types than participants in the uniform condition. In addition to showing that this effect exists across the whole experiment, it is particularly useful to focus on bag 7, as this represents the purest test of whether people were forming theories about bags in general. A two sample Wilcoxon test ${ }^{6}$ applied to the bag 7 data revealed a significant difference ( $Z=-2.09, p=.037$ ). Despite the fact that the final bag was identical in both conditions, participants estimated more unobserved types when the preceding bags had revealed a skewed distributional shape.

## A probabilistic model of the task

This section outlines a computational analysis of the induction problem used in the experiment. The analysis relies on a probabilistic model of how bags of marbles are generated and how observations are sampled from those bags. It is related to the Bayesian concept learning model used by Kemp, Perfors, and Tenenbaum (2007), but differs in a key respect. Kemp et al. (2007) assume the learner knows the true number of object types in advance, whereas the model used here treats the number of types as an unknown quantity that must be inferred. As with most computational analyses, the model does not describe the processes people use to arrive at estimates. Rather, it provides a sensible standard against which human judgments in this task can be assessed.

## Generative model for bags

Suppose that a bag contains $k$ types of marbles, and let $\theta_{i}$ denote the probability that a particular marble will be of the $i$-th type. We may characterize the bag itself using a vector of

[^171]

Figure 5: Structure of the model. Shaded circles denote variables that had been observed by participants on or before trial $b$ of the experiment. Unshaded circles denote variables whose values must be inferred. The question asked of participants on trial $b$ corresponds to the value of $k_{b}$.
type probabilities $\boldsymbol{\theta}=\left(\theta_{1}, \ldots, \theta_{k}\right)$. A set of $n$ observed marbles from the bag $\boldsymbol{x}$ can be treated as a multinomial sample of size $n$ generated with probabilities $\boldsymbol{\theta}$. The unobserved marbles can be viewed as a multinomial sample of size $100-n$ from the same distribution. ${ }^{7}$ This model implies that, in a sample of size $n$, the learner should expect to see $n \theta_{i}$ exemplars of type $i$. As such, if $n$ and $\theta_{i}$ are both small, it is quite possible that zero exemplars of type $i$ appear in the learner's observations; it therefore becomes an unobserved type.

This formalism can be extended to provide a generative model for bags, which comes in two parts. First, the number of types $k$ is sampled from some distribution. This paper uses a binomial distribution for this purpose, though this choice is somewhat arbitrary. Second, once $k$ is sampled, the vector of type probabilities $\boldsymbol{\theta}$ is generated. A convenient choice is a Dirichlet distribution with symmetry parameter $\alpha$. This distribution is widely used by Bayesian concept learning models (e.g. Anderson, 1991; Kemp et al., 2007), and allows the learner to have strong beliefs about the shape of the frequency distribution without knowing a priori which types are more common. If $\alpha$ is small, the learner has a strong expectation that some types of marble will be frequent (Figure 4b) while others will be rare. In contrast, if $\alpha$ is large, the learner possesses a strong expectation that all types of marble should occur with approximately equal frequency (Figure 4a).

An important characteristic of this model is that it satisfies the intuitive constraint illustrated in Figure 1. The uniform distribution in panel a is the expected pattern when $k=3$ and $\alpha$ is large. The skewed distributions in panels c and d are the expected patterns produced by small $\alpha$ values, with $k=3$ and $k=6$ respectively. In contrast, although the distribution shown in panel $b$ is possible within the model, it is not highly likely under any choice of $k$ and $\alpha$.

Formally, the model is written as follows: if bags are generated with symmetry parameter $\alpha$, then we obtain the following sampling model for the observations $\boldsymbol{x}$ :

$$
k \mid \lambda \sim \operatorname{Binomial}(\lambda, n)
$$

[^172]

Figure 6: Schematic illustration of the inferences drawn by the model when the observed data are uniform. Things marked "??" refer to values that are inferred by the model rather than observed.

$$
\begin{aligned}
\boldsymbol{\theta} \mid k, \alpha & \sim \operatorname{Dirichlet}\left(\alpha \mathbf{1}^{(k)}\right) \\
\boldsymbol{x} \mid \boldsymbol{\theta} & \sim \operatorname{Multinomial}(\boldsymbol{\theta}, n)
\end{aligned}
$$

where $\mathbf{1}^{(k)}$ denotes a vector of length $k$ that contains only 1 s , and $n$ is treated as a fixed property of the experiment and is not part of the generative process over observations. The prior over $\alpha$ is assumed to be a gamma distribution.

The structure of this model as a whole is illustrated graphically in Figure 5. On trial $b$ of the experiment, the learner has access to the samples $\boldsymbol{x}_{1}, \boldsymbol{x}_{2}, \ldots, \boldsymbol{x}_{b}$ from the first $b$ bags (shaded circles). The task as stated is to estimate the the number of types in the $b$-th bag, $k_{b}$, which is one of the several unobserved variables (white circles) whose value is inferred via Bayesian inference.

## Learning abstract rules about bags

One of the important patterns in the empirical data is the fact that participants give different responses to bag 7 in the two conditions. The model reproduces this pattern because the symmetry parameter $\alpha$ describes an abstract regularity that attaches to all bags. As such, the model is able to learn the value $\alpha$ across trials. If the model is shown several samples with uniform distributions over observed types, the model will gradually raise the value of $\alpha$. The value of $\alpha$ tends to decrease when the observed type frequencies are consistently non-uniform.

The consequences of this learning are illustrated in Figures 6 and 7. In the bottom row of Figure 6, the observed samples are evenly split across types, so the model infers a large value for $\alpha$ (top row). The most plausible way to have uniform distributions and remain consistent with the raw data is to have no unobserved types (middle row). Contrast this with the skewed-data scenario in Figure 7. Here the model infers a small value for $\alpha$ and assumes that all of the frequency distributions are also skewed (middle row). Skewed distributions over types imply that at least some types are low probability, so it is entirely plausible to believe that unobserved types exist. As a consequence, the model makes different predictions about the final bag in Figure 7 than it does for the exact same bag in Figure 6.

Figure 7: Schematic illustration of the inferences drawn by the model when the observed data are skewed. Things marked "??" refer to values that are inferred by the model rather than observed.

## Model implementation

Although the model specifies many latent variables, the quantity of interest for the $b$-th bag is $P\left(k_{b} \mid \boldsymbol{x}_{1}, \boldsymbol{x}_{2}, \ldots, \boldsymbol{x}_{b}\right)$, the posterior probability that bag $b$ contains $k_{b}$ types of marbles, given all of the samples observed so far. This posterior probability cannot be computed analytically: given this, the model was implemented in JAGS (version 3.1.0) and numerical estimates were obtained using Markov chain Monte Carlo. For each bag $b$, samples were drawn from the joint posterior distribution over all latent variables, and these samples were used to approximated the posterior probabilities of interest.

Because the data presented to participants is different on each trial, fitting the model to the data requires 14 separate model runs. Each of these 1750 model runs involved drawing 1000 samples from the posterior distribution over $k$ after a burn in of 1000 samples. Moreover, because the model predictions depend on the choice of priors, a grid search using 125 different parameter sets was tried. The value of $\lambda$ was varied from .05 to .25 , and the shape and scale parameters for the prior over $\alpha$ were both varied from 1 to 5 . The best performing parameter values correspond to a prior over $k$ that is $\operatorname{Binomial}(0.15,100)$ for all bags, and a prior over $\alpha$ that is $\operatorname{Gamma}(4,2)$.

## Modeling human data

The model predictions are generally in close agreement with human responses, but there are some differences. The main one is that the model never generates extremely large estimates: human participants occasionally guessed that a bag contained more than 5-6 hidden types, whereas guesses of this kind do not appear at all among the 1000 samples from the model posterior. In other words, although the model produces a distribution over responses that is qualitatively in agreement with human responses, it contains fewer very large values. This difference appears to be due to the fact that the model does not incorporate individual differences: it assumes that all participants have the same priors and rely on the same probabilistic assumptions about the task. ${ }^{8}$ Nevertheless, there

[^173]

Figure 8: Comparing the model fits against human responses. The Pearson correlation between model and human is $0.89(p<.001)$.
are individual differences in how people solve the task. There are a few people who consistently estimate large numbers of hidden types, but most do not. This makes it difficult to directly compare model estimate of $k$ against the raw human responses.

A simple solution to the problem is to compare the qualitatively important distinction in the task, namely whether or not a particular response implies the existence of at least one hidden type. That is, instead of fitting the model to the mean number of types estimated by participants (middle columns in Table 1), it is fit to the proportion of human responses in which the number of estimated types was larger than the number of types revealed in the same (right columns in Table 1). These responses are "extrapolative" in that they indicate that the participant has extrapolated beyond the observed data and guessed that there exists at least one hidden type.

Figure 8 plots model estimate of the probability that a bag contains at least one hidden type against the proportion of extrapolative responses in the empirical data. Circles denote bags in the uniform condition, and diamonds represent bags in the skewed condition, and the text denotes bag number. The correlation between model predictions and human responses is $0.89(p<.001)$ for the best fitting parameter values. However, the model fit is robust: the average correlation across all 125 parameter sets was 0.84 , never fell below 0.66 , and was significant at $p<.01$ in all cases.

## Discussion

The close agreement between model predictions and human responses implies that people are sensitive to the information contained in the shape of the distribution of events they have experiences when making inferences about types of events they have never seen. Moreover, the fact that systematic differences existed on the final trial of the experiment, and that these differences are captured via a hierarchical Bayesian
model, implies that people are able to use the information from one context (i.e., one bag) to inform the inferences they draw in another one.

One potential extension to this work is to is to consider the role of information search. In the current study, the number of observations sampled from each bag was fixed by the experimenter. However, in many real world decision making problems, people have some degree of control over how much information they collect before making choices. It seems plausible to think that, when the true event distribution is very uneven, people will adopt a very different search strategy than if the frequency distribution is uniform. As such, the constraint that the number of types and tokens observed needed to be matched across experimental conditions, although important from a methodological perspective, may obscure one of the key differences in how people make inferences and choices more generally. In preliminary work investigating this question, we have found some evidence that information search process is indeed influenced by distributional shape, but this is work in progress.

#### Abstract

Beliefs frequently undergo revisions, especially when new pieces of information are true but inconsistent with current beliefs. In previous studies, we showed that spatial belief revision is often guided by the functional asymmetry between the reference object and the located objects of the spatial relation. Here we first draw a connection between spatial belief revision and grounded cognition. In two experiments, we explored whether imagined physical properties of objects influence which object is relocated and which remains at its initial position. Participants mentally revised beliefs about the arrangement of objects which could be envisaged as small and large (Experiment 1) or easy to move and difficult to move (Experiment 2). The results show that (1) small objects are more often relocated than larger objects and (2) easy to move objects are faster relocated than difficult to move objects. The findings are in line with the idea of grounded cognition.

## Introduction

Imagine you have a date with a friend in a foreign city. He described to you how to come to the meeting point: "When you get off the train, you will see the kiosk to the left of you, and an ice cart to the right of you. To the left of the kiosk, I will wait for you." This description is compatible with the following mental model:
Kiosk - I - ice cart

Almost arriving you get a call from your friend who tells you: "I made a mistake. The kiosk is to the right of the ice cart." On which side is your friend waiting for you? In fact there are two possibilities:

$$
\begin{align*}
& \text { I - ice cart - kiosk }  \tag{1}\\
& \text { Ice cart - kiosk - I }
\end{align*}
$$

In everyday life, we are often confronted with such problems. People describe how to find certain objects and then realize that the description is wrong ("I left your key on the kitchen table, but it is actually on the table in the living room"); someone describes how to find a certain place in a foreign city and on your way, you realize that his
description was wrong; your partner describes where he parked your car, but it is parked somewhere different, and so on.

All this has to do with the field of "belief revision". Researchers in this field explore how people change their mind in the light of new contradicting information. The experimental studies mostly used conditional reasoning problems in which an inconsistency arises between a fact, contradicting a valid conclusion, and the conditional and categorical premises. Within this research, psychologists were able to show that belief revision is affected by many factors, including asymmetries between particular facts and general laws (Revlis, Lipkin, \& Hayes, 1971), conditional and categorical premises (Elio \& Pelletier, 1997; Dieussaert, Schaeken, De Neys, \& d’Ydewalle, 2000; Girotto, JohnsonLaird, Legrenzi, \& Sonino, 2000; Revlin, Cate, \& Rouss, 2001), major and minor premises (Politzer \& Carles, 2001), and reliable and unreliable information sources (Wolf, Rieger, \& Knauff, 2012).

The present work is part of our current attempt to extend the cognitive research on human belief revision to the area of spatial reasoning. Our main motivation is that (1) spatial inferences are ubiquitous in our daily life (Goodwin \& Johnson-Laird, 2005; Knauff, 2013), (2) reasoning with spatial relations is often easier than reasoning with conditionals (Johnson-Laird \& Byrne, 1991; Knauff, 2007), and that space is one of the most fundamental dimensions of our physical and psychological reality (Gattis, 2001; Knauff, 1999, 2013). In our previous work, we have identified three main principle of spatial belief revision (Knauff, Bucher, Krumnack, \& Nejasmic, 2013):

1. Spatial reasoning relies on mental models. A mental model is a unified representation of what is true if the premises are true. Reasoners use the meaning of assertions and general knowledge to construct single models of possibilities compatible with these assertions. Spatial relations are not represented explicitly in a propositional format but rather they are inherent in the model and thus can be (and must be) 'read off' from the model by mental inspection processes (Johnson-Laird \& Byrne, 1991; Polk \& Newell, 1995; Goodwin \& Johnson-Laird, 2005).
2. Spatial belief revision relies on the revision of mental models. If newly available information is inconsistent
with the current model (and new information must be taken for granted), a model revision is necessary to establish consistency. The revision process relies on local transformations in which tokens in the model are moved to new positions. If not all available information can be true at the same time, people "decide" which of the information to retain and which one to discard (Bucher, Krumnack, Nejasmic, \& Knauff, 2011; Krumnack, Bucher, Nejasmic, \& Knauff, 2011; Bucher \& Nejasmic, 2012).
3. The model revision process is sensitive to the functional asymmetry between the "reference object" (RO) and the "located object" (LO). For instance, in the statement " A is to the right of C ", the C is the RO and the A the object that is located in relation to the RO. To regain consistency the LO of the inconsistent statement seems to be relocated within the initial constructed mental model (Bucher et al., 2011; Krumnack et al., 2011; Bucher \& Nejasmic, 2012; Knauff et al., 2013). The distinction has been made by several psychologists and linguists (Miller \& Johnson-Laird, 1972; Talmy, 1983; Landau \& Jackendoff, 1993). The common idea of all these theories is that a spatial relation refers to the position of a particular object in focus relative to another object or area (Tenbrink, Andonova, \& Coventry, 2011).

In the present work we mainly focus on the third principle (LO-RO-asymmetry) and combine it with the idea that cognitive processes are not only abstract symbolic manipulations but grounded in perceptual, motoric, or emotional experience (for an overview, see de Vega, Glenberg, \& Graesser, 2008). Imagine, for instance, you are helping a friend to move into a new apartment. You have to carry many things (sofas, tables, books, porcelain, washing machine, hopefully no piano, etc.) from his old apartment to the furniture truck and then later from the furniture truck into the new apartment. If you do that, it is very likely that you try to avoid carrying heavy objects and prefer to move objects which are less heavy. But, does this heaviness also affect how you think about the location and relocation of objects? In principle, the weight of objects should not matter if we just mentally move objects in a mental model from one position to another. We do not have to carry the objects physically; so why should their weight matter? On the other hand, the theory of grounded cognition claims that such physical properties have an effect on how we think. The process of thought is a mental simulation of bodily experiences and therefore the weight of objects should affect how we mentally process the information from a spatial reasoning problem (Glenberg \& Robertson, 1999; Kaschak \& Glenberg, 2000; Kaschak \& Glenberg, 2002; Rinck \& Bower, 2004; Bergen \& Chan, 2005; Pulvermüller, 2005).

## Two experiments of spatial belief revision and grounded cognition

In the following, we present two experiments on grounded spatial belief revision. In the experiments, participants received spatial information about the location of small or large objects (Experiment 1) or easy to move or difficult to move objects (Experiment 2), and then have to revise their initial model in the light of new contradicting information. Is this revision process affected by the size or movability of the objects that can be relocated? Do people prefer to relocate the smaller and easy to move object as the theory of grounded cognition suggests? We present a pilot study, because we did not want to use the actual physical mass and size of objects but rather how they are psychologically perceived and represented (although that should highly correlate). Then we report two experiments: in experiment 1, the size of the objects was varied; in experiment 2 the movability was varied. These factors were combined with the role of the objects as being the RO or LO of the relation in the newly available information. In our previous experiments, we found a strong preference of relocation the LO because the RO is considered less flexible. Can the size or movability of the envisaged objects overwrite this general preference? In the last part of the paper we discuss our findings and draw some general conclusion about grounded cognition and spatial belief revision.

## Pilot study

Our first task was to define the set of objects to use in our experiments. To select the set of "large" and "small" objects, we developed a questionnaire with 64 objects. 46 participants rated the size of the objects on a five-point scale with the poles "very small" and "very large". Then they rated the same objects regarding movability on a five-pointscale from "easy to move" to "difficult to move". The order of objects was randomized. For the analysis, we computed the means over the group of participants and selected the objects with the lowest and highest mean ratings for size and movability. The objects are presented in Table 1. These objects were used for the following experiments.

Table 1: Objects used in the experiment according to their property

| small | large | easy to <br> move | difficult to <br> move |
| :---: | :---: | :---: | :---: |
| screen | power mast | wheelchair | pillar |
| vase | bridge | bicycle | counter |
| printer | railway station | carriage | gravestone |
| post | high rise | scooter | oven |
| lamp | spire | barrow | hydrant |

## Experiment 1: Small vs. large objects

## Method

Participants. 21 students from the University of Giessen (9 male; age: $M=22.86 ; S D=5.27$ ) were tested individually. They gave written informed consent and received course credits for their participation.

Materials, design, and procedure. Each participant solved 48 revision problems. Six practice trials (not analyzed) preceded the experimental trials. All stimuli were generated and presented using Superlab 4.0 (Cedrus Corporation, San Pedro, CA, 1999) with a RB-530, on a standard personal computer with a 19 " monitor. Number of correct decisions and corresponding revision times were recorded.

The structure of the problems was as follows: First, participants received sequentially two statements, also called premises (1, 2), which described the spatial relation between three objects, for example:

> "A is to the left of $B "$
> "B is to the left of C"

From these two premises the participants inferred that the three objects are in the arrangement $\mathrm{A}-\mathrm{B}-\mathrm{C}$. They did that by choosing one of two arrangements (correct arrangement/correct arrangement mirrored) that were presented on the screen.

In the next step, participants were confronted with an additional statement, e.g., ' A is to the right of C '. This is the critical point in time where participants in our experiments had to realize that something must be wrong with their initial model about the layout of the three objects. Not all three statements can be true at the same time because the third statement contradicts the logical inference from the first two premises. Participants were told that the third statement is irrefutably true so they could not ignore the third statement. The only option was to decide which one of the first two premises may be abandoned. If the first premise is discarded this results in the arrangement $\mathrm{B}-\mathrm{C}-\mathrm{A}$; if the second premise is discarded this results in the arrangement C - A - B. It is essential to see that the first revision strategy corresponds to the LO-Relocation, whereas the second revision strategy corresponds to the RO-Relocation. All statements used the relation "left of" and "right of" and were presented sequentially. Positions of the arrangements as well as the relations were counterbalanced across the experiment.

To study the effect of object size the terms, A, B, C were instantiated with the small and large objects from Table 1. To boost the possible effect of object properties we integrated a "you" into the problems. We expected that this would foster the perspective taking and that the participants are therefore even more sensitive to the object properties.
(1) premise: "The vase is to the left of you."
(2) premise: "You are to the left of the spire."

Initial model: Vase - you - spire
Inconsistent fact: "The spire is to the left of the vase."
Examples of revised orders:
Spire - vase - you ("relocation of the large object") vs. You - spire - vase ("relocation of the small object")

Participants received instructions on the computer screen. They were instructed to imagine an arrangement determined by the premises and subsequently to choose the respective arrangement (on the screen) by pressing the corresponding button. Afterwards participants had to decide whether or not the presented fact is consistent with this model. For the problems with a fact contradicting the initial model (which was the case in half of the problems), participants were asked to revise the arrangement and to define the revised arrangement by pressing the corresponding button.

## Results and discussion

Mean percentage rate of correctly constructed models was $98 \%(S D=2.15)$ and in $94 \%(S D=8.54)$ of the inconsistent problems participants correctly identified the inconsistency between the initial model and the contradictory fact. Erroneous trials were excluded from further analysis.

An ANOVA with the factors object size (small vs. large) $\times$ person's position (leftmost, middle, rightmost) was conducted for the revision choice and the revision times. Level of significance was 5\%.

This ANOVA revealed a significant main effect of object property for revision choices $\left[F(1,20)=8.21 ; p<.05 ; \eta^{2}=\right.$ .29]. The main effect of person's position and the interaction were non-significant ( $p>.87$ ).

T-tests revealed that choosing of revised arrangements were based significantly more often on relocations of small objects ( $M=56 \%, S D=8.95$ ) compared to large objects ( $M$ $=44 \%, S D=8.95 ; t(20)=3.09 ; p<.01$ ) (see Fig. 1).

Results of the ANOVA for revision times were nonsignificant (all $p \mathrm{~s}>.53$ ). Implicitly, the analyses also showed that the differences between LO and RO were less important than the differences between small and large objects.

Here is an example problem:

Figure 1: Relative frequency (in \%) of model selections based on the relocation of small and large objects. Error bars show standard errors.

Our results show that physical properties of objects have an effect on how people revise their existing belief about the arrangement of objects in space. People have a strong tendency to relocate those objects that would also be easier to move physically. This finding agrees with the grounded cognition approach and is more difficult to explain based on purely symbolic cognitive theories. The finding also agrees with the mental model theory of reasoning, in which people reason spatially by constructing, inspecting and varying spatial mental models that mirror the situation described in the premises (Knauff, Rauh, \& Schlieder, 1995; Ragni, Knauff, \& Nebel, 2005; Rauh, Hagen, Kuss, Knauff, Schlieder, \& Strube, 2005; Nejasmic, Krumnack, Bucher, \& Knauff, 2011). If such a model is then contradicted by a new fact, people try to revise the model by local transformations. In fact, they move the objects in the model around to obtain a model consistent with the newly available information. We could show these mental operations are affected by the imagined physical properties of the objects. With the next experiment, we tried to replicate this effect with objects which are easy or difficult to move. The question is again: does object property affect reasoning and belief revision? Is the physical challenge related to a difficult movable object somehow reflected when we manipulate it mentally?

## Experiment 2: Easy and difficult to move objects

## Method

Participants. 24 students from the University of Giessen (5 male; age: $M=22.71 ; S D=6.60$ ) were tested individually. They gave written informed consent and received course credit for their participation. Data from one participant were excluded from the analysis due to a technical problem.
Materials, procedure, and design. The instructions on the computer and the procedure were the same as in experiment

1. The only difference between experiment 1 and 2 was the object property. Again, we manipulated two factors: object mobility (easy and difficult to move objects) and person's position ("you") in the spatial arrangement (leftmost, middle, and rightmost) as the independent within subject factors. Again, the dependent variables are revision choice and revision times.

## Results and discussion

As in experiment 1, participants selected correct arrangements in more than $95 \%(M=97 \%, S D=3.70)$ of the cases. They detected inconsistencies between the initial constructed arrangements and the contradictory facts in 94\% ( $S D=4.97$ ), correctly. Erroneous trials were excluded from further analysis.

An ANOVA with the factors object property (easy and difficult to move objects) $\times$ person's position ("you") in the spatial arrangement (leftmost, middle, and rightmost) was conducted for the revision choice and the respective revision times. Level of significance was $5 \%$.

The ANOVA for revision times revealed a significant main effect of object property $\left[F(1,16)=4.76 ; p<.05 ; \eta^{2}=\right.$ .23]. The main effect of person's position and the interaction were non-significant ( $p s>.23$ ). One-tailed t-tests revealed that participants needed less time for a revision based on a relocation of an easy to move object ( $M=2956.04 \mathrm{~ms}, S D=$ 1257.80) compared to a difficult to move object ( $M=$ $4189.31 \mathrm{~ms}, S D=714.77 ; t(22)=1.93 ; p<.05)$ (see Fig. 2). In this experiment, the ANOVA for revision choices were non-significant ( $p>.41$ ). Although participants did not show a clear preference for a relocation of an easy to move object compared to a difficult to move object, they needed more time to establish consistency, when the revision was based on a relocation of a difficult to move object.

Figure 2: Revision times (in ms) based on the relocation of the respective object. Error bars show standard errors.

## General discussion

We reported two experiments on the connection of spatial belief revision and grounded cognition. We showed that (1) small objects are more often relocated than larger objects
and (2) easy to move objects are faster relocated than objects which are difficult movable. The findings are in line with the idea of grounded cognition. According to this approach, the mind is embodied, and thus cognitive processes must be grounded in perceptual, motoric, or emotional experience (for an overview, see de Vega et al.,2008). From this point of view, human thought is almost exclusively based on perceptual simulations and modalityspecific representations (Barsalou, 2008, 2010).

Our results suggest that object properties effect spatial belief revision. The (imagined) properties of objects can overwrite the general preference for LO-relocation (experiment 1) and the time it takes to revise a mental model can be modulated by different object properties (experiment 2). These findings indicate that the physical effort that would be necessary when an object is actually relocated is reflected in revision preferences and revision speed. Moreover, the effort for different object properties (like size and movability) was reflected by different psychological measures in our experiment. On the one hand, size affected the frequency with which objects were mentally relocated. Participants preferably changed the position of small objects. Large objects were preferably left in the same position. What happens when we transfer this result to the physical world? It basically means that a vase is relocated preferably to a house. That makes sense, given that we indeed relocate vases more often and more easily than houses. On the other hand, movability modulated the time individuals needed for the revision process. This also agrees with real actions in the physical world. We might not have preferences in relocating ovens compared to wheelchairs, but it is more time consuming to move an oven than a wheelchair. Consequently, participants needed more time relocating heavy ovens than mentally "pushing" the wheelchair.

Of course, often size and movability (and many more properties of objects) are confounded. That was also the case in our experiments. However, we made an attempt to disentangle size and movability. Our results suggest that we were successful in doing so. An important corollary from our studies is that different properties affect different dependent measurements. This might be of concern in further experiments in this field.

We are aware that our findings are too weak to make a strong case for the grounded cognition approach in reasoning and belief revision. This is in particular important with regard to findings suggesting that effects of grounded cognition are more based on experimental demand characteristics considering the work of During et al. (2009). Another critical point is that, for instance, research on wayfinding and navigation shows that some kind of spatial representations have an amodal representational format, which does not agree with the embodied cognition approach (Giudice, Klatzky, \& Loomis, 2009). In that sense, our experiments can only be a very first step to draw a new connection between two fields that still work in isolation. However, another corollary from our findings is that the
theory of grounded cognition and the theory of mental models fit well together. The theory of mental models also assumes that we reason by mentally simulating what might be the case. However, the model theory so far has focused on the simulation of spatial relations between objects. Today, the vast majority of researchers consider the model theory to be the empirically best supported theory of human spatial inference (Vandierendonck, Dierckx, \& de Vooght, 2004; Goodwin \& Johnson-Laird, 2005; Knauff, 2009, 2013; for an exception see: van der Henst, 2002). The present work shows that the idea of a mental simulation in mental models can also incorporate other physical features. We will continue to investigate this connection between mental models and grounded cognition in future experiments.

## Acknowledgments

This work was supported by grants of the Deutsche Forschungsgemeinschaft (DFG) to M. Knauff and B. Nebel KN 465/6-1 and KN 465/6-2. We thank Isabell Tapia-Leon for assistance with the experiments.

# Desirable Difficulty in Learning: A Computational Investigation 

Aida Nematzadeh, Afsaneh Fazly, and Suzanne Stevenson<br>Department of Computer Science<br>University of Toronto<br>\{aida,afsaneh,suzanne\} @cs.toronto.edu

#### Abstract

Certain difficulties of a word learning situation can promote long-term learning, and thus are referred to as "desirable difficulties". We use a computational modelling approach to examine the possible explanatory factors of the observed patterns in a cross-situational word learning experiment. Our results suggest that the within-trial ambiguity and the presentation duration of each trial in addition to other distributional characteristics of the input (experimental stimuli) may explain these results. Our findings also emphasize the role of computational modelling in understanding empirical results.

## Introduction

One of the important questions in language acquisition is how people learn the mappings between words and their meanings (Quine, 1960). A number of mechanisms and approaches have been proposed in an attempt to address this question (e.g., Tomasello, 1992; Pinker, 1989). A widelydiscussed mechanism is cross-situational learning, in which people learn word meanings by gathering evidence from various exposures of words in different situations. Recent word learning experiments also confirm that both adults and children keep track of cross-situational statistics across individually ambiguous learning trials, and infer the correct wordmeaning mappings even in highly ambiguous conditions (Yu \& Smith, 2007; Smith \& Yu, 2008). These experiments have gained popularity in recent years (e.g., Yurovsky \& Yu, 2008; Vlach, Sandhofer, \& Kornell, 2008), and provide opportunities for further investigating the observed patterns in naturalistic word learning.

One interesting aspect of word learning that can be studied in such experiments, is its interaction with other cognitive processes such as memory and attention. An example is the experiments of Vlach et al. (2008) on children, which examine the spacing effect, i.e., the observation that people generally learn better when the presentations of the items to be learned are distributed (spaced) over a period of time. This and other similar patterns in human learning are referred to as "desirable difficulties": Although a more difficult learning situation may hinder short-term recall of learned material, it may promote long-term retention.

In this work, we use a computational model to shed light on one such case of an observed "desirable difficulty" in crosssituational word learning, studied by Vlach and Sandhofer (2010). Notably, Vlach and Sandhofer (2010) attribute their findings to desirable difficulties in learning, but do not provide an explanation of why and how the sort of difficulty they focus on facilitates long-term retention of the learned words. Computational modelling enables us to investigate the precise
learning mechanisms, and the variations in the input conditions, that might explain these findings. We first introduce our computational model of cross-situational word learning, and then explain and analyze the experimental data and results of Vlach and Sandhofer (2010) in the context of our model. Finally, we describe the way we simulate these experiments using our model, and how this enables us to examine the role of several different factors in the observed pattern of word learning.

## The Computational Model

In this section, we present our computational model of word learning that was first published in Nematzadeh, Fazly, and Stevenson (2012a). Our model builds on the word learning model of Fazly, Alishahi, and Stevenson (2010), which takes an incremental approach in learning probabilistic associations between words and their meanings. In Nematzadeh et al., we integrated new functionality into this model to capture forgetting (i.e., an effect of memory) and attention to novelty. Our proposed model accounts for several observed patterns of the spacing effect in children and adults, in which experimental subjects learn presented items better when they are spaced apart in time, than when they are shown in immediate succession. We provide a brief overview of the model before turning to modelling of other kinds of "desirable difficulties."

## Learning from an Input Pair

Our model learns about the meaning of words by incrementally processing a corpus that contains a sequence of utterances paired with a semantic representation of a scene, which is the hypothetical perception of a learner upon hearing the utterance. Each input to the model pairs a set of words (the representation of the utterance) with a set of semantic features (the representation of the scene), as in:

```
Utterance: { she,drinks, milk }
Scene: { ANIMATE, PERSON, FEMALE, CONSUME,

```

We create corpora drawn from child-directed speech, in which lemmatized, transcribed utterances are paired with artificially generated semantics, based on WordNet or other semantic featural representations of the entities and actions corresponding to the words. In the experiments here on novel word learning, nonce words are paired with these naturalistic semantic representations, in which features corresponding to meaning properties are probabilistically associated with a word.

When processing an input pair, the model bootstraps its current knowledge of word meanings to hypothesize the
strength of association between the words in the current input and the meaning features in the current scene. These probabilistic alignments between the words and features of the current input are then used to update the model's knowledge of word meanings.

More formally, for each word, the model learns a meaning probability, which is a probability distribution over all possible semantic features. The model starts with uniform meaning probabilities for all words; i.e., before processing any input, all features are equally likely for every word. At each time step $t$, the model processes an input pair and calculates an alignment score, $a_{t}(w, f)$, between each word $w$ and semantic feature $f$ in the input pair. This alignment score reflects how strongly the $w-f$ pair are associated at time $t$, by considering two sources of information: (1) the meaning probabilities of all the words in the utterance $\mathrm{U}_{t}$ (representing the knowledge of the model of word meanings up to that point), and (2) the novelty of words, capturing the attention a learner might pay to the novel words compared to the familiar words (explained below). The alignment score is formulated as:

$$
\begin{equation*}
a_{t}(w, f)=\frac{p_{t}(f \mid w)}{\sum_{w^{\prime} \in \mathrm{U}_{t}} p_{t}\left(f \mid w^{\prime}\right)} * \operatorname{novelty}_{t}(w) \tag{1}
\end{equation*}
$$

where $p_{t}(f \mid w)$ is the probability of $f$ being part of the meaning of word $w$ at time $t$, right before processing the input pair, and novelty $_{t}(w)$ is a multiplicative attentional factor.

This factor, novelty ${ }_{t}(w)$, taps into empirical studies on attention showing that people attend to novel items in a learning scenario more than other items, leading to improved learning of those items (e.g., Snyder, Blank, \& Marsolek, 2008; MacPherson \& Moore, 2010; Horst, Samuelson, Kucker, \& McMurray, 2011). In the word learning scenario, this corresponds to a person focusing on determining the meaning of novel words. We model this observation by incorporating the multiplicative novelty $y_{t}(w)$ in the above formula, providing an increase in word-feature association for a more novel word. The novelty ${ }_{t}(w)$ measures the degree of novelty of a word as a simple inverse function of recency: The more recently a word $w$ has been observed by the model $\left(t_{\text {last }_{w}}\right)$, the less novel it appears to the model at the current time $t$ :

$$
\begin{equation*}
\operatorname{novelty}_{t}(w)=1-\operatorname{recency}\left(t, t_{\text {last }_{w}}\right) \tag{2}
\end{equation*}
$$

where recency $\left(t, t_{\text {last }_{w}}\right)$ is inversely proportional to the difference between $t$ and $t_{\text {last }_{w}}$. We set novelty $(w)$ to be 1 for the first exposure of the word.

## Accumulating Evidence over Time

The model keeps track of the accumulation of all the alignment scores of all word-feature pairs, and uses these scores to update the meaning probabilities of the words. These alignment scores reflect the model's knowledge of the associations between words and various potential meanings. To simulate the effect of forgetting in memory, these alignments undergo
a decay over time. At each time $t$, the strength of association of a word and a feature is formulated as:

$$
\begin{equation*}
\operatorname{assoc}_{t}(f, w)=\sum_{t^{\prime}} \frac{a_{t^{\prime}(w, f)}}{\left(t-t^{\prime}\right)^{d_{a_{t^{\prime}}}}} \tag{3}
\end{equation*}
$$

where $t^{\prime}$ is the time at which the alignment $a_{t^{\prime}}$ is calculated, and $d_{a_{t^{\prime}}}$ is the decay rate associated with this alignment. We note that our formulation of assoc is inspired by the ACT-R model of memory (Anderson \& Lebiere, 1998), in which the sum of individual memory strengthenings for an item determines the item's activation. We assume that stronger alignments should be more entrenched in memory and thus decay more slowly than weaker alignments. Thus, each alignment undergoes a decay which is dependent on the strength of the alignment:

$$
\begin{equation*}
d_{a_{t^{\prime}}}=\frac{d}{a_{t^{\prime}}(w, f)} \tag{4}
\end{equation*}
$$

where $d$ is a constant parameter. Note that the alignments between a word and different features may be forgotten at different rates.

This association score is then normalized using a smoothed version of the following to yield the meaning probability of that feature $f$ for that word $w$ at time $t$ :

$$
\begin{equation*}
p_{t}(f \mid w)=\frac{\operatorname{assoc}_{t}(f, w)}{\sum_{f^{\prime} \in \mathcal{M}} \operatorname{assoc}_{t}\left(f^{\prime}, w\right)} \tag{5}
\end{equation*}
$$

where $\mathcal{M}$ is the set of all observed meaning features.

## Desirable Difficulties in Word Learning

Vlach and Sandhofer (2010) - henceforth V\&S - explore the factors involved in "desirable difficulty" through a set of (now standard) cross-situational word learning experiments on adults, varying the presentation and testing conditions. In each $N \times N$ trial, subjects see some number $N$ of novel objects on a computer screen, while hearing $N$ novel words (in arbitrary order) that label the displayed objects; see Figure 1. In testing, subjects hear a single word, and are asked to select the corresponding object from a display of 4 objects. Across three presentation conditions, the total number of word-object pairs, and the number of times each is seen, are held constant, while there is increasing within-trial ambiguity - i.e., the number of possible pairings between the words and the objects within a single presentation: $2 \times 2$, $3 \times 3$, and $4 \times 4$. Furthermore, participants were tested at each of three times: immediately after training, 30 minutes after, and one week after.

V\&S find that in the immediate testing condition, as expected, the number of correctly learned pairs decreases as the within-trial ambiguity increases. That is, the participants performed the best in the $2 \times 2$ condition and the worst in $4 \times 4$ (Figure 2). However, when tested after 30 minutes of delay, there was no significant difference between the performance

Figure 1: Example stimuli from $2 \times 2$ condition taken from V\&S.
of the participants in the $2 \times 2$ and the $3 \times 3$ conditions, while $4 \times 4$ still had the worst performance. Interestingly, in testing after one week, the participants performed better in the $3 \times 3$ than the $2 \times 2$ condition. (Again, $4 \times 4$ still had the worst performance.) In summary, what should be the "easiest" condition $(2 \times 2)$ has the best performance in immediate testing, but a more difficult condition $(3 \times 3)$ has better performance one week later.

Figure 2: The results of V\&S's experiment.
V\&S relate their findings to "desirable difficulties" in learning: they argue that the difficulty of a learning situation might hinder immediate performance, but promote longer term performance. However, they do not discuss why the performance of the $4 \times 4$ condition is the worst compared to the other conditions for all testing intervals. That is, why is the level of difficulty in $3 \times 3$ desired, but is not so for $4 \times 4$. Moreover, they do not explain why and how difficulty can boost learning in the long term in this learning scenario.

We observe that, in the V\&S experiments, the $2 \times 2$ condition has more learning trials, each of which is seen for less time, than in the $3 \times 3$ condition (and similarly for $3 \times 3$ compared to $4 \times 4$ ). This occurs because the total number of word-object pairs, the number of times each is seen, and the total presentation time of the full set of items, are all held constant across the three presentation conditions. We can thus identify three factors that differ across the V\&S conditions, each of which may contribute to the observed pattern: (1) the within-trial ambiguity, (2) the presentation duration of each trial, and (3) the average spacing interval (where spacing is
the number of trials between the two presentations of a wordobject pair).

Computational modelling can be used as a tool to study the necessity and the interaction of these three factors (the within-trial ambiguity, the presentation time of each trial, and the average spacing interval) in a cross-situational learning scenario. In our model, the increase in within-trial ambiguity results in more competition among the possible alignments since there are more words and meanings to potentially align; this results in lower association scores and therefore decreased performance in word learning. We argue that the second factor, the presentation duration, is related to forgetting. In the following section (Methodology), we will explain how we incorporate differences in the presentation duration into our model. The third factor (the spacing interval) relates to the interaction of forgetting and attention to novelty in the model: As the spacing interval becomes larger, the amount of forgetting increases, resulting in lower association scores between words and features; however, the novelty of words and consequently their association scores increases as the spacing interval gets larger. Thus, varying the spacing interval affects the performance of the model (see Nematzadeh et al., 2012a for more details). We use our model to study the interaction of these three factors, with the goal of providing a more precise explanation for the desirable difficulty observed in the experiments of V\&S. Next, we explain our methodology, including our input generation, and the simulation of the V\&S experiments.

## Methodology

## Input Generation

To generate the input stimuli for our model, we need to pair words with a meaning representation that corresponds to the depiction of the corresponding object in the experimental situation of Figure 1. To do so, we draw on the input-generation lexicon of Nematzadeh, Fazly, and Stevenson (2012b), which was previously used to automatically annotate corpora of child-directed utterances with meaning features corresponding to the words in those utterances. Here, we use the lexicon to provide a source of naturalistic meaning representations ("novel object descriptions") for a set of "novel" words (i.e., the words in the input stimuli are unknown to the model, as in the experiments we are modeling).

The true meaning of each word in the lexicon, $\operatorname{tm}(w)$, is a vector of semantic features and their assigned scores or weights (Figure 3). ${ }^{1}$ When a word is used in an input trial, its meaning features are probabilistically sampled from $\mathrm{tm}(w)$ according to the weight of each feature in the lexical entry of the word. This probabilistic sampling captures our intuition that a participant, when faced with a trial in the crosssituational experiment of Figure 1, will grasp some features of the novel objects but not necessarily all. Each trial of the input is then composed of a set of $N$ words ( 2,3 , or 4 words,

[^174]depending on the condition), paired with a set of features which is the union of the $N$ sets of meaning features sampled for each of the words in that trial.

```
apple: { FOOD:1, SOLID:.72, PRODUCE:.63,
    EDIBLE-FRUIT:.32, PLANT-PART:.22,
    PHYSICAL-ENTITY:.17, WHOLE:.06, .. }
```

Figure 3: True meaning features \& probabilities for apple.

To produce a full set of experimental trials, we first convert the exact stimuli of V\&S to the format of our input. That is, in their stimuli, we replace each word with a specific word from our lexicon, and each object with the probabilisticallygenerated meaning representation for its corresponding word (as explained above). The precise combination of corresponding word/object pairs in each trial, and the order of the trials, are exactly the same as in the V\&S stimuli. We refer to this data as the input of V\&S.

The V\&S input includes 18 novel word-object pairs, each of which occurs 6 times, resulting in 54, 36, and 27 trials in the $2 \times 2,3 \times 3$, and $4 \times 4$ conditions, respectively. We note that the V\&S input, as a specific set of stimuli, might have particular spacing properties that contribute to their results. Thus we also randomly generate input stimuli in order to evaluate the effect of arbitrary variation in the precise presentation order of the word/object pairs. We randomly generate 20 sets of input stimuli for each condition, keeping the number of pairs, their frequency, and the number of trials the same as in the V\&S input. We use the same novel words that we used in generating V\&S data, and randomly generate their meaning representations as explained. The result is that we can experiment both with the precise data of V\&S, as well as 20 randomly generated sets of input stimuli with the same basic properties.

## Modeling of the Presentation Duration

One aspect of the V\&S experimental conditions that we cannot directly replicate in our model is the presentation duration of each trial in a stimulus set. Recall that because of the various properties of the stimuli, the individual trials in each of the three conditions ( $2 \times 2,3 \times 3$, and $4 \times 4$ ) have different presentation durations. Our model does not have a notion of "presentation duration" - it simply processes each input as it receives it. Thus to simulate these differences, different degrees of forgetting decays are used in the model (see Eqn. (4)). The intuition is that subjects forget faster in a condition with a shorter presentation duration, since they have less time to absorb the stimuli in each trial. The forgetting decay is thus set to a larger value in the $2 \times 2$ condition (where the presentation time is the smallest), and successively smaller in each of the $3 \times 3$ and $4 \times 4$ conditions.

## Simulation of the V\&S Experiments

We train our model by presenting the set of inputs for a given condition, where it learns incrementally in response to each trial. Similarly to V\&S, we evaluate our model at three points
of time after training: immediately after processing the last input (time $=t$ ), at $t+30$, and at $t+350$. These times were chosen to loosely reflect the three time intervals in V\&S's experiments. We will use the labels "no delay", "brief delay", and "lengthy delay", to refer to these timings in describing our results.

To evaluate the performance of the model at each testing point, we measure how well each word is acquired by comparing its learned meaning $\operatorname{lm}(w)$ - a vector holding the values of the meaning probability (Eqn. (5)) - to its true meaning $\operatorname{tm}(w)$ from the input-generation lexicon (see Figure 3):

$$
\begin{equation*}
\operatorname{acq}(w)=\operatorname{sim}(\operatorname{lm}(w), \operatorname{tm}(w)) \tag{6}
\end{equation*}
$$

where sim is the cosine similarity between the two meaning vectors, $\operatorname{tm}(w)$ and $\operatorname{lm}(w)$. The higher acq $(w)$ is, the more similar $\operatorname{lm}(w)$ and $\operatorname{tm}(w)$ are. We use the average acq score at time $t$ of all the words in the input to reflect the overall learning of the model at that time.

## Results

We first examine the behavior of our model when trained on the V\&S input, and then compare these with results on our randomly generated stimuli.

## The Input of V\&S

The results of training and evaluating our model on the V\&S input are presented in Figure 4. We see the same interesting pattern as found in V\&S (shown in Figure 2) for the $2 \times 2$ and the $3 \times 3$ conditions. That is, $2 \times 2$ is better with no delay, but similar with brief delay and worse with lengthy delay, even though $3 \times 3$ is "harder" due to its higher degree of withintrial ambiguity. Unlike the V\&S results, $3 \times 3$ and $4 \times 4$ are similar for all delays.

Figure 4: Average acq score of words (from the model) given the three conditions and three time intervals similar to the V\&S experiments.

We consider these findings in the context of the discussed factors of presentation duration, within-trial ambiguity, and average spacing of items, which we proposed might explain
the desirable difficulty in learning. The differences in presentation duration (shortest for $2 \times 2$ and longest for $4 \times 4$ ) entails that, generally, the learning in the $2 \times 2$ condition should decline most steeply over time, and learning in the $4 \times 4$ should decline least steeply: i.e., for each set of same-coloured bars in Figure 4, we expect learning to decrease over time, and more rapidly for lower values of $N$ in the $N \times N$ conditions. We see this predicted behaviour with our model, which results from our modeling of presentation duration with an inversely proportional decay rate (i.e., the shorter the presentation duration, the greater the degree of forgetting).

It is expected that in the absence of other factors, increasing within-trial ambiguity from the $2 \times 2$ to the $4 \times 4$ conditions results in a decline in average acq score, since greater ambiguity should lead to decreased learning. However, in our model, the presentation duration also plays a role. Similar to results of V\&S, we see the decline pattern in the "no delay" condition, and in the "brief delay" condition (albeit with less difference), due to the increased competition for word-meaning alignments that occurs with a higher number of items in a trial (see Figure 4). However, we do not see this pattern in the lengthy delay condition.

To summarize, our results are similar to those of V\&S, who found that while the $2 \times 2$ condition led to best learning when tested immediately, it led to poorer performance than the $3 \times 3$ condition given a lengthy delay before testing - a pattern V\&S attribute to the "desirable difficulty". It seems that these factors of presentation duration and withintrial ambiguity may interact, such that the steep decline in performance in subsequent testing in the $2 \times 2$ condition more than offsets the advantage it has from the lesser within-trial ambiguity.

In the experiments of V\&S, the performance in the $4 \times 4$ condition is always worse than the two other conditions. However, our model produces very similar results for the $3 \times 3$ and the $4 \times 4$ conditions. Also, the role of the spacing interval is not clear in these results. The problem is that by just considering one set of stimuli within each $N \times N$ condition (each of which has a set spacing of items), we do not have a variation of the average spacing interval that is independent of the presentation duration and the within-trial ambiguity. We turn to these issues in the next subsection.

## Randomly Generated Input

We observed that the performance of the model in the $3 \times 3$ and $4 \times 4$ conditions on the V\&S input is very similar. We also investigate a condition here with higher within-trial ambiguity to see if such a condition might be "hard" enough for the model (because of the higher within-trial ambiguity) so that it results in a similar patten to the $4 \times 4$ condition in V\&S. As with the others, we generate 20 sets of input stimuli for this $6 \times 6$ condition, using 18 word-object pairs, each of which occurs 6 times, producing 18 trials. Thus the generated input stimuli for the four conditions allows us to examine both the role of average spacing interval, and the impact of a more difficult condition with higher within-trial ambiguity.

We train our model on the randomly-generated inputs (with different average spacing intervals) for all four $N \times N$ conditions. To evaluate the performance of the model, the average acq score of words for all 20 sets of inputs within a single $N \times N$ condition are averaged (see Figure 5). We can see that when tested with "no delay", the $2 \times 2,3 \times 3$, and $4 \times 4$ conditions have similar scores. Moreover, we can see a pattern similar to V\&S's experiments: the $3 \times 3$ and $4 \times 4$ conditions have the best results after the "lengthy delay". We also observe that by increasing difficulty in the $6 \times 6$ condition (due to the high within-trial ambiguity), the model produces a pattern similar to the pattern observed in the $4 \times 4$ condition in V\&S's experiments. This confirms our hypothesis that for our model, the $4 \times 4$ condition is not "hard" enough to result in a steep decline over time intervals as in the V\&S's results.

Figure 5: Average acq score of words (from the model) given the four conditions and the three time intervals, averaged over 20 sets of stimuli.

However, we also see that, in contrast to V\&S's results (and our model's performance on the V\&S data), the $2 \times 2$ condition with no delay fails to show better learning than the other conditions.

To better understand this difference between the two sets of results, we look more closely at the scores of the individual randomly-generated stimuli sets. We find that there is a notable difference in the average $a c q$ score across the 20 input files for the $2 \times 2$ condition, which shows its maximum value of 0.76 for the V\&S's data, while the minimum is 0.50 . This suggests that the characteristics of the particular input (as a result of varying the average spacing interval) may be responsible for some of the observed patterns in the V\&S's results.

We were interested to understand why the V\&S data has the maximum score, especially since there was a sizable gap between the score of this input and the next best score among the randomly-generated inputs (of 0.64). In an attempt to identify the factor behind this variation, we measured various statistics for each input set, such as the following: (1) the average spacing interval of words, which has been shown to affect learning both in people (Vlach et al., 2008) and in our model (Nematzadeh et al., 2012a); (2) the average time since
the last occurrence of words, that impacts the amount of forgetting that occurs; and (3) the average context familiarity of words (that is, the familiarity of the words that occur with a word in an utterance), a factor that has been noted to affect word learning (see, e.g., Fazly, Ahmadi-Fakhr, Alishahi, \& Stevenson, 2010). However, we found that none of these measures explain the variation of the scores in all the inputs. Future research is needed to fully understand the impact of the properties these measures tap into, and whether they may (individually or in combination) contribute to explaining the pattern of the results.

## Summary

The "desirable difficulty" of a learning condition can promote the long term retention of the learned items. We have used a computational model to investigate the possible factors behind one such case of a "desirable difficulty" in a crosssituational word learning experiment (Vlach \& Sandhofer, 2010). Notably, the experimental results were not clearly pointing to the factors causing the patterns observed in the performance of the human participants. Using a computational model, we have suggested that an interaction between two factors (the within-trial ambiguity of the learning trials, and the presentation duration of each trial) might explain the observed patterns. In addition, our results point to other distributional characteristics of the input (experimental stimuli) that might have an impact on the performance of the learner. These findings illustrate the role of computational modelling, not only in explaining observed human behaviour, but also in fully understanding the factors involved in a phenomenon. There are several factors involved in a cross-situational word learning experiment, such as the contextual familiarity of words, and the average spacing interval of words. Our findings signify the importance of controlling for these factors in order to understand the reasons behind the observed patterns. But it is difficult do so in human experiments because the factors can interact in complex ways.

Our work is an initial attempt at shedding light on the interaction of memory, attention and word learning, and understanding "desirable difficulty" in learning. Other factors (e.g., working memory) might play a role in the performance of people as well. For example, because the number of items that people can store in their working memory is limited (Miller, 1956), the participants might store more trials in their working memory in the $2 \times 2$ condition, compared with the other conditions. The participants might use this information of the multiple trials (in their working memory) to make inferences about word-object mappings that repeat in successive trials. One future direction would be to incorporate a working memory module into our word learning model, and examine the impact of such inferences in a cross-situational learning scenario.

## Acknowledgements

We would like to thank Haley Vlach for valuable discussion, and for providing us with the stimuli of her experiments. We
are also grateful for the financial support from NSERC of Canada, and University of Toronto.

# The Individuation and Recognition of Emotion 

Albert Newen (albert.newen@rub.de)<br>Institute for Philosophy II, Universitätsstraße 150<br>44780 Bochum, Germany

Anna Welpinghus (anna.welpinghus@rub.de)<br>Institute for Philosophy II, Universitätsstraße 150<br>44780 Bochum, Germany

#### Abstract

First, we argue for the metaphysical claim that emotions are individuated as patterns of characteristic features. Our second claim concerns the epistemology of emotion recognition: We demonstrate that emotion recognition is a process pattern recognition that relies on the same type of pattern recognition typical for object recognition. The analogy allows us to defend a variant of a direct perception account of emotion recognition. We distinguish two forms of directly perceiving emotions: 1. perceiving an emotion (almost) without any top-down-processes, 2. perceiving an emotion involving some significant top-down-processes (including expectations and background knowledge), and in addition 3. an inferencebased evaluation of an emotion.

Keywords: Emotion, Philosophical Theory, Nature of Emotion, Recognition of Emotion

## Introduction

What is the nature of emotions and how can we recognize them in other human beings? In this short paper, we cannot do justice to the complex discussions concerning both questions. Nevertheless, we develop our own view with the core claim that emotions are individuated as pattern and that emotion recognition is a process of pattern recognition that has much in common with the recognition of objects by perception. This paper's focus lies on an outline of our account and its advantages, while we only briefly mention the criticism of alternative views.

## The metaphysical debate: An overview

In the metaphysical debate we have two extreme positions: emotions are individuated as social constructs (Lutz, 1986; Harré, 1986), on the one hand, or they are individuated as evolutionary anchored affect programs (Ekman, 1972; Griffith, 1997), on the other. Both accounts have severe deficits (Welpinghus \& Newen, 2012). Let us mention only the two main deficits: psychoevolutionary accounts state that shared evolutionary history is the only criteria to identify types of emotions. They do not provide any classificatory schemes which do not refer to each category's evolutionary history but for many emotion categories referred to not only in everyday speech but also in psychological theories, it is far from clear whether their members share the same evolutionary history. Thus, the psychoevolutionary account has difficulties providing adequate classificatory schemes, for example for studying
emotions in a social context. In principle, psychoevolutionary accounts of emotions can easily account for basic emotions but have problems to account for the role of cognitive contents in so-called cognitive emotions (Zinck \& Newen, 2008). On the other hand, the social constructionist can easily account for the latter including the cultural variety of emotion phenomena but they underestimate the strong overlap of the emotion repertoire despite the cultural variation. Here Ekman (1972) has shown that basic emotions like joy, fear, anger, sadness etc. are accompanied with the same facial expression. There is an open debate which phenomena are basic emotions but a strong part of the community presupposes that there are basic emotions which are evolutionary old, shared with animals and develop early in ontogeny (Ekman, 1999; Griffiths, 1997; Zinck \& Newen, 2008). The evolutionary anchor of basic emotions constraints our emotion repertoire and undermines the social constructivist view that emotions are entirely created by cultural factors. What could be an alternative? We need to do justice to both features, the evolutionary anchor of basic emotions and the cultural dependence of some emotions. We suggest that the claim that emotions are individuated as pattern is the best alternative: 1. pattern can easily involve both, evolutionary anchored as well as culturally shaped features and thus account for both observations; 2. this view especially helps to distinguish emotion concepts in a society and their natural basis, i.e. some emotions concepts are categorizing only conventional constructs while others are actually anchored in natural kinds (which empirical science has to discover). 2. The account of emotion as pattern is nicely connecting with our folk psychological way of thinking about emotions (noticing the many faces of emotions), 3 . the best reductive scientific accounts of emotions have (at least so far) not succeeded in reducing emotions to a very few necessary features which are constituting a type of emotion, 4. furthermore, we observe a great variety of realizations of one type of emotion (e.g. types of fear; types of phobia which are classified according to the intentional object but also according to other features) which indicates that the analysis as a pattern consisting of characteristic features is the best we can gain because it makes it easy to account for the variety of emotion types without loosing the evolutionary anchor. Let us illustrate some of these points while enfolding the view that emotions are individuated as pattern. One important aspect of pattern is that in principle all
features are dispensable: there only has to remain a minimal package of features constituting the phenomenon but none of them is necessarily instantiated. Even this radical feature of pattern is true for several emotions but not for all. ${ }^{1}$

## Emotions as patterns

The idea that emotions are organized in patterns and that thus the recognition of emotion is basically a process of pattern recognition is not new (e.g. it is used in Izard, 1972 and Izard et al., 2000). But we aim to develop a detailed own account of it that enables us to analyze emotion recognition in more detail. We will now list and shortly characterize all types of features relevant for the individuation of emotions before focusing on the recognition part:
(1) Autonomic physiological responses: William James (1884) famously claimed that an emotion is the perception of bodily changes, especially changes in autonomic nervous system (ANS) activity. Physiological parameters controlled by ANS activity are crucial for Jamesian emotion theories. However, since not every emotion has a clearly distinct ANS pattern, especially when it comes to more fine-grained distinctions, even clearly Jamesian accounts of emotion such as the account of Prinz (2004) have to provide an account of emotion which grants that two different emotions need not have different patterns of ANS activity. They can be distinguished by other features. ${ }^{2}$
(2) Expressive actions and action tendencies: The psychologist Nico Frijda has coined the term 'action tendency' (which stems from Arnold, 1960) for a felt urge to perform a certain kind of action. This urge is also manifest in bodily changes which are suitable preparations for these actions. He largely equates emotions and felt action tendencies (Frijda, 1986, 71), a move we do not share. Specific actions or action tendencies as the only features are neither constitutive for every type of emotion nor can they alone constitute any emotion: Emotions like happiness are not accompanied by a specific action tendency. An action tendency may become manifest in actual expressive actions or not. Although actions out of emotions are rather flexible, there are typical behaviors for some emotions, such as freezing or fleeing in fearful situations. We routinely rely on expressive actions as well as signs for mere action tendencies for emotion recognition.
(3) Bodily expression: Bodily expression can be divided into (a) facial expression, (b) posture (c) gesture, (d) vocal

[^175]expression such as screams, roars or laughter and (e) tone of voice. We subsume these under the heading 'bodily expression' because all of these depend on muscle contractions and because these components are usually perceived together. We see a proud person talking: We see her smile, her erect posture; we hear her self-satisfied tone of voice. This leads to an overall impression of her as proud; under normal conditions, we do not pay attention to any of these components separately. Laboratory studies point towards an early integration of these visual and auditory cues (Campanella \& Belin, 2007). On the other hand, experiments show that face (Ekman, Friesen \& Ellsworth, 1972), but also posture and gesture alone is sufficient to recognize some coarse-grained distinctions (Atkinson et al., 2004).
(4) Phenomenal experience: Emotions are normally accompanied by a particular phenomenal quality or feeling. We do not consider phenomenal experience as necessary because there may be rare cases of emotions in the absence of such feelings, when typical physiological, expressive and cognitive aspects are present (the paradigmatic case is a person with a strong disposition to repress her fear [Sparks et al., 1999; Weinberger, 1990; Weinberger \& Davidson, 1994]).
(5) Cognitive features comprise (a) attitudes and (b) shifts of attention and perception. Emotions are often accompanied by cognitive attitudes. Belittling thoughts about the rival are characteristic for jealousy and a judgment that one has been treated unfairly is characteristic (though neither necessary nor sufficient) for anger, to give two examples. Furthermore, sometimes such attitudes are manifest in behavior or are verbally reported. Cognitive components that are less demanding than attitudes are e.g, a shift of attention, for example being alert to dangers in a state of fear. Through such shifts, emotions can make us perceive things we otherwise would not have perceived. They also make us perceive things in a certain light. Some theorists put characteristic ways of perceiving the world at the center of their theory of emotion (Döring, 2003). We will not equate emotion with ways of perceiving a world, but we do acknowledge the role of changes in perceiving the world due to having an emotion connected with a special phenomenology and its role in guiding behavior.
(6) The intentional object: 'Intentional object' is a technical term for the object the emotion is about. 'This can be a particular thing or person (that pudding, this man), an event or an action (the earthquake, your hitting me), or a state of affairs (my being in an aeroplane)' (Goldie, 2000, 16-17). It is not always real. The intentional object (or the type of object) is crucial for the more fine-grained classification of emotions, for example for distinguishing envy from jealousy. ${ }^{3}$

[^176]The features can be thought of as variables, which can take different values (the variable facial expression can take the values 'fearful expression', 'sad expression', etc.) Some values are likely to occur together, others are very unlikely to occur together. This is due to a range of causal mechanisms and constraints, but probably also constitutive and conceptual links. Illuminating these links further is a task for the empirical sciences as well as philosophy. Because some values are likely to occur together, we can learn to distinguish typical patterns of values and form a concept of the overall phenomenon. To illustrate, figure 1 shows a fear pattern.

Figure 1: Fear pattern.

## Our understanding of 'being constitutive of an emotion'

Are these features constitutive of an emotion? This depends on the underlying conception of 'constitution'. According to an essentialist conception of constitution, a constitutive part of something is also an essential part, a necessary part in all possible worlds. If the part was taken away, the leftovers could not form the same type of phenomenon as before anymore. According to our view of emotions as patterns, emotional features are not constitutive in the essentialist sense, because we do not rule out the possibility to have a token of the same type of an emotion lacking some characteristic features. We think that if there are only a few characteristic features they can be sufficient for an emotional episode to constitute it to be a token of the type anger. Those features of an emotional episode which contribute to it being a token of a specific emotion type are the constitutive parts of an emotion pattern ${ }^{4}$. The fact that a
entail the claim that the object is partly the bearer of the mental state in this case.
${ }^{4}$ We are presupposing a realism about patterns such that in principle for each combination of features it is possible to clarify whether this is an instantiation of the relevant pattern or not. We can of course grant that there are borderline cases and there exists a bundle of transfer cases.
person is sitting in a car during her angry episode may be part of a token of anger but it is not constitutive of her anger. We suggest a notion of being constitutive for X that accounts for X being a pattern. A feature f is constitutive for a pattern X if it is part of at least one set of features which is minimally sufficient for a token to belong to a type X. 'Minimally sufficient' means that these features are jointly sufficient for the episode to be of type X , but if one of them would be taken away the episode would not count as a instance of X anymore. According to our view, emotions usually include overt bodily features (expression or characteristic actions) - if characteristic expressive aspects occur during an emotion episode, they are constitutive and not just an effect of the proper emotion, or a cause for it but emotions do not always involve expressive components. ${ }^{5}$

One might wonder whether our list of features is exhaustive. ${ }^{6}$ Should we include neural correlates, for example? Features like ANS response, behavior, cognitive attitudes, perceptual shifts, and expression all have neural correlates. Neural correlates are insofar not an extra component in addition to the others - we could mention them as part of the individuation features of emotion but we do not have to. ${ }^{7}$ They may be used in a clinical or scientific context to infer whether a person is having emotions but are not used in ordinary contexts, since we cannot access them in an everyday context. Also, it is crucial to distinguish the factors relevant for individuating emotions from those which facilitate (or impair) the recognition of emotions. Contextual factors for the recognition of emotions include most prominently (a) the pragmatic context in which it occurs and (b) the personality, goals, beliefs, etc. of the person having the emotion. These features do not belong to the emotion pattern but are only relevant for the recognition

[^177]of other people's emotions. ${ }^{8}$ One may also wonder whether the list of features includes too many features and whether some can be reduced to others: This may be possible - and desirable - in principle but given the state of art in cognitive sciences we have no convincing candidate for a theory which reduces emotions to fewer features and would nonetheless allow us to describe the great variety of emotion phenomena.

## Emotion recognition as pattern recognition

Pattern recognition is a general method of classifying world phenomena. We aim to analyze the recognition of emotion as a process of pattern recognition on the basis of perceiving characteristic features and integrating them into a unity by recognizing an emotion and ascribing it to the other. ${ }^{9}$ The latter presupposes observers possessing normal conceptual ${ }^{10}$ competences. In providing a new version of explicating emotion recognition as pattern recognition we propose a new variant of a perceptual theory of recognizing emotions. We will characterize the process of pattern recognition as one of cue combination and cue integration that culminates in an activation of the most plausible representation of an emotion pattern. This pattern recognition involves a multifactorial weighting process organizing sensory cues from different sense modalities, on the one hand, and accounting for other cues, like social and personal background information, on the other. It is fruitful to distinguish between two types of emotion recognition: The process of pattern recognition by activating the most likely representation of an emotion pattern can take place either without almost any top-down processes or strongly constrained by those. We understand top-down processes as specific processes involving prefrontal activation of the brain; this presupposes as a minimal consensus that prefrontal activation of the brain is necessarily involved in the activation of complex cognitive processes which can be loosely understood as conceptual. We can rely on studies which show that such prefrontal activation is at least sometimes involved in standard perceptual processes. ${ }^{11}$ Thus, we distinguish 1. (a basic form of) perceiving an emotion (almost) without any top-down-processes, 2. perceiving an emotion by strongly involving top-downprocesses (a strongly concept-modified form of perception).

[^178]Both types of perceiving emotions can be distinguished from 3. an inference-based evaluation of an emotion pattern. The latter presupposes a stable evaluation of an emotion as being F , which then may be modified or reevaluated by reflecting on the information (Newen \& Welpinghus, under review).

## Cue combination and cue integration in recognition of emotions

We have argued that emotions are individuated on the basis of a number of features that constitute an emotion pattern. Our aim now is to characterize the relevant process of pattern recognition in the case of emotions in more detail. To reach that aim, we analyze the process of recognizing emotions in parallel to the process of perceiving objects. We take the relevant model of object perception from Ernst and Bülthoff (2004): It describes how a stable percept is developed by merging the senses in a process of cue combination and cue integration. This model of object recognition can be directly transferred into a model of emotion recognition including four aspects: (i) The bottomup processes that start with sensory cues of an emotion, which lead to a first estimate of an emotion. A detailed analysis of emotion recognition would have to distinguish at least the following cues: facial expression (F), the gestures (G), the whole body posture (B), the tone of voice (T), autonomic features like sweating (A), the movement/action of the person (M) and the event whose registration triggers the emotion (C). Registering these features also leads to an internal activation of my own, the perceiver's bodily state, e.g. mirror neuron activation, which has been shown at least in the case of seeing disgust in the face of the other person (Calder et al., 2000), and (at least) sometimes also of a visceral activation. (ii) The relevant sensory cues are used for cue combination (combining nonredundant features) and cue integration (selecting one dominant out of a group of redundant features); it is plausible that the process of registering an emotion starts with cue combination of complementary features like F and M producing an intermediate (normally unconscious) estimate E1 of an emotion state, as well as a combination of G, B, A and M, which may constitute a different (normally unconscious) estimate E2 of an emotion state. In a second step, we are in need of integration of redundant cues like E1, E2 and E3 while the latter may be triggered by the auditory cue (T) together with registering the cause (C). (iii) Cue combination and integration leads to an activation of the most likely emotion pattern (on the basis of Bayesian principles) which is connected with a (normally conscious) stable percept. Thus, there is a plausible sense in which we can say that we see an emotion while seeing a person having the features mentioned above. The percept we have is directly associated with the activation of an emotion pattern which we are able to distinguish from others. (iv) Furthermore, the development of an emotion percept may be influenced by top-down processes. Thus, the percept of an emotion is a product of sensory cue combination and
integration influenced by top-down processes: In the case of emotions, situational and person-specific background knowledge can modify the basic bottom-up processes that predicted the emotional state of the other.

## Concluding remarks

Describing emotions as patterns of characteristic features has a number of advantages: First, in the debate between evolutionary theorists and social constructionists, it offers an account that allows to integrate evolutionary anchored as well as culturally shaped features. This especially helps to distinguish emotion concepts in a society and their natural basis, i.e. some emotions concepts are categorizing only conventional constructs while others are actually anchored in natural kinds. The pattern theory accounts for a significant degree of conceptual flexibility in the realm of emotions - based on formal objects and on similarity relations among the various emotion features; given the nature of our affect programs we can actually form a number of coherent classificatory schemata for emotions. Social constructionists often concentrate on emotion categorization in different culture which may be different even if the behavioral dispositions of the people from different cultures would be very similar. We can account for this by characterizing emotions concepts by the significant pattern including behavioral as well as cognitive features. Evolutionary theorists claim that despite cultural variation that any real emotion is constituted by an underlying common core of a few evolutionary anchored features, e.g. fear involves the disposition to freeze or to initiate flight behavior, it has its typical phenomenology. These observations are accounted for by distinguishing rather inflexible and more flexible features of an emotion type. On the basis of the metaphysical view that emotions are individuated as pattern, we argued for a theory of emotion recognition such that it is a process of pattern recognition which is furthermore parallel to object recognition: the same processes of cue combination and cue integration are relevant to develop a percept of an emotion when observing the affective state of another human being. We indicated that we can characterize the perceptual access to emotions as direct, i.e. unmediated by any inferences but we could not develop this view in detail here: we only outlined that the direct perception thesis needs qualification by working out the role of top-down processes in emotion recognition (see Newen/Welpinghus under review). But despite the difference in the relevant features of recognition, both recognition of emotions as well as of objects are analyzed as relying on the same functional processes constituting perception of entities (of any kind). Thus, our model has the advantage of being very parsimonious.

# Schema-Driven, Space-Supported Random Accessible Memory Systems for Manipulation of Symbolic Working Memory 

Nader Noori (nnoori@usc.edu), Laurent Itti (itti@usc.edu)<br>Department of Computer Science, University of Southern California Los Angeles, CA 90089 USA

#### Abstract

We present an execution model for manipulation of working memory content during intellectual symbolic working memory tasks, which allows random access of WM content through a schema-operated sensory-motor spatial working memory. The core concept of this framework is binding symbolic items to spatial locations which are accessible via selective mechanisms of attention in space. An operational schema implements basic WM management operations such as insertion, deletion and fetching through sequences of shifts in spatial attention towards registry locations. We apply the model to a serial recall task (both forward and backward orders). We show that the model provides a better fit to human data in backward recall compared to forward recall, which conforms with the evidence for leveraging spatial strategies for backward recall and phonological strategies for forward recall in normal subjects. We discuss additional possible implications of our model and its assumption of spatial organization of WM content and access through shifts of attention.

Keywords: Memory Manipulation; Operational Schema; Forward Recall; Reverse Recall; Computational Modelling; Intellectual Tasks; Working Memory.

## Introduction

Cognitive psychologists use the term working memory (WM) to emphasize on the use of temporarily stored information in connection with cognitive tasks that involve processing information (Baddeley, 1992). However, a review of the literature shows that the information processing aspect of cognitive tasks mostly applies to and have been explored using intellectual tasks with symbols. Tasks such as random digit generation, forward and backward digit or word span, mental arithmetic, $n$-back recall, double counting and sorting are prevalent in the context of cognitive psychology to explore the ability for manipulation and maintenance of information in working memory (see Repov and Baddely's review paper (Repovs \& Baddeley, 2006)).

Although the credit for popularizing the term working memory goes to cognitive psychologists, the concept of working memory as the ability of temporarily storing information for the use in the upcoming task has been applied in other domains and to tasks that lack symbolic or intellectual features. For example, working memory which is of the interest in the perception community is related to maintenance and manipulation of information for sensory tasks such as visual search (Oh \& Kim, 2004), or in action-perception domain for performing action routines (Arbib, 1987).

However what distinguishes WM in different domains is beyond differences in particular instances of information and indeed is mostly related to their execution models: the functional principles for management or manipulation of information. In particular what different models of working memory
in the domain of cognitive psychology ( CP ) share is a metaconcept for their execution models which can be referred to as the dichotomy of process-storage. Applying this metaconcept to management of information for human working memory was one the most important contributions of Alan Baddeley and Graham Hitch to cognitive psychology which was originally presented in their seminal work (Baddeley \& Hitch, 1974), and ever since has become the common denominator of all models of WM in CP. In this dichotomy which was inspired by Von Neumann's architectural design for modern digital computers (Von Neumann, 1982), the role of execution and processing is given to a central processing unit -namely the Central Executive (CE)—which controls the flow of information between and within storage slave units. However, a long debate over the nature of storage in CP community (Jonides et al., 2008) has restricted elaborations on functional mechanisms of CE.

The concept of CE in WM management did not prove as successful as its counterpart in Von Neumann's proposal in achieving a working memory management schema which helps information processing. What distinguishes the central processing unit (CPU) in Von Neumann's architecture from CE in Baddeley's proposal is that the CPU had all mechanisms for control of storage units built in, while Baddeley and Hitch use the central executive as a metaphor for a central and powerful executive unit with no specific detail as to how CE controls slave storage units (Baddeley, 1992). As Baddeley himself has stated in several occasions because of this lack of specificity, CE has become the rag bag of unanswered questions(Repovs \& Baddeley, 2006) or a homunculus (Repovs \& Baddeley, 2006; Baddeley, 1996). What is known about the executive role of the central executive, for the most part, is postulated by Baddeley and colleagues. Inspired by Norman and Schallice's idea of the Supervisiory Attentional System (SAS) (Norman \& Shallice, 1986), Baddeley has proposed that CE plays a role in controlling limited resources of executive attention (Repovs \& Baddeley, 2006; Baddeley, 1996). However, adding the function of controlling executive attentional resources has not been able to fill the void of a paradigm for an executive model for manipulation of information and to yield a model that explains how executive paradigm are encoded.

To give an example of an alternative meta-concept for manipulation of information we can refer to Arbib's work on information processing in perception-action loops. Arbib in his neuroethologic studies used the concept of information processing in a mechanistic fashion (Arbib, 1980) which was in-
formed by Norbert Wiener's theory of control and the concept of interplay between information and action in controlling biological organisms (Wiener, 1948). The term 'Schema' was the key concept in Arbib's terminology for describing how neural systems interplay to exchange information to achieve a biological goal (Arbib, 1992). In his later work on modeling visually-guided actions, he included the concept of working memory as a mechanism for sustaining information representations relevant to upcoming actions, as long as they remain relevant (Arbib, 1987).

While we share our target of study with contemporary cognitive psychologists, in devising an execution model for manipulation of information in the intellectual and symbolic domain, we are influenced by Wiener's system-theoretic and biologically-plausible concept of flow of information, and by Arbib's schema-theoretic approach (Arbib, 1992). We also have one specific additional assumption for our execution model for memory manipulation, which is the use of spacesupported sensory-motor systems in manipulation of information. We argue that, from an evolutionary standpoint, it is plausible that the capacity of performing intellectual symbolic tasks, which are very recent in our evolutionary history, might have emerged by re-using or co-opting rudementary systems for action and perception. Thus, we try to re-use sensory-motor systems as the building blocks of our approach to a model of working memory for intellectual working memory tasks.

We refer to this schema-driven and space-supported sensory-motor system which provides a random-accessible memory system for manipulation of information as the spatial registry system (SRS). The following section of this paper explains the general concepts of SRS. To demonstrate the power of this paradigm, we present a simple SRS model for immediate forward and backward recall. We show that the model explains the human patterns of errors in backward recall, which has been argued to utilize space for memory organization. Finally, we discuss what we learned from this simulation effort.

## The Spatial Registry System (SRS)

The focus of this section is description of a system for random access of symbolic content of working memory during intellectual mental tasks. Random-accessible working memories are the critical components for dynamic manipulation of information. Yet, they are not the only working memory systems in the context of intellectual working memory tasks. We later discuss a serially-accessible memory as an additional utility memory which collaborates with SRS systems for achieving a complete functioning working memory system.

We propose that symbolic items of the working memory can register with spatial locations in a grounded sensorymotor system which is supported by a spatial representation. Examples of such system -as we presented elsewhere (Noori \& Itti, 2011) - can be occulomotor system, or a kinesthetic system that helps proper configuration of body parts in
space using proprioception and muscle movements (think of a profoundly blind individual's ability for performing tasks in space without any visual reference).

This registry mechanism provides spatial addressing for random access to items of working memory. What is critical is how this addressing is used in the process of memory manipulation. The critical component is spatial selective attention (SSA) as a means to shift between items that are registered with space. An operational schema (OS) defines the sequence of shifts between registry locations.

For example, imagine the case of a concurrent mental headcounting of adults and children in a party. As your gaze shifts to a person in the living room, first your visual system becomes engaged in identifying whether the person at focus is an adult or a child. In the next step, one of two running counts that matches the identified category should be increased by one. The challenge is keeping track of two numbers and associating them to categories. A spatial registry strategy is associating the existing count of adults $n_{a}$ to location $l_{a}$ (e.g., left side in visual field or under pinky finger of the left hand) and the existing count of children $n_{c}$ to location $l_{c}$ (e.g., right side of visual field or under index finger of the left hand). Identifying the next child will trigger a shift of spatial attention to $l_{c}$, to fetch the current count of children. Once the increment operation is applied on the current count the result will replace (by first deletion and then insertion) the old count. Note how attention shifts might be used both for perception of the external world and for selection of WM items, which, under the SRS hypothesis, might give rise to conflicts in some situations, which in turn provides ways to test the hypothesis (see Noori and Itti's paper in this proceedings (Noori \& Itti, 2013) where they report the effect of congruency of shift of spatial attention for target detection and shift of selective attention in internal domain during triple-counting of visual targets).

The operational schema can be conceptualized as a list of mappings of the current state onto the next action. Here is a formal representation of an alternative OS for our head-counting scenario.
OS $1:\left\{\right.$ child $\Rightarrow$ shift to $l_{c} ;$ adult $\Rightarrow$ shift to $\left.l_{a}\right\}$
$O S_{2}:\left\{\right.$ at $l_{c} \Rightarrow$ fetch $n_{c} ;$ at $l_{a} \Rightarrow$ fetch $\left.n_{a}\right\}$
$O S_{3}:\left\{\right.$ at $l_{c} \& n_{c}$ is retrieved $\Rightarrow n_{c} \rightarrow n_{c}+1$
; at $l_{a} \& n_{a}$ is retrieved $\left.\Rightarrow n_{a} \rightarrow n_{a}+1\right\}$
$O S_{4}:\{$ shift the gaze to next person \& identify the category $\}$
Each of these schemas may include other sub-schemas. For example $n_{c} \rightarrow n_{c}+1$ in $\mathrm{OS}_{3}$ may include a sequence of operations over internal representation such as deletion and insertion (binding to space).

We have discussed the neural evidence for this hypothesis elsewhere (Noori \& Itti, 2011). Here we only mention one neuropsychological study which provides a critical evidence for our proposed model(Koenigs, Barbey, Postle, \& Grafman, 2009). Koenig et al. showed that patients who have sustained damage to their superior parietal lobule (SPL) generally lose their capacity for mental operations that need rearrangement
of information and thus they concluded that SPL is critical for manipulation of information in working memory. Interestingly, SPL is a part of the association cortex in the posterior parietal cortex (PPC) and sits at the junction of several sensory processing regions, with projections to motor area of the brain. SPL is shown to be critical for a wide range of routines that need sensory-motor integration, such as navigation, visual search, etc (Rizzolatti, Fogassi, \& Gallese, 1997).

We need to add that the spatial registry system is not a unitary system and several SRS systems might collaborate in running the executive machinery of working memory. However, what all SRS instances have in common is, first, their build-in internal space representation, second, a mechanism to shift the attention to those locations, and, third, a binding mechanism which can associate locations with symbolic representations.

In our view, spatial registry systems are complemented by other systems that mimic a serially-accessible memory, to provide a layer of working memory for intellectual symbolic tasks. An example of such system can be the sensory-motor system that supports speech perception-vocalization (Wilson, 2001) which is believed to be critical for spoken language acquisition (Baddeley, Gathercole, \& Papagno, 1998).

## A Spatial Registry System for Serial Recall

Here we present an SRS model for the immediate serial recall task for both forward and backward recall directions. As we will discuss later in our review of the literature, experimental evidence suggest that forward and backward recall draw on different brain systems. Forward recall seem to take impact from phonological characteristics of the list items (Bireta et al., 2010), suggesting that forward recall relies on phonological resources of the brain. On the other hand, backward recall is disrupted in individuals with deficit in spatial cognition (Rudel \& Denckla, 1974), suggesting that backward recall relies on spatial encoding. We used a spatial registry model applied to both directions of recall; however, as we will discuss, we learned that our SRS model provides a better fit for human behaviour, which conforms with what is assumed about involvement of different systems of working memory in two immediate recall directions.

## A brief review of the literature

Serial digit span tasks are common in both clinical assessment and neuropsychological studies (Rudel \& Denckla, 1974). However, forward recall, disproportionately, has received more attention in modeling attempts. This is mainly related to the importance of temporal serial order in everyday tasks (Glasspool, 2005). As the result, there are many neural models, behavioural models, and mathematical models dedicated to describing forward recall. In contrast, for backward recall, theoretical efforts mostly have focused on augmenting or reusing models of forward recall. In the face of abundant behavioural and neural evidence that serial recall in forward and backward directions draw on different brain mechanisms, it is not surprising that models of backward recall
have obtained remarkably less success in describing human behaviour compared to forward recall (Bireta et al., 2010). Only flexible mathematical models with enough degrees of freedom ,such as the Temporal Ratio Model (Brown, Neath, \& Chater, 2007), have been able to successfully model both recall tasks in one shot (Bireta et al., 2010).

In terms of similarity, recalling in both orders shows recency and primacy effect (Henson, 1996; Li \& Lewandowsky, 1995). Yet ,in forward recall a stronger primacy effect is observed (Henson, 1996), while in backward recall a stronger recency effect is observed ( Li \& Lewandowsky, 1995). Several studies have revealed the difference between recalling in two directions. Bireta et al. tested four benchmark effects that demonstrate the role of phonological resources in immediate forward recall tasks the word length effect, the irrelevant speech effect, the acoustic confusion effect and the concurrent articulation effectfor both directions of recall. They reported that the benchmark effect 'was either absent or greatly attenuated with backward recall despite being present with forward recall'. On the other hand, Li and Lewandowsky observed that altering visual-spatial characteristics of the recall list affected backward recall and not forward recall (Li \& Lewandowsky, 1995).

Neuropsychological evidence also supports that neurological damage to phonological resources of the brain impairs forward digit span while damage to spatial resources of the brain impairs backward digit span (Rudel \& Denckla, 1974). Consistent with these observations, neuroimaging studies also have revealed differences in cortical regions which are active during the two different recall orders (Sun et al., 2005; Hoshi et al., 2000). In particular, these studies have revealed significant activation of cortical areas with spatial processing characteristics in backward recall compared to forward recall.

In terms of modling efforts, Bietra et al. have briefly reviewed existing models. Their review indicated that those models that take the phonological aspect of forward serial recall are not successful in modeling backward recall, and only models that are agnostic to the difference in underlying mechanisms of serial recalls in two different directions are relatively successful in modeling both tasks.

In sum, available evidence suggests that a model that confers a special role to space may be necessary for a mechanistic model for the backward recall. In the following section we detail such a model, built based on the specifications of the SRS model for visuospatial working memory as the spatial registry.

## Simulation

A population coding of a one dimensional space in the form of an array of neurons was used as the registry space. Population coding of neurons has been extensively explored (Pouget, Dayan, \& Zemel, 2000) in the literature and is popular for neural modeling of visuospatial working memory (Constantinidis \& Wang, 2004). This array of neurons encoded a parametric space spanning the range of -1 to 1 . The
tuning curve for neurons in this array was characterized by $\sigma_{0}+x_{n} \times \kappa$ where $\sigma_{0}$ is the tuning band parameter of the neuron at the center of space, $x_{n}$ is neuron's peak response location, and $\kappa$ a constant which controls the variability of tuning band in the array of neurons.

Registering with a specific location would trigger noisy activation in the population around the target memory field. The share of a registry at $x_{r}$ in activation amplitude of a neuron at $x_{n}$ is determined by $A_{0} e^{-\frac{\left(x_{r}-x_{n}\right)^{2}}{2 \times \sigma_{n}{ }^{2}}}$. In case of registering several items in the activation of a neuron is defined as the sum of evoked signals of all registries as long as the sum of signals is less than a saturation value $\mathcal{S}$. So the base response amplitude of neuron $n$ is defined as follow:

$$
\begin{equation*}
\max \left(\mathcal{S}, \sum_{i=1}^{N} A_{i}(t) \times e^{-\frac{\left(x_{r_{i}}-x_{n}\right)^{2}}{2 \times \sigma_{n}^{2}}}\right) \tag{1}
\end{equation*}
$$

where $i$ is the index for registered items, $x_{r_{i}}$ is the registry location of the item $i$ and $A_{i}(t)$ denotes the effective amplitude of the ith registry at time $t$ which is defined by:

$$
\begin{equation*}
A_{0} \times e^{-\frac{t-t_{i}}{\tau_{d}}} \tag{2}
\end{equation*}
$$

where $t_{i}$ is the registry time of item $i$ and $\tau_{d}$, the damping factor, controls the decay rate of registry effects.

The schema for the immediate recall task includes two phases: binding and recall. During the binding phase, independent of the recall order, items of the list orderly register with locations from left to right so that each item in the list registers on the right side of previously registered item (except the first item). The exact times and locations of registries are perturbed by different random distributions. The distances between registry locations are determined by a Weibull distribution with two parameters (shape factor and scale factor). Duration of registry and recall processes are defined by two separate Gaussian distributions, which adds four more parameters to our model.

In the recall phase, a part of the schema is independent of recall direction, which is the condition for identifying the most active neuron, and for selecting the next item (until all items are removed from the registry space). Neurons in the array compete for gaining control of a registry recalling unit. The item at the closest registry location to the selected neuron will be recalled. Recalling memory items from registry involves inhibiting neurons in the array associated with registration of the recalled item.

Another part of the recall schema which is sensitive to the direction of recall is characterized by a bias. The bias is applied by a multiplicative exponential factor of the position which acts as a biased modulation of neural activities. For forward recall, this bias will enhance the activity of neurons on the left side of the space, and during the backward recall this bias enhances activities of neurons on the right side of the space. So, a part of the schema for recall is selecting the bias direction; however, once the bias direction is selected items will be selected only based the order of most active neurons.

| Par | Description | Par | Description |
| ---: | :--- | ---: | :--- |
| $\sigma_{0}$ | Spatial tuning at the center | $\kappa$ | Tuning band var factor |
| $\beta$ | Bias factor | $\nu$ | Noise factor |
| $\tau_{d}$ | Damping factor | K | Binding shape factor |
| $\lambda$ | Binding scale factor | $\mathcal{S}$ | Saturation factor |
| $\mu_{b}$ | Mean for binding duration | $\sigma_{b}$ | STD for binding duration |
| $\mu_{r}$ | Mean for fetching duration | $\sigma_{r}$ | STD for fetching duration |

Table 1
Parameters of the SRS model for serial recall

Figure 1: Positional error for the best two-way fit for both directions of recall compared to the human performance.

This implementation only accommodates positional or movement errors in which items are recalled in the wrong order. This type of error is the most prevalent error among adults (McCormack, Brown, Vousden, \& Henson, 2000) in recall tasks. However there are other types of errors such as omissions, intrusions and repetitions with less significant effect. Table 1 summarizes all parameters of this implementation.

## Results and Discussion

To explore tuning parameters we used serial position error for a list of five items from Li and Lewandowsky's study (Li \& Lewandowsky, 1995). An evolutionary algorithm was used to optimize the parameters based on the sum of absolute distance of predicted positional error over the ground truth data for both directions. So optimization of parameters was performed with regard to ground truth data for both directions simultaneously and forward and backward error data played equal roles in the evaluation function. However a closer inspection of the result revealed that the final parameters shifted in favour of the backward data. The best fitting parameters among 2857 independently generated solutions yielded a prediction for backward recall with $5.6 \%$ absolute distance to the human data (out of $500 \%$ maximum possible distance) while the same set of parameters yielded a prediction for the forward recall with $14.8 \%$ absolute distance to the human data (see Figure 1). Further analysis of best first 100 independent solutions of the optimiza-
tion process showed that the quality of predicted solution for backward recall was significantly better than forward recall $(t(198)=47.93, p<0.0001)$, where the difference between mean of fitness qualities was $6.6 \%$ in favour of the backward recall.

Moreover, a closer inspection of all generated parameter sets during during optimization process revealed two highly distinguishable modes for $\sigma_{0}$, the first order tuning curve parameter. A population of solutions with narrow tuning curve at the center peaked around $\sigma_{0}=0.04$ which included 847 solutions all with $\sigma_{0}<0.1$. Another population of wide tuning curve at the center peaked around $\sigma_{0}=0.57$ all with $\sigma_{0}>0.38$ included 2010 solutions. Later analysis of the fitness values of these solutions showed that the population of wide tuning curve (WTC) on average scored better fitness value than the population of narrow tuning curve (NTC). The wide tuning curve population (WTC) generally scored better in each of recall types compared with the narrow tuning curve population. Moreover, WTC and NTC populations were also highly separable with regard to other parameters including the bias factor, and temporal characteristics of binding and recall of item. In particular the for WTC the average duration of the task was correlated with the damping factor of neural activity while the duration of the task was independent of the damping factor of neural activities. In sum, WTC population provided both better solutions and more plausibility.

To test the predicting power of the model we used the parameter of the best solution discovered in the optimization of the previous phase to simulate the movement errors (the distance between order of an incorrectly recalled item, and its true order; e.g., if item 3 is recalled as item 2, the movement error is 1) in forward recall data for six items, from another study (McCormack et al., 2000). Note that number of items for training was different than for testing. Moreover, positional error data, which is used for optimization of parameters, is independent of movement errors (which we confirmed through simulation, not shown here).

Figure 2 shows the result of our simulation in the same graph with the data of two adult human subject groups, tested in two different experiments with different settings for a forward recall task (McCormack et al., 2000). Our simulation result sits in between the data points for two different results for adult human subject groups, which demonstrates that our prediction is in the range of the variability of the performance of human subjects, and clearly demonstrates the predictive power of the model.

In sum, the result of our simulation shows that SRS for immediate serial recall can account for human behaviour. However, as it was explained, the quality of our solution for backward recall is significantly better than the quality of our result for forward recall once both recall orders played the same role in optimization of parameters. This may be related to the fact that normal subjects leverage their phonological resources for forward recall (Bireta et al., 2010).

This does not mean that visual-spatial resources cannot be
used for forward recall. In fact previous studies have shown that articulatory suppression during working memory task with written verbal material can eliminate the effect of other signature effects such as word length effect or acoustic confusion effect without diminishing subjects' capacity for remembering the serial order (Wilson, 2001). These evidences suggest that once the speech recognition-vocalization system as the primary source of encoding serial recall is no longer accessible (by articulatory suppression) and working material are presented in visual format, another mechanism is utilized for encoding serial recall which does not rely on phonological resources. We argue that one could use a visual-spatial strategy for forward recall too. In this case, the prediction of our SRS model is that the overall performance would not be significantly better (see Figure 1a). However, using phonological resources for the forward recall has at least one advantage, which is freeing visual-spatial resources for other tasks. In contrast the ability to perform a backward recall task with impaired spatial resources is restricted (Rudel \& Denckla, 1974), in agreement with our finding that visualspatial resources are used for backward recall.

Figure 2: Prediction of SRS model along experimental data for movement errors during serial recall of six items.

## General Discussion

In this paper we presented the idea of a space-supported, schema-driven, random-accessible memory system in the domain of intellectual working memory tasks of cognitive psychology. Our proposal included a strong evolutionary assumption about what would constitute an executive model for a working memory system in the intellectual domain, which can be built atop sensory-motor systems that support perception-action routines. Perception-action routines, such as prey catching, evolutionarily, preceded the intellectual routines, such as mental subtraction, and thus we suggest that sensory-motor working memory systems for regulating the former routines might have been reused for maintaining and
manipulation of information needed by the evolutionary more recent latter routines.

The presented model provides a randomly-accessible working memory, yet to get a full-function working memory model that explains human behaviour across different domains, one may need to take a serially-accessible working memory subsystem into consideration too. A speech perception-vocalization subsystem -which resembles the phonological loop in Baddeley and Hitch's three-component model of working memory (Baddeley \& Hitch, 1974)- may be considered as an alternative serial component of working memory machinery in the domain of symbolic tasks. However, we argue that a serial system is not sufficient to explain humans' flexible memory manipulation of symbolic information in the intellectual domain, and one may need to include a faster and more flexible working memory system for random access to its content.

Finally one may argue that the visuospatial sketchpad in Baddeley and Hitch's model (Baddeley \& Hitch, 1974) can achieve the same function of our proposed SRS system. We can summarize the differences or our spatial registry system and the visuospatial sketchpad as follow.

First, while visuospatial sketchpad is merely a visualspatial system our SRS is a generic schema-driven system and as previously suggested several instances of sensory-motor working memory systems (e.g. occulomotor or kinesthetic system) may fulfil the characteristics of SRS.

Second, our SRS comes with a built-in executive system in the form of the operational schema (OS), while the visuospatial sketchpad outsources the execution functions to the CE, with no specifications of how this executive functions are exerted. In this sense, SRS provides a mechanistic model of manipulation of WM items while the sketchpad is a passive storage resource.

Third, in Baddley's model visuospatial sketchpad is a domain-specific storage slave unit which stores task-relevant visual-spatial information, while in our proposal an SRS system may play a general role in manipulation of symbolic information with no immediate visual or spatial features.

# Auditory Overshadowing in Preschoolers: A Preference for the Input, the System, or Both? 

Allison O’Leary (oleary.83@osu.edu)<br>Department of Psychology, 1835 Neil Avenue<br>Columbus, OH 43210, USA

Vladimir M. Sloutsky (sloutsky.1@osu.edu)<br>Department of Psychology, 1835 Neil Avenue<br>Columbus, OH 43210, USA

#### Abstract

Auditory overshadowing occurs when the presence of an auditory stimulus interferes with visual processing. The current study tested whether this occurs due to a privileged attentional status of auditory input or due to the dynamic characteristics of auditory input. To address these questions, preschoolers completed one of four discrimination tasks. In the sound, motion, and item baseline conditions, children discriminated these single information types by judging whether paired stimuli were the same or different. In the combined condition, children discriminated changing sounds, motions, or items in the face of competing input in the other two dimensions. Although children's discrimination of all information types attenuated in the combined condition relative to baseline, motion and item discrimination attenuated more than auditory discrimination. This provides evidence that early in development auditory information receives privileged processing in the face of competing input.

## Introduction

To successfully navigate and form an understanding of our environment, we must develop the ability to efficiently integrate information from multiple sensory modalities. There is evidence that some multisensory integration occurs even in neonates, as demonstrated by the structural convergence of input from different sensory modalities (Stein \& Meredith, 1993). However, it is clear that the ability to integrate multimodal information is not fully mature at birth and, in fact, exhibits a protracted developmental trajectory. For example, in contrast to normally functioning adults, infants and young children exhibit a phenomenon known as auditory overshadowing (Robinson \& Sloutsky, 2004b). This occurs when the presence of an auditory stimulus interferes with one's processing of a visual stimulus. That is, infants and young children more easily discriminate visual stimuli when presented in isolation than when paired with labels or sounds. In some cases, children completely fail to discriminate changes in a visual stimulus when presented simultaneously with a sound (Napolitano \& Sloutsky, 2004). Importantly, although visual discrimination is impaired in the presence of auditory information, auditory discrimination does not suffer in the presence of visual
information (Sloutsky \& Napolitano, 2003; Robinson \& Sloutsky, 2010b).

The importance of audio-visual integration is especially apparent for processes like word learning, where individuals must map verbal labels to objects in visual space. If visual processing is inhibited when an auditory stimulus is present, auditory overshadowing could be a major contributor to the difficulty children face mapping words to objects. Indeed, 10 -month-olds encoded only auditory information when presented with visual information and a verbally presented label. However, 16-month-olds demonstrated able processing of both the visual information and the label (as indicated by looking time preferences; Robinson \& Sloutsky, 2004a).

Although the ability to process auditory and visual information progresses through infanthood, even preschoolaged children show difficulties discriminating static visual stimuli in the presence of sounds and labels. Napolitano and Sloutsky (2004) demonstrated that 4-year-olds were susceptible to auditory overshadowing when asked to discriminate changes in the visual and auditory aspects of a target stimulus. Specifically, this effect was most profound when the visual and auditory stimuli were unfamiliar. Further, the authors demonstrated that this overshadowing was resistant to explicit instruction, in that it still occurred when children were asked to attend exclusively to visual information.

More recent research has aimed to detail the conditions in which auditory overshadowing occurs and to elucidate the basic cognitive mechanisms underlying these effects. Input from the visual and auditory modalities seem to "compete" for processing resources early in development, whereas adults are able to process multimodal information (Robinson \& Sloutsky, 2004a). Robinson and Sloutsky (2007a) also argued that overshadowing may occur during initial processing/encoding as well as during response selection. In addition, unfamiliar auditory stimuli slow visual processing, whereas familiar auditory stimuli do not (Robinson \& Sloutsky, 2007b). Despite our understanding of the subtleties of the effect, major questions remain regarding the privileged status of auditory input and a number of hypotheses explaining auditory overshadowing effects have been proposed.

One possibility is that auditory and visual information are processed serially, and that auditory stimuli are processed more thoroughly because they are faster to engage attention. Visual processing may be inhibited until attention is disengaged (Robinson \& Sloutsky, 2010a). However, there are at least two possible explanations as to why auditory input would more easily engage attention. First, adults process auditory information more quickly than visual information, which may reflect privileged processing of auditory input per se (Green \& von Gierke, 1984). Because the auditory system begins maturing before the visual system, it is possible the auditory system processes information more efficiently even during childhood. Alternatively, it is possible that the nature of the input plays a role. For example, auditory stimuli are typically dynamic (i.e., exhibit change over time) and have more abrupt onset than visual stimuli. Perhaps it is this dynamicity that quickly engages attention.

However, previous research could not distinguish between these possibilities because all previous studies of auditory overshadowing have utilized static visual stimuli. The current study aimed to test these explanations by increasing the dynamicity of visual stimuli. This was done by adding motion to the visual stimulus, which is a powerful bottom-up attentional cue (Egeth \& Yantis, 1997). If the dynamic nature of auditory input is responsible for auditory overshadowing, one would expect the increased dynamicity of the visual stimulus to attenuate auditory overshadowing, resulting in more thorough visual processing. In this situation, visual information may even overshadow auditory information. On the other hand, if the auditory system itself is privileged, one would not expect such attenuation, even if the visual cue is dynamic. Distinguishing between these possibilities would result in better understanding of the mechanisms underlying auditory overshadowing.

In previous studies where young children were presented with auditory and visual information, visual discrimination attenuated significantly whereas auditory discrimination showed no significant attenuation. The current study aimed to investigate the effect when presented stimuli had an auditory, visual, and motion component. In this "combined" condition, target and test stimuli included all of these components. Children were instructed to say "same" if the target and test stimuli were the same in all 3 aspects. Children were instructed to say "different," however, if the sound component changed, the motion component changed, or the item appearance component changed. To determine the extent of overshadowing, we assessed children's discrimination of changes in the sound, image, or motion of these more complex stimuli relative to their ability to discriminate these types of information when presented in isolation (i.e., sound, motion, and item discrimination baselines). If auditory overshadowing stems from the dynamic nature of sound, then the dynamic motion cue should attenuate auditory processing.

## Method

## Participants

Eighty-two four-year-olds (41 girls and 41 boys, $M=4.48$ years, $S D=.28$ years) participated in this experiment. Children completed one of four conditions: sound baseline ( $N=20$ ), motion baseline ( $N=20$ ), item baseline ( $N=20$ ), or a combined (sound-motion-item) condition ( $N=22$ ). Children were recruited through local daycares and preschools located in Columbus, Ohio. The majority of participants were Caucasian.

## Stimuli

In the combined condition, children saw two moving "toys" which were each paired with a sound, and were asked to discriminate changes in the sound, motion, or appearance of these toys. Each stimulus in this condition consisted of a sound, motion, and an object, referred to as "item". There were 8 sound, 8 motion, and 8 item appearance possibilities. All of these were intended to be novel to children, as overshadowing effects are sensitive to stimulus familiarity (Robinson \& Sloutsky, 2010b). For example, auditory stimuli consisted of dynamic sounds like camera clicks and notes from an organ. Each auditory stimulus was 1500 ms in duration. The 8 items all consisted of a central ' $X$ ' on which four colored shapes were placed. Each of these items was animated in 8 different motion patterns (e.g., $360^{\circ}$ rotation, looming) to produce 512 total sound-motion-item combinations. Each stimulus presentation proceeded in the following way: children viewed the static image in silence for 500 ms , after which the motion and sound began simultaneously, lasting for the remaining 1500 ms of stimulus presentation.

Each of the baseline conditions aimed to assess children's discrimination when a single type of information is presented. In the sound baseline, children were asked to discriminate 2 of the 8 sounds used in the combined condition. In this baseline, the only visual stimulus was a small fixation cross presented in the center of the screen. In the motion baseline, children were asked to discriminate 2 of the 8 motion types. Here, the same item was used throughout the task, and these visual stimuli were presented in silence. In the item baseline, children discriminated 2 of the 8 items, presented statically and in silence.

## Procedure

In all conditions, children observed pairs of stimuli presented sequentially and were asked to indicate whether the two stimuli were the same or different. Because of their novelty, the experimenter described the stimuli as "toys from outer space." Children were told they would see two of these toys and that their job was to tell the experimenter whether the two toys were different in any way (i.e., if they noticed a difference in the item, motion, or sound). During each trial, children were first presented with a fixation cross in the center of the screen. Once the child fixated on this

Figure 1. Target and test stimuli used in the sound, motion, and item baseline conditions. The top images depict example target stimuli. Bottom images depict potential test stimuli for that target.

Figure 2. Target and test stimuli used in the combined condition.
cross, the experimenter pressed the spacebar to present the target stimulus. The child then saw another fixation cross.

Upon the child's fixation, the experimenter pressed the spacebar to present the test stimulus. Each target and test stimulus was 4000 ms in duration. Following test stimulus presentation, the child was asked to indicate verbally whether the two toys they just observed were the same or different. Half of the trials were "same" trials, in that the target stimulus was identical to the test stimulus. The remaining half of trials were "different" trials, such that theitem, motion, or sound presented at test differed from that in the target. Each child completed 4 blocks which each consisted of 12 trials. Children saw a 12 -second cartoon between blocks.

In the combined condition, each target trial consisted of a moving toy paired with a sound. Each sound, motion, and item was selected randomly. During the "same" test trials, children were presented with a stimulus identical to the target stimulus. In one third of the "different" trials, only the sound changed at test, and the item and motion remained the same. In one third of these trials, only the motion of the item changed, and the item itself as well as the sound remained the same. In the remaining third of these "different" trials, the item changed, but the motion and sound remained the same. Of interest was whether children showed differential ability to discriminate these 3 types of information when presented simultaneously, relative to when presented in isolation (i.e., performance in the respective baselines).

The baseline conditions assessed children's ability to discriminate sound, motion, and item information individually. In the sound baseline, target trials consisted of an auditory stimulus (selected randomly from the 8 possibilities) presented with only a fixation cross in the center of the screen. During "same" trials, children heard the same sound. During "different" trials, children heard a different sound. The same structure applied to the motion and item baselines.

## Results

To ensure that children understood and were engaged with the tasks, only those children whose overall performance was above chance ( $50 \%$ accuracy) were included in subsequent analyses. This eliminated 2 children in the sound baseline condition, 2 children in the motion baseline condition, and 2 children in the item baseline condition.

## Baseline conditions

To evaluate the meaning of differential performance (discriminating sound, motion, and item) in the combined condition, it was necessary to first establish children's ability to discriminate each type of information presented independently. Children demonstrated high performance across the sound ( $M=.91, S D=.08$ ), motion ( $M=.87, S D$ $=.10)$, and item $(M=.92, S D=.07)$ baselines. A one-way ANOVA indicated no significant differences between children's performance in these three conditions, $F(2,51)=$ 2.03, $p=.142$.

A one-way ANOVA comparing children's reaction times to "different" trials in the 3 conditions (including only correct responses) revealed a main effect of information type, $F(2,51)=8.77, p<.005$. Post hoc multiple comparisons using Fisher's LSD revealed that individuals in the item baseline condition $(M=1486.81, S D=1066.36)$ discriminated more quickly than those in the motion ( $M=$ 2409.69, $S D=817.29$ ) and sound ( $M=2653.24, S D=$ 724.60) baselines. Average RTs in the motion and sound baselines did not differ significantly from one another. These results suggest that item discrimination was somewhat easier than discrimination of sounds or patterns of motion.

## Combined condition

In the combined condition, children indeed showed differential accuracy discriminating sound, motion, and item changes, $F(2,63)=7.11, p<.005$. Post-hoc multiple comparisons indicated children were significantly more accurate when discriminating sounds $(M=.70, S D=.25)$ than both motions ( $M=.48, S D=.30$ ), and items ( $M=.39$, $S D=.30$ ). Children's discrimination of motions and items did not differ significantly. Further, children's reaction times did not differ significantly when discriminating the different information types, $F(2,63)=1.45, p=.242$.

## Comparing baseline and combined conditions

Because the assessment of overshadowing requires the comparison of performance on the between-subjects baseline conditions and the within-subjects combined condition, we calculated difference scores to describe each individual's attenuated performance in the combined condition relative to baseline. For example, we subtracted the mean accuracy of all individuals in the sound baseline from each individual's average accuracy to "different sound" trials in the combined condition.

As indexed by these difference scores, children's performance in the combined condition attenuated significantly across all the information types (i.e., all difference scores differed from zero): sound, $t(21)=-3.83, p$ $<.005$; motion, $t(21)=-6.03, p<.001$; and item, $t(21)=-$ $8.29, p<.001$.

A one-way ANOVA comparing children's difference scores revealed a main effect of condition, $F(2,63)=7.472$, $p<.005$. Post-hoc multiple comparisons using Fisher's LSD revealed children's performance in the combined condition attenuated less in the auditory condition $(M=-.20, S D=$ $.25)$ than in the item condition $(M=-.53, S D=.30)$ as well as the motion condition ( $M=-.39, S D=.30$ ). Difference scores in the item and motion conditions did not differ from one another. Children's reaction times differed amongst the baseline and combined conditions only when it came to discriminating item information, $t(38)=-2.53, p<.05$.

Figure 3. Proportion of accuracy to "different" trials for sound, motion, and item information by condition.

Figure 4. Average reaction time to discriminate "different" trials for sound, motion, and item information by condition. Baseline reaction times include only correct responses.

In sum, children's discrimination of sound, motion, and item information attenuated when presented simultaneously rather than in isolation. Sound discrimination attenuated the least, followed by motion discrimination, and then item discrimination, which attenuated most. These results indicate that auditory information was more likely to overshadow visual motion than the other way around.

These findings, in turn, suggest that processing of auditory information may indeed be privileged compared to visual information, even if visual information is dynamic in nature.

## General Discussion

The current experiment compared children's ability to discriminate motion, sound, and item appearance information when presented simultaneously versus in isolation. When combined, children's discrimination of all 3 information types attenuated relative to baseline performance. This indicates that all 3 types of information were somewhat susceptible to interference from one another. It is well established that when auditory and static visual stimuli are presented simultaneously, processing of the visual stimulus suffers whereas auditory processing remains intact. Thus, the additional motion information in the current study contributes to the overshadowing of auditory processing. This provides support to the idea that the dynamicity of visual and auditory input plays a role in the allocation of attention to these two modalities.

Although children in the baseline conditions exhibited high accuracy across the board, the levels of attenuation in the combined condition differed significantly across information types. The most attenuation occurred for item discrimination, followed by motion discrimination, and the least attenuation to sound discrimination. The fact that auditory discrimination was overshadowed least suggests that the auditory system may have privileged status early in development.

Interestingly, children's reaction times in the item discrimination baseline were significantly faster than in the other baseline conditions. Note that accuracy in this condition was high and equivalent to the other conditions. Therefore, it is unlikely that differential attenuation occurred due to differences in baseline discrimination. If this had been the case, one would have expected the least overshadowing for item discrimination.

Overall, the current study demonstrates that there may be multiple influences at play in the manifestation of auditory overshadowing of visual information. Pulls on attention appear to be sensitive to increased stimulus dynamicity. In addition, auditory information receives privileged processing even in the face of competing dynamic visual input. In terms of the directionality of overshadowing effects, however, the current study is limited in its potential conclusions. Children were exposed to one information type in the baseline conditions and all three information types in the combined condition. It is impossible to speculate the direction of overshadowing effects without comparing the extent of children's overshadowing in the combined condition to conditions involving only two types of information. For example, this would allow us to compare overshadowing when sound, motion, and visual information are combined to the traditional overshadowing effect involving only auditory and static visual stimuli. Without this manipulation (which is currently in progress), we are unable to identify whether the additional motion
information contributes to the attenuation of item discrimination.

Further research will also need to elucidate whether increasing the dynamicity of visual input could benefit young children's word learning. Previous work indicates that, in some cases, novel sounds like the ones used in the current experiment overshadow visual input, whereas familiar sounds and words do not. Perhaps the use of more familiar auditory stimuli would result in less overshadowing overall. If this were the case, this increased attention to visual and motion information would provide more optimal conditions for learning object-word mappings. Future work could also investigate whether these mappings occur more easily when visual stimuli are presented dynamically.

In addition, it will be interesting to investigate the developmental trajectory of auditory overshadowing in the context of dynamic visual input. Perhaps there are times throughout development in which motion facilitates visual processing, and times when it hinders or distracts. Further, a developmental investigation can help us identify related processes that could help explain the typically observed reduction in overshadowing with age. For example, perhaps increases in working memory capacity are associated with the developing ability to bind auditory and visual information (Allen, Hitch, \& Baddeley, 2009). This research could illuminate ways of presenting particular stimuli to encourage processing between different modalities. Once we understand the developmental process contributing to audio-visual association, we can apply those principles to identify optimal learning conditions in order to teach children more efficiently.

## Conclusions

In sum, the current research points to several important findings. When auditory stimuli were presented with dynamic visual stimuli, children's processing of auditory information attenuated. This finding is the first evidence that visual information may interfere with auditory processing early in development. Although auditory discrimination attenuated, it attenuated less than the discrimination of motion patterns or item appearances. The combination of these findings indicates that auditory overshadowing may have multiple underlying causes. Children's attention to dynamicity in the visual modality seemed to pull attention ordinarily devoted to auditory processing. However, the auditory information was still processed better than motion or item appearance information in the face of this competing input. Thus, auditory overshadowing seems to be a function of privileged processing of auditory information.

## Acknowledgements

This research was supported by a National Science Foundation (NSF) grant (BCS-0720135) to Vladimir Sloutsky. We thank the children, parents, and preschools that participated in this research.

# The interaction of different working memory mechanisms and sentence processing: A study of the P600 

Polly O’Rourke (porourke@casl.umd.edu)<br>Center for the Advanced Study of Language<br>University of Maryland, $700552^{\text {nd }}$ Avenue<br>College Park, MD 20742 USA

#### Abstract

While previous research has shown that working memory capacity (WMC) predicts sentence processing ability, the understanding of the relationship is limited as almost all studies have used the reading span task as their sole measure of WMC. The current study examined how the effects of garden-path sentences and filler-gap dependencies (as indexed by the P600) related to four measures of working memory (reading span, operation span, anti-saccade and $n$-back). P600 effects for garden-path sentences correlated positively with operation span score while effects for object relatives correlated negatively with n-back accuracy. These results indicate that, though both sentence types are associated with increased working memory demands, the resolution of temporary syntactic ambiguity and filler-gap dependencies recruit distinct working memory mechanisms.

Keywords: Garden-Path; Object Relative, Reading Span, $N$ back, P600.

## Introduction

Two major sources of difficulty in sentence processing are temporary syntactic ambiguity and syntactic complexity (see sentences 1 and 2, respectively). Sentences containing temporary ambiguities (i.e. garden-path sentences) usually lead to an initial incorrect parse of the syntactic structure which must be reanalyzed when the temporary ambiguity is resolved in order for the sentence to be correctly interpreted. In sentence 1 below, the initial interpretation may be that the patient met the doctor and the nurse but upon arriving at the word "showed" (the disambiguating verb), it is apparent that that interpretation is incorrect and must be revised. A prime example of syntactic complexity is an object relative which represents a filler-gap dependency in which direct or indirect object is displaced from the verb from which it gets its thematic role. In order to resolve the filler-gap dependency, the object ("to whom" in sentence 2 below) must be maintained active until it can be mapped onto the thematic grid of the relevant verb ("showed").

1. The patient met the doctor and the nurse with the white dress showed the chart during the meeting.
2. The patient met the doctor to whom the nurse with the white dress showed the chart during the meeting. ${ }^{1}$
[^179]Behavioral research has shown longer reading times and reduced comprehension accuracy for sentences with gardenpath sentences (Frazier \& Rayner, 1982; Ferreira, Bailey \& Ferraro, 2002) and object relatives (Frazier, 1987; King \& Just, 1991) compared to simple controls. Research using the noninvasive event-related potential (ERP) technique of recording brain activity has also provided evidence for the increased difficulty of these sentence types. The key potential of interest is the P600, a positive shift which emerges 500 to 800 ms post-stimulus, typically largest over posterior sites. The P600 is generally considered to be an index of syntactic integration difficulty (Kaan et al., 2000). It is elicited by syntactic violations of all types but is also sensitive to syntactic ambiguity and syntactic complexity in well-formed sentences. Garden-path sentences elicit P600 effects relative to non-garden-path sentences (Osterhout, Holcomb \& Swinney, 1994; Kaan \& Swab, 2003; Gouvea, Phillips, Kazanina \& Poeppel, 2010). In addition, several studies have found P600 effects when comparing sentences containing object relative clauses to simple declarative sentences (Kaan, Harris, Gibson \& Holcomb, 2000; Gouvea et al. 2010). Gouvea et al. (2010) found that the P600 effect for garden-path sentences is more robust and of longer duration than that of unambiguous object relative structures.

One potential source of the increased difficulty is the increased demand these sentences place on working memory resources. Working memory (WM) is "a multicomponent system responsible for active maintenance of information in the face of ongoing processing and/or distraction" (Conway, Kane, Bunting, Hambrick, Wilhelm \& Engle, 2005, p. 770) which facilitates goal directed behavior. Individual differences in working memory capacity (WMC) impact sentence processing ability. A number of studies have found that individuals with high WMC have faster reading times and improved comprehension performance for garden-path sentences (Just \& Carpenter, 1992; Friederici, Steinhauer, Mecklinger \& Meyer, 1998) and object relative dependencies (Just \& Carpenter, 1992; King \& Just, 1991) than low WMC participants. The P600 is modulated by WMC as well. ERP studies have shown that individuals with high WMC have greater P600 effects at the disambiguation point of sentences containing temporary ambiguities (Friederici et al., 1998; Vos, Gunter, Schriefers \& Friederici et al., 2001; Vos \& Friederici, 2003; Bornkessel et al., 2004), indicating increased reanalysis in the high WMC participants. Neither

Bornkessel et al. (2004) nor Friederici et al. (1998) found group differences in the P600 effects for syntactically complex sentences which did not contain temporary ambiguities. This suggests that the resolution of syntactic ambiguity and of filler-gap dependencies differ in terms of working memory demands.

Understanding of the relationship between WMC and different types of syntactic processing is limited by the fact that the vast majority of studies that have examined the connection have used the reading span task (Danemann \& Carpenter, 1980) as the sole index of WMC, while many different assessments, which tap different working memory mechanisms, exist (Conway, Kane, Bunting, Hambrick, Wilhelm \& Engle, 2005). This makes it impossible to determine if the difference between the working memory demands of two syntactic processes are quantitative or qualitative. Parsing complex but unambiguous syntax may be less costly than reanalysis of garden-path structures, or it could recruit working memory mechanisms not indexed by the reading span task.

The goal of the current study was to determine if working memory mechanisms other than those indexed by reading span are relevant to the online sentence processing as indexed by P600 effect size. To this end, WMC was assessed using four different measures: reading span, operation span, $n$-back and anti-saccade. The reading span is a complex span task which assesses an individual's ability to maintain and process information (i.e. read sentences) under divided attention. Operation span, another complex span task, is very similar except that the processing component is the performance of mathematical operations. These two tasks correlate with each other (Conway et al. 2005) and both have been shown to predict sentence comprehension performance (Turner \& Engle, 1989). Also, as mentioned before, reading span has been found to predict P600 effect size for garden-paths (Friederici et al., 1998; Vos et al., 2001, Vos \& Friederici, 2003; Bornkessel et al., 2004). $N$-back performance reflects the ability to maintain, monitor and regularly update information. The relationship between $n$-back and sentence processing is unclear and largely untested. Sprouse, Wagers and Phillips (2012) found no evidence of a relationship between $n$-back performance and island effects (i.e. effects of syntactic complexity) on acceptability judgments. Novick and colleagues, however, found that individuals who improve their $n$-back performance via training show reduced garden-path effects in their comprehension accuracy relative to those who do not respond to training (Novick, Hussey, Teubner-Rhodes, Dougherty, Harbison \& Bunting, in press). The anti-saccade task tests the ability to suppress a prepotent response. Bilinguals are known to out-perform monolinguals in tasks tapping this skill (Bialystok, 2006, Bialystok, Craik, \& Luk, 2008), suggesting a possible connection with language processing. By including a wider range of working memory assessments, the current study aimed to enrich understanding of the cognitive underpinnings of sentence processing.

## Methods

## Participants

Data was collected from 65 right handed participants. Data from two participants was excluded because it was revealed that they didn't meet the participation criteria. Six participants were excluded due to technical issues with data collection. An additional 6 were excluded due to excessive EEG artifacts. Data from the remaining 51 participants (29 female) between the ages of 18 and 40 (mean age $=21.5$, S.D. $=2.33$ ) were included in the analysis. All participants were neurologically normal, native speakers of English. None had had started learning a second language before age 12.

## Sentence Stimuli

The sentence stimuli consisted of garden-path, object relative and control sentences (see 3-5 above, respectively. The critical word in each condition was a ditransitive verb ("showed" below). A total of 108 triplets were prepared using 108 different critical verbs such that each sentence in a triplet is identical except for the region at the beginning of the second clause (bolded below). Ninety of the 108 came from Gouvea et al. (2010)'s stimuli set. In the garden-path sentences, the critical verb indicated the need for reanalysis. In the object relative sentences, the critical verb indicated the thematic position of the wh-phrase ("to whom") and, thus, allowed the resolution of the filler-gap dependency. Each list contained 36 sentences in each condition. The presentation of sentences was counterbalanced such that each sentence appeared in one condition per list. In addition, 72 filler sentences (matched for length and complexity) were included. Fifty percent of all sentences were followed by a comprehension question. Questions came either from Gouvea et al. (2010)'s stimuli or were created for the new sentences. The comprehension questions did not specifically target the resolution of the garden-path structure. In total, six lists were created such that each sentence appeared in each condition, with or without a comprehension question, across lists.
3. The patient met the doctor and the nurse with the white dress showed the chart during the meeting. (Garden-Path)
4. The patient met the doctor to whom the nurse with the white dress showed the chart during the meeting. (Object Relative)
5. The patient met the doctor while the nurse with the white dress showed the chart during the meeting. (Control)

## Working Memory Tasks

Reading Span Automated Reading-Span (Unsworth, Heitz, Schrock \& Engle, 2005) was used in this experiment. Participants were presented with a series of sentences and asked to indicate, via button press, if the sentences make
sense. After each sentence they were then presented with a letter that they must remember. At the end of the sequence, they had to recall the letters in the order of presentation. Their score reflects the total number of letters recalled in the correct order.

Operation Span Automated Operation-Span (Unsworth et al., 2005) was used in this experiment. Operation span is identical to reading span as described above except instead of making sense judgments on sentences, participants had to solve math problems involving multiple operations.
$N$-Back In the $n$-back task, participants were presented with a sequence of single letters and asked to judge if the current letter is the same as the one that occurred $n$ places back in the sequence. For example, in a 4-back task, the third " X " in the following sequence would be a target: X U P X X U U. Lures, which appeared one space before a target ( $n-1$; the second "X") or one space after a target ( $n+1$; the third "U") were also included. Participants in the current experiment performed 2-back and 4-back. Accuracy for four item types (target, non-target, $n-1$ lure and $n+1$ lure) were averaged across $n$ level (2-back and 4-back).

Anti-Saccade In the anti-saccade task, participants performed a letter monitoring task. They were first presented with a flashing cue that appears on either the left or right side of the computer screen. The cue was followed by a letter. The letter was either on the same side of the screen as the cue (pro-saccade) or on the opposite side (antisaccade). Participants had to suppress the impulse to shift their gaze to the cue in order to maximize performance. Accuracy for anti-saccade trials was included in the analysis.

## EEG Recording

Electroencephalographic (EEG) data was acquired using the Electrical Geodesics Inc. (EGI) NetStation 128-channel system. The HyrdoCel Geodesic Sensor Net is an elastic structure containing $\mathrm{Ag} / \mathrm{AgCl}$ electrodes, individually housed underneath a sponge pedestal, which is soaked in a saline solution ( KCl ) and placed carefully over the participant's head. The signal was high-pass filtered online at 0.1 Hz , low-pass filtered at 100 Hz , and notch filtered at 60 Hz . The EEG signal was sampled at 250 Hz . Impedances were kept below $50 \mathrm{~K} \Omega$ where possible and otherwise under $100 \mathrm{~K} \Omega$. Prior to averaging, drift, eye blinks and other movement artifacts were corrected via either the EP Toolkit for MatLab (Dien, 2010). EEG were recorded using CZ as a reference and later re-referenced to the global mean.

## Procedure

After signing a consent form and background questionnaire, the experimenter applied the sensor net. Participants were seated in a sound attenuated booth using a chin rest in order to reduce movement artifacts. EEG data was collected during the sentence processing task. Sentences appeared
word-by-word in a rectangular box in the center of a high resolution computer screen. The rectangular box appeared continuously on the monitor. Each word was presented for 300 ms , followed by a blank of 200 ms . The final word of the sentence was presented with a period sign and was followed by a 5.5 second rest period. $50 \%$ of the test sentences were followed by comprehension questions. The questions were presented in their entirety above the rectangular frame for 2500 ms , followed by a rest period of 3500 ms . Key presses with the right and left index fingers (counterbalanced across subjects) were used to for yes and no responses to the questions. Within the session, the stimuli were broken into 6 runs consisting of 27 sentences and lasting approximately 8 minutes each. The EEG session, including electrode application and removal, lasted approximately 1.5 hours. After electrode removal, participants performed the four working memory assessments (also in a sound attenuated booth). The order of the four working memory tasks was counterbalanced across participants. Completion of the working memory tasks took no more than one hour and, thus, the entire session lasted approximately 2.5 hours.

## Data Analysis

Upon completion of pre-processing, ERPs were computed for each individual in each experimental condition for a 1500 ms interval time-locked to the presentation of the critical verb ("showed" above) relative to a 200 ms prestimulus baseline. The following time windows were considered in the analysis: 500-700 and 700-900. The analyses were performed on midline, dorsal and ventral electrodes. The midline electrodes were divided into anterior (FPZ, FZ, FCZ, CZ) and posterior (CPZ, PZ, POZ, $\mathrm{OZ})$ sections. The dorsal electrodes were grouped by anterior-posterior (AP) location and hemisphere: Left anterior (FP1, AF3, F3, 20, FC3, C3), right anterior (FP2, AF4, F4, 118, FC4, C3), left posterior (CP3, 53, P3, P1, 59, PO7) and right posterior (CP4, 86, P4, P2, 91, PO8). The ventral electrodes were similarly grouped: Left anterior (F7, FT7, FC5, T10, 40), right anterior (F8, FT8, FC6, T11, 109), left posterior (T3, TP7, CP5, 50, P5, T5, P9) and right posterior (T4, TP8, CP6, 101, P6, T6, P10).

The effects of the garden-path/object relatives compared to controls on brain activity were assessed in the dorsal and ventral regions with three way ANOVAs (sentence type $x$ AP $x$ hemisphere) and in the midline electrodes with a twoway ANOVA (sentence type x AP). In addition, the mean amplitude in posterior midline electrodes in the $700-900 \mathrm{~ms}$ time window was used in the correlational analyses of the working memory assessment and behavioral data.

Scores and accuracy data from the four working memory assessments were used in the correlational analysis. First, the correlations between the working memory measures were assessed. Second, the correlations between the WM measures and garden-path/object relative effects in the comprehension accuracy and P600 data were assessed. The sentence type effects were calculated for the comprehension
data by subtracting accuracy for control sentences from that of garden-path/object relatives. Likewise, for the ERP data, the mean amplitude at over posterior midline electrodes during the $700-900 \mathrm{~ms}$ time window for the control sentences was subtracted from that of garden-path/object relative sentences.

## Results

## Behavioral Data

Accuracy was lower for garden-path (79.2\%, S.D. 17.1) and object relative ( $80.6 \%$, S.D. 19.0) sentences than for controls $(84.3 \%, 15.3)$. There was an effect of sentence type for the garden-path/control comparison $(F(1,50)=4.03, p=$ .050 ) but not for the analysis of object relatives ( $p>.2$ ).

## ERP Data

In the $700-900 \mathrm{~ms}$ time window, garden-path sentences elicited increased positivity compared to controls. At midline regions, there was a significant interaction of type and $\mathrm{AP}(F(1,50)=6.08, p<.05)$ such that garden-paths are more positive than controls at posterior sites. Simple comparisons showed a marginal effect in posterior sites $(\mathrm{F}(1,50)=3.61, \mathrm{p}=.06)$. Over dorsal regions, there was a main effect of sentence type $(\mathrm{F}(1,50)=5.39, \mathrm{p}<.05)$ and an interaction of sentence type and AP $(F(1,50)=5.24, p<.05$. Simple comparisons showed a significant effect of type at posterior electrodes $(F(1,50)=10.4, p<.005)$ such that garden-paths elicited greater positivity. There was also an interaction of sentence type and AP over ventral sites $(F(1,50)=4.28, \mathrm{p}<.05)$. Simple comparisons revealed no significant effects. For the object relatives, there was a main effect of sentence type $(\mathrm{F}(1,50)=4.12, \mathrm{p}<.05)$ such that object relatives were more positive.

## Correlations

The correlational analysis of the working memory assessments showed significant correlations between operation span and reading span ( $r=.353, p<.05$ ), operation span and anti-saccade accuracy ( $r=.334 . p<.05$ ), and anti-saccade and $n$-back target accuracy $(r=.349, p<$ .05).

Analysis of the accuracy effects showed a correlation between garden-path effects and reading span ( $r=-.294, p<$ .05). There was also a significant correlation between object relative effects and accuracy for $n+1$ lures in the $n$-back task ( $r=.317, p<.05$ ). A similar pattern was seen in the P600 data. The P600 effect for garden-path sentences correlated positively with operation span score ( $\mathrm{r}=.381, \mathrm{p}<.01$ ) and marginally with reading span score ( $r=.266, p=.06$ ). The P600 effect for object relatives correlated negatively with $n$ back accuracy for $n-1$ lures ( $r=-.352, p<.05$ ) and $n+1$ lures ( $r=-.332, p<.05$ ).

## Discussion

The effects of sentence type (both P600 and accuracy) are consistent with previous findings. The effects for gardenpath sentences were significant and typical in terms of distribution and time course. With respect to object relatives, Gouvea et al. (2010) got no significant effects for object relatives versus controls while the current study found a main effect of sentence type (with no interactions with topographical factors). This difference is likely due to power as the current study had 50 participants while Gouvea et al. (2010) had twenty. Accuracy for garden-path sentences was significantly lower than controls, as in previous studies (Frazier \& Rayner, 1982; Ferreira, Bailey \& Ferraro 2002) but there was no effect for object relatives. Gouvea et al. (2010) with almost the same materials got no effects of sentence type whatsoever in the accuracy data. Though the garden-path effects differ from Gouvea et al. (2010) in this respect, they are consistent with previous studies. The cross-correlations between the working memory measures (specifically the lack of correlation between the complex span tasks and $n$-back) were also consistent with established findings (Kane, Conway, Miura \& Colflesh, 2007; Unsworth, Schrock \& Engle, 2004). The two complex span tasks (reading span and operation span) did correlate significantly with each other which was also expected based on previous findings (Conway et al. 2005). The correlational analyses between the WM and sentence processing effects were, therefore, run on data showing standard effects and not anomalous in any way.

The key finding of the correlational analysis is that, while performance on the complex span tasks (reading span and operation span) does predict garden-path effects, it is $n$-back accuracy that predicts the effect for object relatives. This is seen in both P600 data and accuracy. Though this is a novel finding, both assessments are intuitively related to their respective sentence types.

In garden-path sentences, individuals must maintain the linear sequence of words active in memory while reanalyzing the syntactic structure. The resolution of a garden-path does, therefore, require dividing attention between storage and sentence processing as does the reading span task. The correlation with operation span was positive for the P600 effect, indicating greater effects for individuals with higher operation span. The marginal correlation with reading span was also positive. These findings are consistent with the Early Commitment Model (Friederici et al., 1998) which argues that high span individuals, when faced with a syntactic ambiguity, commit early to one structure and proceed accordingly rather than entertaining multiple possibilities. The consequence, in the case of a garden-path, is that they then must execute the costly reanalysis process (Friederici et al., 1998). Reading span score correlated with the garden-path effect on comprehension accuracy, similarly predicting greater effects for high span participants. Taken together, these results affirm complex span performance as a predictor online and offline garden-path effects.

In the object relative sentences, the relative pronoun must be maintained active and eventually matched to the appropriate thematic position. This involves assessing each new word in the sentence sequence to determine if it is the relevant predicate. In this way, the process resembles $n$-back in which each new letter must be checked against the letter that is $n$ places back in the sequence. The correlation was negative for the P600 effect suggesting that increased $n$ back accuracy is associated with either (1) reduced sensitivity to structural relationships or (2) increased efficiency in that processing such that complex syntactic structure is less disruptive. The positive correlation between the comprehension accuracy effects accuracy for $n+1$ (indicating reduced effects of syntactic complexity among individuals with high $n+1$ lure accuracy) does not enable a distinction between the two accounts, as both would predict reduced differences between object relative and control sentences. While this is a question for future research, the finding remains that working memory mechanisms reflected in $n$-back are recruited during the resolution of filler-gap dependencies.

The lack of a relationship between n-back accuracy and garden-path effects is somewhat surprising given the findings of Novick et al. (in press). This could be due to methodological differences (for example, Novick et al. used self-paced reading). It could also indicate, in addition to increasing n-back accuracy as a result of training, participants gained some strategic skills that facilitated task performance.

In contrast to the n-back and complex span tasks, antisaccade also showed no relationship with the online and offline sentence type effects. Mendelsohn (2002) also failed to find a relationship between anti-saccade and garden-path effects but he did succeed in with a verbal sorting task that also measured the ability to inhibit automatic responses. It is possible that anti-saccade is a poor predictor of language performance.

The finding that separate working memory measures correlate with P600 effects for the two sentence types leads to the speculation that the late positive components elicited by these two processes may be categorically distinct. The notion of distinct late positive components is not new (see Kutas, van Petten, \& Kluender 2006 for review) but findings have been mixed. Friederici, Hahne and Saddy (2002) found differences in time course and topographical distribution in the P600s effects of grammaticality and syntactic complexity. Kaan and Swaab (2003), however, found no difference in P600 effects of grammaticality and dispreferred structure. The current results, that late positivities elicited by the resolution of temporary syntactic ambiguity and syntactic complexity are underpinned by distinct working memory mechanisms provides a fresh perspective on this question. In addition to the correlational effects, the two effects did show topographical differences such that the garden-path sentences elicited a late positivity with a posterior distribution while that of the object relatives was not limited to posterior sites. While this difference is
slight, due to the relatively coarse topographical analyses it is not possible "to rule out the possibility that the P600 is the consequence of a disparate set of processes that happen to elicit topographically similar responses" (Gouvea et al. 2010, p. 177). While the proposal is speculative at this time, consideration of the relationship of working memory mechanisms to these components in future research will likely provide valuable insights.

In conclusion, the results of the current study suggest a more complex relationship between working memory mechanisms and online sentence processing than has previously been considered, such that different working memory mechanisms support the resolution of different types of difficult structures. Furthermore, the findings provide evidence for functionally distinct late positive ERP components. Future research on the interaction of working memory and language must include a variety of working memory assessments in order to increase understanding of the cognitive underpinnings of sentence processing.

#### Abstract

Questionnaires to assess goal orientation are widely used. However, recent research indicates some shortcomings. Most significantly, questionnaire data are unable to capture developments and changes in students' goal orientation during the learning process. Therefore, it seems appropriate to supplement questionnaire data with online measures that directly tackle students' behavior. We analyzed data of 57 students who participated in a study with the Cognitive Tutor Geometry. Specifically, we analyzed relationships between questionnaire data on goal orientation, the use of hints and a glossary while working with the Tutor as potential online indicators for goal orientation, and learning outcomes. Results of our analyses show that our potential online indicators systematically differ from questionnaire data of goal orientation, yet have high predictive power for learning outcomes. Therefore, online indicators may be used to supplement questionnaire data of goal orientation and/or to further optimize adaptation in intelligent tutoring systems.

Keywords: Motivation, Goal Orientation, Self-regulated Learning, Intelligent Tutoring Systems

## Introduction

Motivation and self-regulated learning are inseparably intertwined. One specifically important and wellinvestigated area of motivation is that of achievement goal theory (Pintrich, 2000). Initially, the theory's basic distinction was between mastery goal and performance goal orientation (e.g., Dweck, 1986). Mastery goal orientation refers to the goal of reaching understanding and mastery in a field. Performance goal orientation refers to the goal to perform better in comparison to others (Elliot \& McGregor, 2001). Mastery goal oriented students have often been found to show more effort and persistence during learning and, as a result, better learning outcomes compared to performance goal oriented students (Urdan, 1997). Elliot and McGregor (2001) introduced "valence" as an additional dimension to describe goal orientation; that is, approaching success versus avoiding failure. This additional distinction leads to four aspects of goal orientations: mastery-
approach, mastery-avoidance, performance-approach, and performance-avoidance goal orientation.

Initially, goal orientation was regarded as a relatively stable personality trait (e.g., Dweck \& Leggett, 1988). Later studies, however, put an emphasis on the influence of situational variables and task characteristics on goal orientation (e.g., Butler, 1993). Some researchers pointed out as early as in the 90s, that students may not clearly belong to one or the other group of learners in classroom situations (i.e., performance versus mastery goal oriented or approach versus avoidance oriented). In contrast, it is highly plausible that students show both mastery and performance goal orientations at the same time, albeit at different levels. Also, there may be variations in the students' predominant goal orientation during learning phases depending on the task at hand and level of expertise (e.g., Meece \& Holt, 1993). In analogy to the state-trait concept of anxiety first introduced by Cattell and Scheier (1961), recent research points to the reciprocal influences of state and trait measures in the field of goal orientation (Chen, Gully, Whiteman, \& Kilcullen, 2000).

Typically, goal orientation is measured via self-report questionnaires. This approach is rooted in the traditional view of goal orientation as a personality trait and can be considered to measure habitual goal orientation. Despite their long tradition and proven utility in the field, interpretation of questionnaire data of achievement goal orientation can be problematic. More specifically, ambiguity between different questionnaires with respect to their conceptual overlap often makes it difficult to compare findings from different studies (Hulleman, Schrager, Bodmann, \& Harackiewicz, 2010). Also, data measured before or after a learning phase using self-report questionnaires lack the ability to capture decisions and states of the learners as they arise from circumstances in the learning environment and develop during the learning process (Richardson, 2004). Consequently, recent research calls for measurement of achievement goals not only by questionnaires but also by online measures to grasp
moment-to-moment actions and thereby the state aspect of goal orientation at a fine-grained level. One way to track goal orientation online is through traces in online learning environments (e.g., Zhou \& Winne, 2012).

In an attempt to investigate potential relationships between online and offline measures for goal orientation and their predictive power for learning outcomes, Zhou and Winne (2012) enriched an instructional text presented online with a set of hyperlinks and tags referring to the four different goal orientations (mastery-approach, masteryavoidance, performance-approach, performance-avoidance). Hyperlinks to be selected were presented next to the text (e.g., "take a practice test on this"; performance-approach). Within the text students could use highlighting to structure the text and label highlights (e.g., "I want to learn more about this"; mastery-approach; Zhou \& Winne, 2012, p.415). Selection of hyperlinks and tags were interpreted as online traces for the respective goal orientation. Zhou and Winne (2012) found that goal orientation as assessed by questionnaire data do not correlate with goal orientation as assessed by the traces captured online during the learning process. These findings are in line with earlier research indicating that self-reported measures of study tactics do hardly correspond to respective online measures collected during learning (Jamieson-Noel \& Winne, 2003). The differences between online measures and questionnaire data for goal orientation could be partly seen as an indication of state-trait differences in goal orientation. Additionally, Zhou and Winne found an advantage of online traces over questionnaire data to predict learning outcomes, which raises the following question: Are online measures "better" than questionnaire data to assess goal orientation for educational purposes?
Another potential advantage of measuring goal orientation online is that it is less obtrusive compared to explicitly asking questions upon which students have to reflect. For example, intelligent tutoring systems could use tracking data that are collected during the learning process to estimate students' goal orientation at any given point in the learning phase and adapt their responses to the students' motivation and attitudes (e.g., Arroyo, Cooper, Burleson, \& Woolf, 2010). Such adaptation could make intelligent tutoring systems even more effective (for an overview of recent advances in intelligent tutoring systems, see Graesser, Conley, \& Olney, 2012).

Cognitive Tutors and other intelligent tutoring systems have proven to be very effective in supporting individual students' learning in a variety of domains such as mathematics or genetics (for an overview, see Koedinger \& Corbett, 2006) and are widely used in schools across the United States as part of the regular mathematics curriculum. Based on an online assessment of students' learning, Cognitive Tutors provide individualized support for guided learning by doing. Specifically, the Tutor selects appropriate problems, gives just-in-time feedback, and provides hints. Additionally, students can use a glossary to look up definitions and explanations. Hints provide direct
instructions for the next step a student has to determine; they are context sensitive and therefore adaptive to the situation. The glossary offers definitions and explanations for principles to be understood and learned; it is context insensitive and therefore not adaptive to the specific situation (Koedinger \& Aleven, 2007). In light of achievement goal theory one could interpret the use of hints as performance-goal oriented and the use of a glossary as mastery-goal oriented behavior. Although hints can be used in a mastery-goal oriented way, specifically if students reflect upon them, they are often not used in this way. Their adaptive nature to the problem at hand suggests their use in order to immediately solve a problem rather than to deeply reflect and understand the underlying principle. Sometimes students even abuse hints in order to proceed quickly through the learning environment, a behavior referred to as "gaming-the-system" (Baker, Corbett, Koedinger, \& Wagner, 2004). The glossary, in contrast, is not directly related to a to-be-determined problem step at hand. Therefore, we assume that it is consulted whenever students are interested in information that goes beyond the immediate problem-solving step. We claim that this behavior may be related to mastery-goal orientation as, in contrast to hint use, it does not primarily improve immediate performance in the learning environment but understanding. Using online tracking data of hint and glossary use could therefore be an unobtrusive and more proximal, "state-like" indication of goal orientation compared to the more reflected and "trait-like" measures gained by questionnaires. In addition, the data are tracked automatically, not taking up additional resources on either the side of the program or the learner.

## The Present Study

Attempting to test if the findings of Zhou and Winne (2012) can be conceptually replicated in a different learning environment, and if hint and glossary use could be valid behavioral indicators for goal orientation, we reanalyzed a data set from an earlier study where students learned geometry principles using the Cognitive Tutor Geometry ${ }^{\circledR}$ (Salden, Aleven, Renkl, \& Schwonke, 2009). First, we tested if self-reported goal orientations as assessed by a questionnaire correspond to the respective online measures.

Second, we assumed, as in the study by Zhou and Winne (2012), a positive relationship of glossary use and learning outcomes (i.e., understanding) and a negative relationship of hint use and learning outcomes. In our study, the learning outcome tests (i.e., posttests) - presented immediately after the learning phase and one week later - measured not so much knowledge of routines but application and understanding of the principles learned in the Cognitive Tutor. Our expectations were also in line with earlier studies showing better learning outcomes for masteryoriented students than for performance-oriented students (for an overview, see Urdan, 1997). In addition, other studies on the Cognitive Tutor found negative relations between hint use and learning outcomes (e.g., Aleven \&

Koedinger, 2001).
Third, while Zhou and Winne (2012) did not find a significant relationship of questionnaire data with performance on posttest, theoretical considerations as well as earlier studies led to the expectation that such a relationship may exist (for an overview, see Urdan, 1997). We therefore addressed the ("two-sided") research question (as did Zhou and Winne) if online and questionnaire data alike relate to learning outcomes.
Fourth, we checked if behavioral indicators for mastery as well as performance goal orientation (i.e., glossary and hint use, respectively) are stronger predictors of learning outcomes than respective questionnaire data.
To even out potential influences of prior knowledge on posttest performance we controlled for math grade (the strongest predictor of learning outcomes in this study) in all calculations involving posttest performance. More specifically, we addressed the following research questions:
(RQ1) Do self-reported goal orientations from the questionnaire correlate with respective behavioral indicators (i.e., hint use with performance goal orientation and glossary use with mastery goal orientation)?
(RQ2) Is there a positive relationship between glossary use and learning outcomes and a negative relationship between hint use and learning outcomes?
(RQ3) What is the relationship between questionnaire data of goal orientation and learning outcomes?
(RQ4) Are behavioral indicators for goal orientation better predictors of learning outcomes than the respective questionnaire data (i.e., are glossary and hint use better predictors for learning outcomes than selfreport measures)?

## Method

## Sample and Design

Participants in our study were 57 students (19 in $9^{\text {th }}$ grade and 38 in $10^{\text {th }}$ grade; age: $M=15.63, S D=.84$ ) from a German "Realschule", which is equivalent to an American high school. The original study comprised three conditions to which participants were randomly assigned resulting in an equal distribution of 19 students per condition. In two conditions students were provided with worked examples to solve the mathematical problems. Worked examples were either faded out according to a fixed procedure (fixed fading condition) or according to the student's individual skill level (adaptive fading condition). The third condition served as a control and did not receive any worked examples (problem condition; Salden et al., 2009). For the purpose of the reanalysis of our data for this paper, that is to investigate potential relationships between online and questionnaire measures of goal orientation and learning outcome, we examined all 57 participants as one group. To preclude potential influences of conditions on the observed
relationships, however, we routinely calculated all analyses for the separate conditions and checked for potential significant differences. However, no such differences were found.

Learning Environment - The Cognitive Tutor

Figure 1. Screenshot of the Cognitive Tutor Geometry®
Cognitive Tutors provide adaptive feedback and model students' skill acquisition based on two algorithms: model tracing and knowledge tracing (Koedinger \& Corbett, 2006). Simulating the problem solving process enables the Tutor, for example, to provide specific hints for a problem situation. Also, all steps (i.e., all actions a student takes while working with the program) are tracked in a logfile. This data are used online for adaptation. For the purpose of this paper we analyzed part of this logfile data, specifically the amount of hint and glossary use (percentage in relation to all activities of the student in the learning environment), and correlated them with offline data of a goal orientation questionnaire and posttest scores.

Learning Materials During the learning phase with the Cognitive Tutor we asked students to work on fifteen problems in a Cognitive Tutor lesson on geometry, covering four geometry principles. The first eight problems required the application of only one geometry principle. The last seven problems combined different principles and were therefore more complex. Before the learning phase we provided students with instructions about the different tools in the Tutor. More specifically, after giving an overview of the learning environment, hints were introduced as an assistance tool to use when "having trouble solving a task or when reaching an impasse. The glossary was introduced as an assistance tool to use if "you are unsure when to use a certain mathematical principle or which is the corresponding formula". These instructions were routinely used in several of our studies involving the Cognitive Tutor Geometry (e.g., Salden et al., 2009; Schwonke et al., 2012).

## Instruments

Pretest The pretest was integrated in the Cognitive Tutor and consisted of four geometry problems related to the lessons taught later during the learning phase with the program. All Cognitive Tutor help facilities (e.g., hints) were disabled during the pretest. On average students needed 21 minutes to complete the pretest. Mathematics grade was a significantly stronger predictor of posttest performance than the pretest. Therefore, we included mathematics grade and not pretest scores in all analyses referring to posttest performance.
Goal Orientation Questionnaire Before solving the posttest, students were asked to answer 8 items concerning their learning goal orientation while working with the program on a scale from 1 to 6 . Items were adapted from Elliot and McGregor (2001) and reflected mastery-approach and performance-approach goal orientations only.

Posttest A posttest consisting of the same problems as the pretest was implemented in the learning environment. Additionally, all participants were asked to complete a paper-pencil test immediately after working with the Tutor and one week later (delayed posttest). Immediate and delayed posttests were identical. On average students needed 31 minutes to complete the posttest and 21 minutes to complete the delayed posttest.

## Procedure

The first experimental session lasted 90 minutes on average and was divided into three parts: pretest and introduction, learning phase in the Cognitive Tutor, and questionnaire on goal orientation as well as posttest. First, students' general prior knowledge was assessed by their mathematics grade together with additional demographic data such as age and gender. Then they received a brief introduction on how to use the Cognitive Tutor followed by a short pretest implemented in the Tutor measuring their prior knowledge. After completing this pretest, students read an instructional text providing information about the rules and principles that were later addressed in the Cognitive Tutor. In the tutoring part, students worked with their respective version of the Cognitive Tutor. This learning phase was followed by a questionnaire measuring goal orientation with self-report measures and a knowledge test. The students worked again on the knowledge test in a second session (one week later).

## Results and Discussion

To test if questionnaire data for goal orientation align with respective online measures (RQ1) we determined Pearson's correlations between assumed behavioral indicators for goal orientation (i.e., glossary use for mastery goal orientation and hint use for performance goal orientation) and self-report questionnaire data. There was no significant relationship between glossary use and mastery goal orientation ( $r=.13, \mathrm{p}=.339$ ) or hint use and performance goal orientation ( $r=-.14, \mathrm{p}=.298$ ). These
findings are in line with Zhou and Winne (2012). The missing relationship between behavioral data collected online and questionnaire data collected after the learning phase may indicate that the two measures capture different constructs. One theoretically plausible interpretation is, that both the online measures collected by Zhou and Winne and our behavioral data, that is, hint and glossary use may reflect state goal orientation while questionnaire data may capture the trait aspect of goal orientation. However, one could argue that state and trait measures of other psychological constructs are generally correlated which raises the question of construct validity of the online measures. Therefore, more data is needed to decide if online measures and specifically behavioral data as the ones used in our study can be validly used as indicators for (state) goal orientation, if they differ systematically from the assumed trait measures of questionnaire data, and how both state and trait mutually affect each other. However, our data provides some initial evidence for the validity of hint and glossary use as measures for goal orientation:

First, we determined the correlation between glossary and hint use and found a very strong negative correlation: $r=-$ $.84, \mathrm{p}<.001$. This indicates that students had a relatively clear preference for either hints or glossary which is in line with the assumption that the type of tool use indicates whether the students were primarily concerned about solving the problems (i.e., performance orientation) or understanding the principles (i.e., mastery orientation) while working on the Cognitive Tutor lessons.

Second, we tested if glossary use is positively related and hint use is negatively related to learning outcomes (RQ2) which should be the case if these online measures can be associated with goal orientation. We determined partial correlations between glossary and hint use and the immediate and delayed posttest performance, controlling for prior knowledge. Results indicate a significant positive relationship for glossary use and immediate ( $r=.37, \mathrm{p}=$ .008) posttest score. Correlation of glossary use and the delayed posttest score slightly failed to reach statistical significance ( $r=.28, \mathrm{p}=.050$ ). There was a significant negative relationship between hint use and performance on the immediate ( $r=-.48, \mathrm{p}<.001$ ) as well as the delayed ( $r=$ $-.36, \mathrm{p}=.009$ ) posttest score. These relations can be seen as evidence that glossary and hint use may indeed be valid indicators for goal orientation. This may specifically be true as our posttests measured deep understanding of the principles learned in the Cognitive Tutor and not so much knowledge of routines. In a test measuring the later, differences between primarily performance versus mastery goal oriented students may not be as pronounced. Additionally, interpreting hint use as a measure for performance goal orientation may provide one explanation for the repeatedly found negative relations between hint use in the Cognitive Tutor and performance on posttest.

We further tested the relationship between self-reported mastery and performance goal orientation (i.e., questionnaire data) and learning outcomes (RQ3). We
found a significant positive relation between mastery goal orientation and delayed posttest scores ( $r=.41, \mathrm{p}=.003$ ). The relationship between mastery goal orientation and immediate posttest scores ( $r=.25, \mathrm{p}=.076$ ) slightly failed to reach statistical significance. There was also no significant relationship between self-reported performance goal orientation and immediate posttest scores ( $r=-.21, \mathrm{p}=$ .144); the relationship between performance goal orientation and delayed posttest scores ( $r=-.24, \mathrm{p}=.086$ ) failed to reach statistical significance. These results are, at least partly, in contrast to Zhou and Winne (2012) who observed no statistically significant correlations between self-reported goal orientations and posttest performance. However, the results are in line with theoretical assumptions and earlier studies using questionnaire data on goal orientation and further corroborate the aforementioned relation between goal orientation and learning outcomes.
To test if online measures or their respective questionnaire data are better predictors for learning outcomes (RQ4) we calculated separate stepwise linear regression analyses, one for mastery goal orientation (glossary use and respective questionnaire data) and one for performance goal orientation (hint use and respective questionnaire data) as potential predictors for immediate and delayed posttest performance. Concerning the predictive power of mastery goal orientation (glossary use vs. questionnaire data) for posttest scores results are mixed: While glossary use was the sole best predictor for immediate posttest scores, questionnaire data was the best predictor for delayed posttest scores (Table 1). With regard to the predictive power of performance goal orientation (hint use vs. questionnaire data) for posttest scores, there was a clear advantage of the behavioral data: Hint use was the sole best predictor for both immediate and delayed posttest scores (Table 2). Taken together, our results indicate that specifically for mastery goal orientation questionnaire data might yield predictive power beyond behavioral online data, at least for long-term learning effects. These results are not fully in line with Zhou and Winne (2012) who consistently found online measures to be the stronger predictors of learning outcomes in regression models. There might be methodological explanations for the differences between the two studies: We used a different questionnaire as basis for our goal orientation items and measured only two and not four aspects of goal orientation. Also, the questionnaire used by Zhou and Winne did not relate significantly to learning outcome measures. In addition, utilizing hint and glossary use as indicators for goal orientation might be a little more "indirect" as compared to the online data collected by Zhou and Winne (2012). For example, hint use might also be elicited by errors made when trying to determine solution steps, that is, it may be related to rather poor performance in the learning environment. However, the very strong negative correlation of $r=-.84$ between hint and glossary use cannot be explained by these errors (partial correlation controlling for errors is still highly significant with $r=-.73$,
$p<.001$ ).
Table 1: Glossary Use and Mastery Goal Orientation as Predictors for Learning Outcomes

Taken together, both behavioral online and offline questionnaire data provide us with important insights for understanding learners' goal orientation and can be used to supplement rather than to replace each other for the sake of scientific advancement. Given the high predictive value of behavioral online data, however, their use should be considered for educational purposes in classrooms and specifically in online learning environments, where an unobtrusive and efficient collection of goal orientation data could improve adaptation in intelligent tutoring systems and thereby foster the learning process. In addition, one should keep in mind that self-report measures of characteristics such as goal orientation are potentially subject to a social desirability bias which could be circumvented with (indirect) online measures.

Can help seeking behavior in intelligent tutoring systems be used as online measure for goal orientation? Even
though we cannot answer this question based on our data conclusively, our results provide a first and promising indication that online behavior in intelligent tutoring systems provides an unobtrusive and efficient additional or even alternative measure to questionnaire data to assess goal orientation in educational settings.

#### Abstract

Semantic interference in word retrieval has been observed for both well-learned and ad hoc inter-item relations. We tested whether such semantic interference extends to the blocked cyclic naming of racially homogeneous vs. heterogeneous faces. No information except arbitrarily assigned names was provided for novel faces. Yet we observed interference in naming individuals in homogeneous groups. Moreover, consistent with other findings in the social domain, interference occurred for other-race but not for own-race faces. Because this interference effect does not require a rich knowledge base about individuals, it is consistent with the view that interference arises in adjustments to the strength of conceptual-lexical links rather than in knowledge structures themselves. Evidence of modulation by target race further suggests that interference effects may provide an effective tool for exploration of social categorization processes.

Keywords: Semantic interference; language production; blocked cyclic naming; social categorization; intergroup bias

## Introduction

This paper presents an initial investigation of how basic memory retrieval and language production processes are affected by social context. When people name objects, they often exhibit semantic interference in which retrieving a target word from memory disrupts retrieval of words that belong to the same semantic category (e.g., Damian, Viglocco \& Levelt, 2001). In the current research, we examined whether similar interference effects occur when naming faces of members from social categories, specifically, racial groups. We further investigated whether people exhibit a 'name retrieval bias', such that there is greater interference when naming other-race compared to own-race faces.

## Semantic Interference in Language Production

Semantic interference highlights the competitive nature of word selection in language production. In the blockedcyclic naming paradigm, for example, participants repeatedly name small sets of pictures (e.g., four pictures each named individually four times). The pictures are either presented in homogenous blocks in which they share a common semantic relation, or in heterogeneous blocks in which they do not have identifiable semantic links. Naming times are slower in homogeneous than heterogeneous blocks, and the level of interference often increases over cycles (e.g., Damian et al., 2001; Schnur et al., 2009). Semantic interference occurs in this and similar paradigms because retrieving a word co-activates semantically related words, which compete with and slow selection of the target word. Further, retrieving a word primes its subsequent retrieval, making it a stronger competitor when later naming related words (Howard, Nickels, Coltheart \& Cole-Virtue, 2006). The change in lexical accessibility is long lasting, suggesting that a learning mechanism that damps accessibility of competitors while strengthening the current item, rather than short-term modulation of activation, is at the core of semantic interference (Oppenheim, Dell \& Schwartz, 2010; see Navarrete, DelPrato \& Mahon, 2012). fMRI studies have localized lexical selection to left inferior frontal gyrus [LIFG] (believed to be involved in competition resolution) and linked areas of temporal cortex (Schnur et al., 2009).

Traditionally, semantic interference experiments have investigated how shared membership in fixed taxonomic categories (e.g., animals, vegetables, minerals) generates interference. In these cases, items share both category memberships and overlapping semantic features (e.g., legs, heads, locomotion). However, recent research has also shown interference for items linked by a semantic theme
(e.g., garden links slug, gardener and rake; see Abdel Rahman \& Melinger, 2007), as well as for items that are linked as members of an ad hoc category. Abdel Rahman and Melinger (2011) had participants complete a cyclicblocked naming task with pictures that had no obvious semantic relation to one another (e.g., stool, knife, bucket, river), but that could be combined as members of an ad hoc category (e.g., "things present on a fishing trip"). No interference was found when participants were unaware of the ad hoc category; however, interference (longer naming latencies) arose when participants were informed about the category. These findings demonstrate the highly dynamic nature of the semantic system, such that items without fixed shared semantic features nevertheless rapidly become associated (i.e., exhibit shared activation and competition) when linked by a thematic context.

## Effects of Social Categories

Social categories (e.g., racial group memberships) function in many ways like other categories. People tend, for example, to exaggerate within group similarities and between group differences for both social and non-social categories (e.g., Levin \& Angelone, 2002; Tajfel \& Wilkes, 1963). As such, by virtue of their category membership, individuals are assumed to possess common features, and are often stereotyped accordingly (e.g., Kunda \& Spencer, 2003). Further, the effects of social categories often emerge rapidly and automatically (e.g., Devine, 1989). For example, ERP studies have observed category-based differences in neural signals associated with early visual processing of different race faces (Ito \& Bartholow, 2009). In these studies, white participants show heightened P100 and N170 responses (which have been linked to early face processing) when viewing White versus Black faces (e.g., Ito \& Urland, 2003; Cunningham, Van Bavel, Arbuckle, Packer \& Waggoner, 2012). The robust influence of social categories extends to a wide range of cognitive and affective processes, ultimately shaping behaviors including affiliation, cooperation and conflict (Turner, Hogg, Oakes, Reicher \& Wetherell, 1987).

Prior research has also shown effects of social categories on language use, such that people strategically use language to enhance ingroups and derogate outgroups. In a phenomenon known as the 'linguistic intergroup bias', people tend to describe positive ingroup and negative outgroup behaviors more abstractly than they describe negative ingroup and positive outgroup behaviors (Maass, 1999; Maass, Salvi, Arcuri \& Semin, 1989). The use of relatively abstract words (e.g., adjectives - helpful, aggressive) to communicate "our" desirable and "their" undesirable actions implies that these are enduring and global characteristics. In contrast, using relatively concrete words (e.g., action verbs - help, hit) to communicate our undesirable and their desirable actions conveys that these behaviors are situationally-specific and transient.

In the current research, we investigated whether social categories affect basic language production processes under
controlled experimental conditions. We did this in the domain of face naming. Specifically, we asked whether shared social categories induce semantic interference effects during person (face) naming. We had participants learn the names of 16 novel faces belonging to four different racial groups (four faces in each). They then completed a blocked-cyclic naming task with these faces. In homogenous blocks, participants cycled through naming four faces that all belonged to the same racial group; in heterogeneous blocks, participants cycled through naming four faces that each belonged to a different racial group.

In contrast to common objects, faces are processed through partly specialized cortical networks, including fusiform gyrus. In addition, because person names are arbitrary, their retrieval from face configurations may be more difficult than object naming (e.g., Valentine, Brennen \& Brédart, 1996; see also Griffin, 2010). However, given that social categories exert robust effects on a wide range of psychological processes and function similarly to non-social categories, we expected to observe semantic interference in face naming. Due to their common category membership (and overlapping visual and possibly semantic features e.g., stereotypes), retrieving the name of one group member should increase co-activation of the names of other members, which will compete with and slow selection of the target name.

## Social Categorization Biases

Social categories are not entirely analogous to non-social categories. In particular, people often exhibit intergroup biases, such that members of ingroups and outgroups are processed differently (e.g., the linguistic intergroup bias described above). These biases come in different forms, but many are reducible to the observation that outgroup members tend to be processed more categorically than ingroup members. Whereas ingroup members are typically individuated and treated as distinct entities, outgroup members are often treated as relatively interchangeable exemplars of their group (Brewer, 1988; Fiske \& Neuberg, 1990).

One such bias emerges in facial recognition. The 'other race effect' (or 'own race bias') refers to the well-replicated finding that people are generally better at recognizing members of their own versus other racial groups (e.g., in incidental recognition paradigms). Although perceptual expertise is a contributor (i.e., people typically have more experience processing own than other race faces), recent research suggests that this bias is largely a categorization driven effect (Hugenberg, Young, Bernstein \& Sacco, 2010; Van Bavel, Packer \& Cunningham, 2011). According to Hugenberg et al.'s (2010) Categorization-Individuation Model, for example, classifying faces as exemplars of a category focuses attention on category-diagnostic (shared) features, which reduces subsequent ability to discriminate among category members. In contrast, when faces are not categorized but instead individuated, attention is focused on distinct features, enhancing the ability to discriminate them
later. Critically, intergroup biases in facial recognition emerge because outgroup faces tend to activate their categories more strongly than ingroup faces (Hugenberg et al., 2010; Levin, 1996, 2000; Stroessner, 1996).

We anticipated that a similar bias might also occur in name production. If outgroup faces invoke categorization more strongly than ingroup faces, semantic interference should be stronger for outgroup than ingroup faces. Retrieving an outgroup member's name should co-activate the names of other outgroup members. In contrast, because ingroup members tend to be individuated, retrieving the name of an ingroup member should not increase activation of other ingroup members' names, at least not to the same extent. If so, homogenous ingroup naming may not differ from heterogeneous condition naming.

To summarize, we predicted semantic interference during naming of faces when they are racially grouped. Based on ingroup/outgroup differences in social-cognitive processing, we further hypothesized that such interference would be stronger for other-race than own-race faces.

## Methods

## Participants

Eighteen introductory psychology students at Lehigh University participated for partial course credit. This sample size provides good power because the repeated measures design collects many observations from each participant. The average age was 19.22 years, and there were 9 males and 8 females (one did not report gender). All participants spoke English as a first language, and reported European ethnic origins during pre-testing. A racially homogeneous sample was important in this case for testing hypothesized ingroup/outgroup differences. During testing, one participant indicated a mixed ethnic background (European and Asian). Analyses including vs. excluding this participant yielded identical findings; we therefore report analyses including all participants.

## Design

We used a 2 (Context: heterogeneous, homogeneous) X 4 (Race: Asian, Black, Middle-Eastern, White) X 4 Replication (1, 2, 3, 4) within subjects design.

## Procedure

Learning Phase. After familiarization with the picture naming set-up, participants first learned arbitrarily assigned names for 16 male faces. Four faces belonged to each of four racial groups: Asian, Black, Middle Eastern and White. All names were single syllable, of European origin, and common in the North American context. Each name also started with a different letter (e.g., Bill, Chris, Dan). The names were assigned to faces in two different randomizations, which were counter-balanced across participants. Participants initially viewed the 16 face/name pairings in a randomized $4 \times 4$ matrix on the computer
screen for 2 minutes, and were instructed to try to memorize as many as they could. Each face/name was then presented twice for two seconds in random order, with participants instructed to read the names aloud.
Testing Phase. The testing phase consisted of four replications, each containing eight sets of 16 trials. Each set comprised four faces repeated semi-randomly (for each participant) across four repetition cycles. Four of the sets were racially homogenous, four were racially heterogeneous, and the order of sets within each replication was randomly determined for each participant. In total, participants completed 512 trials.

At the beginning of each set, participants were shown four faces along with their names and were asked to read each name aloud. Then, to confirm that they remembered the names, they were presented with each face individually (in random order) and were asked to provide the name (which appeared on the screen upon vocalization to confirm or correct participants' responses). This was repeated until participants named all four faces correctly. In most cases, no repetitions were required.

Each trial began with a fixation cue $\left(^{*}\right)$ displayed for 100 -milliseconds (ms), along with a warning sound, followed by a face. Naming latencies were measured with a voice key. The face remained on the screen until a name was produced, or for a maximum of 1500 ms . After naming, the face disappeared and was followed by a blank screen for 1500 ms . Participants were instructed to speak clearly, and to name the faces as quickly and accurately as possible.

## Results

Following standard practice for this type of design, the heterogeneous context responses in each replication were sorted to match the corresponding homogeneous groupings. We then conducted a 2 (Context: heterogeneous, homogeneous) X 4 (Race: Asian, Black, Middle-Eastern, White) X 4 Replication (1, 2, 3, 4) analysis on the speed with which participants named faces. Specifically, we implemented a multi-level model in which trials were nested within participants using the PROC MIXED procedure in SAS. Multi-level models allow for more accurate estimates of effects by accounting for interdependence among trials within participants. We removed error trials on which participants named a face incorrectly (1.7\%), the voice key was triggered by something other than a name (e.g., a cough or stutter, $0.9 \%$ ) or participants did not respond within the time window (1.0\%). We also removed trials with RTs < 200 ms .

Extending prior research on semantic interference effects in blocked cyclic naming paradigms, there was a significant main effect of Context, $\mathrm{F}(1,17)=20.05, \mathrm{p}<.001$. Overall, participants were slower to name faces in racially homogeneous ( $\mathrm{M}=701, \mathrm{SD}=179$ ) versus heterogeneous contexts $(M=671, S D=160)$. Critically, however, the effect of Context was modulated by Race [Context x Race interaction: $\mathrm{F}(3,51)=3.56, \mathrm{p}<.05$ ]. As shown in Figure 1 A , naming faces in homogenous (vs. heterogeneous)
contexts produced statistically significant interference effects for Asian ( $\mathrm{p}<.05$ ), Black and Middle-Eastern faces (ps <.01). However, there was no evidence of an effect for White faces ( $\mathrm{p}>.30$ ). The Context X Race interaction was not moderated by Replication ( $\mathrm{F}(9,107$ ) $=0.85, \mathrm{p}>.50$ ), indicating that the pattern was stable throughout the experiment.

Although they were relatively rare, examination of naming errors showed that they exhibited the same pattern as the reaction time data. Specifically, naming errors were more frequent in homogeneous than heterogeneous contexts for faces of all races except White (see Figure 1B)

## Discussion

Our study shows several novel findings. First, we observed semantic interference in proper name retrieval in blocked cyclic naming. To our knowledge, this has not been reported previously. Second, the basis of the interference was racial grouping of the faces, extending previous reports of semantic interference among taxonomic, thematic or ad hoc associates to social categories instantiated by facial features. In this domain, the basis for interference in name retrieval is quite slender, comprising modulation of the mapping from face to name by the mere knowledge that the named individuals belong to a distinct racial group. Third, the effect was present for three "other race" groups, but was absent for the "own race" of the white participants. This is interesting both as a new manifestation of the own race bias (i.e., a name retrieval bias), and as evidence that semantic interference does not arise under all conditions. The set of white faces could certainly be construed as a category in the context of this experiment, and yet we observed no evidence of interference. The error data even suggest that naming of homogeneous white faces may have been facilitated.

Previous researchers of semantic interference have taken pains to show that the effect is not an artifact of visual similarity (e.g., Damian et al., 2001). This concern also arises in the case of face naming, because racially homogeneous faces might be more difficult to discriminate. However, the data do not support this possibility. The visual similarity explanation would predict a context effect for all of the groups (not the case), and greater difficulty in naming outgroup than ingroup members in heterogeneous contexts (also not the case). Thus our findings are clearly driven by categorization of outgroup faces and not by a perceptual similarity confound.

One way to interpret our findings (and link them to previous findings with ad hoc categories) is that an autonomous face recognition process is followed by categorically constrained name retrieval. Against this, however, is the finding of Van Bavel et al. (2011) that social categories other than race affect the functioning of the fusiform face area and that nonracial group affiliations can even trump visually salient characteristics such as race. If context dynamically modulates the functioning of face processing areas, it may be more appropriate to conceive of

Figure 1: Response Times and Error Rates as a Function of Race and Heterogeneous or Homogeneous Context. (RTs and their standard errors (pooled) are estimated from the multi-level model).

## A. Response Times

B. Face Naming Errors

semantic interference in name retrieval as engaging relatively extensive neural networks.

To our knowledge, the present study is the first to demonstrate interference in name retrieval for faces from different racial categories. Research currently under way in our research group attempts to shed light on the basis of this effect by teasing apart whether common category membership, overlapping semantic features, or even shared visual features contribute to the effect. Another question we may examine in future is the cultural domain of the names. In this experiment, the names were all European in origin and they may have been perceived as more congruent with the White category. It is not clear, however, that this could account for the observed pattern of effects because tighter linkages among the names within the White category should presumably tend to increase rather than decrease interference and vice-versa for the other ethnic groups.

Additionally, we are investigating whether the observed name retrieval bias is specific to racial groups or extends to other social categories. Ongoing research is, for example,
using a minimal group paradigm in which participants are randomly assigned to novel and arbitrary groups (e.g., teams). Minimal groups trigger many of the same biases as other social categories (e.g., in face recognition; Van Bavel et al., 2011), and we anticipate that they may in this domain as well. Importantly, minimal groups do not differ systematically in visual features (e.g., members of all groups can belong to the same race), and participants do not possess semantic information (e.g., stereotypes) about the groups. To the extent that similar effects are observed with minimal groups, it will illuminate the role that categorization per se can play in interference effects. Our research contributes to the mounting evidence that influences of categorization on interference effects in word/name retrieval are dynamic, shifting as a function of currently available or salient categories (Abdel Rahman \& Melinger, 2011).

## Wider Implications

The own race bias in facial recognition has profound and disturbing social implications. For example, difficulties distinguishing between members of other races may be a significant cause of eyewitness misidentification and wrongful conviction in criminal cases (Scheck, Neufeld \& Dwyer, 2003). The current research suggests that a similar bias may occur in name retrieval, such that people have greater difficulty retrieving the names of other race individuals. Most of the time, the consequences of a name retrieval bias may be minor, but in certain contexts this bias could have pernicious effects. For example, teachers may be less likely to call on other race students, perhaps particularly if those students tend to be encountered proximally (e.g., seated together). The correlates and consequences of the name retrieval bias shown here merit further investigation.

#### Abstract

Decision making is a dynamic process. Alternatives compete over time, and this competition plays out in sensorimotor processes. This is true not just for perceptual decisions or simple categorisation tasks, but also for moral decisions, which are the outcome of a complex interplay of intuition, emotion and reasoning. In this experiment, we first establish a descriptive and causal link between gaze and moral judgement. We then use eye movements to track the time course of participants' moral decisions and show that by interrupting their decision process based on their gaze position, we are able to influence what they decide. We interpret this as evidence for a dynamical systems view of decision making and argue that our results provide new insights into how judgements are reached and constructed in our embodied minds.

Keywords: Decision making; morality; dynamic systems; eye tracking

Imagine a jury, evenly split over a verdict concerning a murder. One jury member is yet to make her decision, which will decide the fate of the accused. She weighs up her choice, looking between the faces of those who argued for and against conviction, glancing at the evidence and police reports on the table. The foreman clears her throat: the jury must take a vote now.

The jury member's decision could be analysed in terms of the evidence that is presented and how it is framed, and many experiments have investigated such factors. But here we are interested in one particular, often overlooked aspect: the precise moment of choice, in this case when the foreman cleared her throat. We claim that the precise timing of events like these may have a causal influence over a decision. To make our case, we adopt a perspective viewing decision-making as a fundamentally dynamic process. In the decision process, two, or more, options compete over time until one option reaches a threshold or the process is interrupted and the system is forced to reach a conclusion. Secondly, we present evidence that eye movements can reveal something of this process. Where the jury member looked, moment-by-moment showed what option she was considering. Our novel claim is that by manipulating when someone is forced to make a decision, and, hence, knowing
where they are in their decision trajectory, an influence can be exerted of what is decided

## Process of moral judgements

Recent research in moral psychology emphasizes how contextual factors influence processes underlying moral judgements, factors such as emotional state (Wheatley \& Haidt, 2005), political preferences (Graham, Haidt \& Nosek, 2009) and causal structure of the moral problem (Cushman, Young \& Hauser, 2006). In particular the interplay between intuitions, emotions and reasoning has been of central concern.
In two of the most influential models in this tradition, Haidt's Social Intuitionist Model (Haidt, 2001) and Greene's Dual Process Model (Greene et al. 2008), moral cognition is viewed as being comprised of a number of modules each dedicated towards processing specific forms of information. These modules then discretely combine their output to produce a moral judgement, however, the computational properties of the system are typically not spelled out nor how strict the modular metaphor is to be interpreted.

Taking a cue from dynamical systems modelling of cognition we propose an alternative to stage-based accounts. We view the processes of making moral judgements as a stochastic system of graded, probabilistic representations, in which a judgement can be understood as a temporary settling of the system around an attractor basin in a decision space (McKinstry, Dale \& Spivey, 2008; Spivey, 2007). In this study, we exploit a proposed coupling between cognition and gaze behavior to show the dynamic nature of moral judgements.

## Dynamic and embodied minds

Minds can be understood and modelled as complex dynamic systems. The discrete symbol and motor output that characterises language and action according to standard models can be generated by graded, probabilistic processes on a continuous timescale, extending beyond the discrete partitions that our everyday practices impose on our understanding of ourselves (Spivey, 2007; Van Orden,

Holden \& Turvey, 2005). There is evidence for the neural plausibility stemming from studies measuring and influencing saccades and saccadic programming in real time (Gold \& Shadlen, 2000) as well as the large scale probabilistic nature of neural populations (Pouget, Dayan \& Zemel, 2003).

A key element of this dynamic view of mind is the tight coupling between sensorimotor outputs and cognitive processing in general - an embodied view of cognition. This is evidenced, for example, during linguistic processing where persons glance towards phonological competitors while viewing an array of objects, by for example looking towards a candle when hearing 'candy' (Tanenhaus, SpiveyKnowlton, Eberhardt \& Sedivy, 1995) and when two people are engaged in a conversation with each other (Richardson, Dale \& Tomlinson, 2009). Eye movements have been shown to closely follow cognition during spatial indexing tasks in adults (Hoover \& Richardson, 2008) and infants as young as 6 months old (Richardson \& Kirkham, 2004).

Similarly, mouse movements will show curvature towards distracting alternatives indicating competition in categorisation tasks, for example when classifying whales as being fish or mammals, or, analogously with the eye movement result above, when processing linguistic inputs (Freeman, Dale \& Farmer, 2011).

Graded representations have also been found in more advanced reasoning tasks. In one study, participants were asked to judge the truth of a number of propositions that were selected to represent various steps of veridicality. For the propositions with intermediate truth values mouse movements would veer longer between answers thus tracking the more arduous cognitive task of assigning a truth value in these trials (McKinstry et al., 2008).

## Gaze preference and choice

The link between gaze and decision making has also been investigated by a number of studies investigating preference formation and decisions. In one study participants were asked to choose which of two faces they found more attractive. Their eye movements exhibited a bias towards the about to be chosen alternative, a finding dubbed the gaze cascade effect (Shimojo et al. 2003). The increasing likelihood to gaze towards a preferred alternative has also been demonstrated for participants considering difficult moral dilemmas (Pärnamets, 2008), indicating that gaze could contribute to moral judgements as well.

In addition, the experiment by Shimojo et al. (2003) demonstrated a possibility to bias preference judgements by actively directing gaze towards one face for longer periods of exposure than the alternative. Similar methods have been utilised to bias consumer decisions for candy bars (Armel, Beaumel \& Rangel, 2008). In all these experiments, however, different information is being presented to participants by artificially directing their gaze towards different alternatives.

By contrast, we propose in our experiments that choice can be influenced by manipulating only the timing of the decision and not the stimuli the participant attends to.

## Hypothesis

We investigated whether the coupling between eye movements and cognitive processes could be leveraged to influence the discrete end-state of the dynamic process.

We hypothesised, as suggested by pilot experiments from our lab (Richardson, Spivey \& Hoover, 2009), that the direction of participants' gaze could be an index of which attractor basin in their decision space they are gravitating towards. Using this information we would be able to collapse their decision function and bias their judgement to the currently favoured alternative, even if that alternative might not have been the option they would have preferred, had the decision process been allowed to take its noninterrupted course.

## Experiments

We devised a series of experiments that attempted to bias participants' decisions by monitoring their gaze. The first experiment, comprised of two studies (1a and 1b), was designed with a view of establishing an upper bound for our expected effect as well as exploring the link between gaze, as an index of thought, and judgement necessary for our paradigm to work. The second experiment replicates findings for face preference and consumer decisions by manipulating direction and duration of gaze and allows us to establish a causal link between gaze and choice for moral judgements.

The third experiment is our main study which demonstrates the hypothesised effect; influencing decisions solely on the basis of timing. Experiment 4 addresses a possible objection to our procedure and replicates our main finding.

## Equipment and materials

Eye tracking was performed using an SMI RED 250 eye tracker running at 250 Hz on a 19" screen with a resolution of $1680 * 1050$ pixels. Stimuli were presented using PsychoPhysics Toolbox (Kleiner, Brainard \& Pelli, 2007) running on MatLab 2010b (The MathWorks, Natick, MA.). Gaze was sampled by the MatLab script with 10 ms intervals. Calibration was performed on each subject at the start of the experiment using 5 points followed by 4 validation points. Calibrations with error exceeding $1^{\circ}$ visual angle in more than one case were rerun. Average error was less than $0.5^{\circ}$.

There were a total of 98 items that participants were asked to listen to and make judgements about. Of these, 63 were moral items and 35 were factual items. The factual items were used previously in our pilot studies (Richardson et al., 2009) and were all propositions that have an average $50 \%$ truth value, meaning that a large sample of persons were found equally likely to judge the propositions as being true
or false. An example proposition would be "Is coffee bad for your health?" with the alternatives "Yes" and "No".

The moral items were derived from Moral Foundations Theory (MFT, Graham et al., 2009) and propositions were designed to fit with each of the five categories found in MFT. In addition a few propositions were of a meta-ethical character. An example item is "Murder is sometimes justifiable" with the alternatives "Sometimes justifiable" and "Never justifiable". The alternatives were such that it would be informative to view both for the participant.

## General Procedure

Participants were asked to sit in front of a computer screen wearing a pair of headphones. They were instructed that during each trial they would hear a sentence stating either a moral or a factual proposition. Two alternatives would then be shown on the screen, one on the left-hand side of the screen and the other on the right-hand. Their task was to use their judgement to select the alternative that they thought was right in relation to the sentence they heard.

Participants indicated their selection by clicking the right or left mouse button, where the buttons corresponded to the alternatives presented on either the right or left side of the screen. The alternatives were visible for a maximum of 3000 ms , or until the experimental 'trigger' went off. This trigger, based on their eye movements, varied between experiments as explained below. The participants then saw a prompt asking them to "Choose now!" Participants were instructed to respond quickly once the prompt was shown on the screen. After each trial, a 1-7 continuous confidence scale was also presented.

Participants were told that the alternatives would be visible for a random and short amount of time each trial and were asked to view both alternatives. Unbeknownst to the participants the timing of each trial was dependent on their eye movements which were being concurrently recorded. The experimental trigger determining the length of each trial was based on the input from the eye tracker during each trial. It was sent to go off as soon one of the alternatives had accumulated at least 750 ms of dwell time and the other alternative had accumulated at least 250 ms of dwell time. These criteria ensured that the trigger would not go off until both alternatives had been seen by the participant. The exact conditions governing the trigger varied between the experiments and are detailed below.

If participants did not set off the trigger then the trial would time out after 3000 ms , and the participants would then be asked to make a choice. Trials timed out either because the participants failed to look at both alternatives, or because the eye-tracker momentarily lost track of the participants' gaze and so failed to capture when the participants shifted their focus between the two choice options. In both cases, there is no way for us using this paradigm to interrupt a decision process where participants are drawn between two competing alternatives. All such time-out trials were removed from further analysis.

Participants indicated during debrief that they occasionally would fail to understand an item and in those cases typically indicated very low confidence following that trial. Trials with confidence $<1.5$ of 7 were removed for that reason.

## Experiment 1a

Procedure In this first experiment we wanted to establish that the coupling between eye movements and cognition would be present even for our moral items. We did not attempt to bias participants' decisions at this point. We simply wanted to show that there is a relationship between the distribution of gaze across two alternatives, and which alternative is eventually chosen. This also allows us to establish an upper bound for the effect size of our later attempts at influencing decisions.

In each trial of this experiment the first 300 ms of viewing time were not counted towards the trigger, giving participants some extra time to orient themselves during each trial. From 300 ms onwards, we kept track of how long the participant looked at each alternative. As soon as one alternative was viewed for at least 750 ms and the other for 250 ms , the trigger was set off. We termed the alternative that had been looked at the longest the target. A success was counted if that alternative was chosen, otherwise a failure.

Fifteen persons (11 female) participated in this experiment with a mean age of $20.80 \quad(\mathrm{SD}=2.04)$. Participants were recruited through both the public and student-based subject pools at University College London.

Results and Discussion For the moral items 603 trials ( $67.67 \%$ ) were successful ( $p<0.0001$, Binomial test). For the factual items 280 trials ( $65.57 \%$ ) were successful ( $\mathrm{p}<0.0001$, Binomial test) (see figure 1).

This version demonstrates the plausibility of using gaze as an index of mental trajectories and using this information to collapse decision space towards an alternative under consideration. We used a 300 ms wait time in order to follow the procedure of our pilot work (Richardson et al. 2009). But these early eye movements could presumably also contribute to the decision vector. We therefore ran a second version of the experiment without the 300 ms wait time to investigate this.

## Experiment 1b

Procedure This Experiment was identical to 1a above, apart from we did not use a 300 ms wait time before eye movements to both alternatives were measured. Twenty persons ( 10 female) were recruited through both the public and student-based subject pools at University College London. Participants had a mean age of $27.20(\mathrm{SD}=8.07)$.

Results and discussion For the moral items, 716 trials ( $60.02 \%$ ) were successful ( $p<0.0001$, Binomial test). For the factual items 385 trials (68.14\%) were successful ( $\mathrm{p}<0.0001$, Binomial test) (see figure 1 ).

From Experiments 1 a and 1 b we conclude that eye movements are closely linked to the decision making process. If we actively interrupt participants during their deliberation, they are more likely to choose the alternative they have looked at for longer, even for complex moral judgements. We cannot yet claim the causal connexion between the timing of our interruption and the content of the judgement, of course. However, these experiments allow us to establish an upper bound for an expected effect size for the later experiments in which we attempt to bias their decisions in a predetermined manner.

## Experiment 2

In experiment 2 we wanted to establish the causal connexion between gaze and choice for the judgements which we were interested in. We adopted the methods used by, for example, Shimojo et al. (2003), where the combination of gaze and exposure, but not exposure alone, had been shown to influence choice. We constructed an experiment where we would be directing participants' gaze towards alternatives so that they would be more exposed to the target alternative compared to the non-target.

Procedure. The procedure in Experiment 2 differs significantly from the general procedure of the other experiments reported here.

Once participants had heard the item, they were presented with one alternative at a time with each presentation lasting 400 ms . One alternative was always shown on the right-hand side and the other on the left-hand side. The different alternatives appeared pseudo-randomly, such that the target alternative was given a $3: 1$ exposure weighting. Total combined viewing time for both the alternatives was 3200 ms . Target and non-target alternatives were presented in random order. Choice was indicated after the presentation sequence had completed, as in Experiment 1. Nineteen persons ( 13 female, mean age 22.36, $\mathrm{SD}=3.82$ ) participated in Experiment 2. Participants were recruited through both the public and student-based subject pools at University College London.

Results and discussion For the moral items 600 (53.29\%) trials were successful ( $\mathrm{p}<0.05$, Binomial test), while 287 (54.99\%) trials were successful for the factual items ( $\mathrm{p}<0.05$, Binomial test) (see figure 1 ).

We conclude that there is a causal connexion between gaze and choice. In addition, we demonstrate the possibility to bias moral and factual judgements with the help of directed gaze and exposure effects, and this on the relatively small time scales that our paradigm is operating on. Typical trials in the literature using this method usually last around twice as long as ours.

Additionally, to our knowledge, this is the first empirical demonstration of this effect for moral judgements, and as such, it is a remarkable finding in itself.

## Experiment 3

Our goal in this experiment was to exert an influence over the decisions that participants made by manipulating nothing but the timing of their decisions. On each trial, we randomly determined which alternative we would try to bias the participant towards. Unlike in previous experiments that have biased decisions by changing stimuli or directing gaze, including our Experiment 2, our participants looked freely at the alternatives in front of them. We simply tracked the time course of their eye movements during the decision process, and prompted the participants to decide when we judged that their gaze suggested they were at a particular point in their decision space that favoured the option we were trying to influence them to choose.

Procedure Experiment 3 was identical to experiment 1 b in all respects except that here the experiment program would, for each trial, randomly designate one alternative as the target. The trigger would only go off if that target alternative had accumulated at least 750 ms of dwell time and the other, non-target, alternative had accumulated at least 250 ms of dwell time.

Twenty persons (14 female, mean age 29.60, $\mathrm{SD}=13.14$ ) participated in experiment 3. Participants were recruited through both the public and student-based subject pools at University College London.

Results and discussion For the moral items 609 (58.22\%) trials were successful ( $\mathrm{p}<0.0001$, Binomial test). For the factual items 282 (56.51\%) of trials were successful ( $\mathrm{p}<0.005$, Binomial test) (see figure 1 ).

This finding demonstrates that we are able to influence participants' judgements in both moral and factual decisions by tracking their gaze alone. We merely asked them to respond at a given point in time when their eye movements reveal them being in a position in their decision space that indicates them gravitating towards a given alternative. We claim that this finding supports our view of the dynamic nature of judgements, where judgements can be understood as trajectories in decision space travelling between alternatives conceived of as attractor basins in that space.

We also wish to highlight the difference between this experiment, where participants are using their gaze actively and are unconstrained in the environment, and Experiment 2 where participants, while moving their eyes, are passive recipients of information. Given this difference and the fact that our paradigm allows varying degrees of relative exposure to the alternatives, in virtue of how the trigger is set up, we argue that our finding in Experiment 3 represents a novel connexion between gaze and choice.

## Experiment 4

One possible objection to our claims is that perhaps participants have already made their decisions well before the trigger is set off. It is conceivable that participants gaze towards the target for longer than 750 ms , settle on that alternative, and then simply avert their gaze towards the
other alternative out of boredom, which sets off the trigger. Participants then choose the designated target, and the trial is counted as a success. But, the objection goes, if they were allowed to indicate their choice as soon as they'd made it, they would have clicked much earlier in the trial. Experiment 4 was designed to meet this objection by removing the constraint that participants are unable to respond before the prompt screen.

Also, in addition to confidence ratings two extra followup questions were asked of participants after each trial. One concerned asked if they had been able to hear the items and see the alternatives properly. The second concerned asked how important the issue raised by the item was to them, which pertained primarily to the moral items. The two additions were made to meet to further objections to experiment 2 , namely that participants would only be biased towards our target on items they felt were unimportant or where they failed to fully understand the item or alternative. These were also set in terms of 1-7 continuous scale.

Procedure The trigger was set up to work as in experiment 2. In addition, time participants were instructed that they could also indicate their choice when they had made up their minds, clicking the mouse in the same way as they would during the 'Choose now!' screen.

21 persons ( 17 female, mean age 21.81, $\mathrm{SD}=5.38$ ) participated in experiment 3. Participants were recruited through both the public and student-based subject pools at University College London.

Results and discussion For the moral items 240 (21.27\%) trials were such that the participant responded before the experimental trigger was activated. The corresponding number for the factual trials was 264 ( $45.28 \%$ ). Since these are cases where the trigger has not been activated, these trials were not analysed further.

Of the remaining trials 496 (55.86\%) were successful ( $\mathrm{p}<0.001$, Binomial test) for the moral items, and for the factual items 189 (59.24\%) trials were successful ( $\mathrm{p}<0.005$, Binomial test) (see figure 1). Analysing the various ratings participants made after their decision, we found that there were no significant difference between trials that were

Figure 1: Results from the experiments for all items. $95 \%$ confidence intervals are shown.
successfully biased and those that were not. For moral items, there was no difference in comprehension between successful trials ( $\mathrm{M}=6.57$ ) and unsuccessful trials $(\mathrm{M}=6.50)$ $(\mathrm{t}(809.223)=1.67, \mathrm{p}=0.09)$; and no difference in perceived importance on successful trials ( $\mathrm{M}=4.98$ ) and unsuccessful trials $(\mathrm{M}=4.92)(\mathrm{t}(847.692)=0.57, \mathrm{p}=0.57)$. Similarly, for factual items there was no difference in comprehension between successful trials $(M=6.55)$ and unsuccessful trials $(\mathrm{M}=6.52)(\mathrm{t}(262.72)=0.261, \mathrm{p}=0.79)$; and no differences in importance ratings either ( $M=3.53$, successful, $M=3.35$, unsuccessful, $\mathrm{t}(268.412)=0.92, \mathrm{p}=0.36)$.

We find in this experiment that there are trials where participants make up their minds before our manipulation is triggered. But these cases do not explain our findings, since when they are excluded from the analysis, our biasing effect remains. Experiment 4 still demonstrates judgements malleable to influence depending solely on the timing of judgement based on measuring gaze indexed thought trajectories.

## General Discussion

We have argued that decision making is a dynamic system exhibiting a tight coupling between eye-movements and judgement. We have demonstrated a causal link between gaze and choice using a paradigm utilising exposure and directed gaze. We then, following the logic of dynamical systems, have shown that we are able to influence participants' moral and factual judgements using gaze only as an index of thought, and by manipulating nothing but the timing of the decisions. The results from Experiment 4 suggest that our effects are no mere artefacts of the experimental procedure.

A surprising aspect of our results is the demonstration of the malleability of moral judgments on very small timescales across the wide spectrum of moral domains which our stimuli encompass. This malleability is present even when we manipulate only the timing of decisions, rather than by adding information to the situation, as has typically been the case in the literature. We emphasise that while we interpret our findings in the light of a dynamical systems perspective on mind, the effects on moral judgements are of significant interest by themselves for understanding our moral mind.

One valid concern about our findings is the relatively small effects sizes. This is not too surprising, however, due to the fact that gaze and decision making processes, while linked, cannot be not rigidly yoked together. For one thing, eye movements have various biological constraints and are necessarily discrete, whereas thought processes could be continuous and graded; for another, one can chose between options while fixating a single point. Given the partial though pervasive (Spivey, Richardson \& Dale, 2009) - link between eye movements and cognition, it is not surprising that gaze is an imperfect indicator of decision processes, and our bias effects are the size that they are. Indeed, we would argue that it is remarkable that they exist at all.

A significantly higher effect size would be surprising for other reasons as well. One reason is that this would jar with our capacity to, at times, be moral agents. Recall, we are not making a claim about a possible lack of moral agency in our participants, only a claim about morality's dynamic nature. In a sense the size of our effect says something very real about the strength of our participants' moral systems. It opens up avenues for a more detailed exploration of individuals' and groups' moral landscapes, as well as understanding the complex interplay between cognition, sensorimotor systems and the environment.

In future work we hope to expand the range of moral decisions under examination, and develop computational models of the process. The class of judgements we have used here are first person judgements about one's personal moral values. These are judgements which are known to be open to manipulation (Hall, Johansson \& Strandberg, 2012). In further research we plan to extend our results to third person judgements and concrete moral action. Eventually, we hope to model the dynamics of moral decision marking. Drawing on our current findings, we aim to develop a model that exhibits the same drift towards attractor states when interrupted as we found in our participants and compare this to alternative accounts such as drift-diffusion and accumulator models. But from the results we have presented here, we hope the case has been made that that much can be learned about our moral selves by focusing on the deep integration between cognitive and perceptual functions and how this integration plays out in time.

## Acknowledgments

This research was made possible with the support of Stiftelsen Erik och Gurli Hultengrens fond för filosofi vid Lunds universitet and Makarna Ingeniör Lars Henrik Fornanders fond to P.P. We thank Abigail Hodder for lending her voice to recordings of the items used in these experiments.

# Multimodal Networks of Interpersonal Interaction and Conversational Contexts 

Alexandra Paxton (paxton.alexandra@gmail.com) Rick Dale (rdale@ucmerced.edu)<br>Cognitive and Information Sciences, University of California, Merced Merced, CA 95341 USA

#### Abstract

In interpersonal interaction, the terms synchrony or alignment refer to the way in which communication channels like speech or body movement become intertwined over time, both across interlocutors and within a single individual. A recent trend in alignment research has targeted multimodal alignment, exploring how various communication channels affect one another over time (e.g., Louwerse et al., 2012). While existing research has made significant progress in mapping multimodal alignment during task-based or positively valenced interactions, little is known about the dynamics of multimodal alignment during conflict. We visualize multimodal alignment during naturalistic affiliative and argumentative interactions as networks based on analyses of body movement and speech. Broadly, we find that conversational contexts strongly impact the ways in which interlocutors' movement and speech systems self-organize interpersonally and intrapersonally.

Keywords: alignment; conflict; conversation; interaction; movement; network; speech; synchrony

## Introduction

Interpersonal communication is a multimodal activity. Conversation incorporates multiple channels of communication that enrich the interaction, like hand gestures, facial expressions, posture, and speech. To effectively communicate with one another, interlocutors cue in to each of these channels simultaneously, often without realizing the importance placed on each of them.

Considerable work has surveyed multimodal qualities of interaction (e.g., Norris, 2004). However, in general, experimental study of interpersonal communication in cognitive science tends to target single behavioral channels. This has led to significant advances in our understanding of these specific channels, but there is still much work to be done in investigating the connections among them. Continued multimodal research will likely yield interesting-and possibly unexpected-relationships among channels that have been extensively explored unimodally. For this reason, the current research explores multimodal alignment situated within different conversational contexts.

Specifically, the present research examines interpersonal communication through alignment dynamics. Research on interpersonal alignment focuses on how affect, behavior, and cognition of interacting individuals affect one another over time. Over the past several decades, researchers have explored interpersonal alignment over a range of channels, from movement (e.g., Richardson et al., 2007) to speech (e.g., Garrod \& Pickering, 2004) to cognition (e.g., Brennan, Galati, \& Kuhlen, 2010). As aforementioned, the majority
of this work centers on one or two behavioral channels, but a growing body of literature has begun to investigate how multiple channels align during communication (e.g., Louwerse, Dale, Bard, \& Jeuniaux, 2012).

A distinction can be drawn between alignment in a general sense and synchrony. ${ }^{1}$ We use the term alignment to refer broadly to the concept that individuals, over time, change their affect, behavior, and cognition as a direct result of their interaction with another individual. This umbrella term encompasses everything from mimicry, in which individuals are performing highly similar behaviors to their interaction partner (e.g., Chartrand \& Bargh, 1999), to more complementary behavior patterns like synergy (e.g., Riley, Richardson, Shockley, \& Ramenzoni, 2011). Synchrony, on the other hand, can be considered a specific pattern of alignment and refers exclusively to the in-phase entrainment of behavior or communication channels.

In the spirit of intrapersonal alignment research spanning the last several decades (e.g., Haken, Kelso, \& Bunz, 1985), the current research explores the dynamics of interpersonal alignment as a self-organizing property of human interaction. The present research focuses specifically on two channels of communication-speech and body movementand the ways in which these channels are affected by each other, by conversation partners, and by the conversational context. If it is true that human interaction self-organizes around, for example, conversational goals, we should expect to see multimodal alignment patterns changing across these different contexts.

## Body Movement and Speech Alignment

Previous work on speech and body movement demonstrates rich interactivity between and within individuals. Some of the earliest work in alignment research presents evidence for interpersonal and intrapersonal multimodal alignment between movement and speech channels (Condon \& Ogston, 1966). Since then, research has continued to explore intrapersonal alignment, both in speech (Reitter, Moore, \& Keller, 2010) and movement (Beek, Peper, \& Daffertshofer, 2002). However, body movement and speech have both been studied extensively within the interpersonal alignment literature as well, generally within affect-neutral, positively valenced, or task-oriented settings.

Studies of body movement alignment have spanned a wide variety of behaviors, including gesture (Bernieri \&

[^180]Rosenthal, 1991), stepping (Miles, Griffiths, Richardson, \& Macrae, 2010), and overall levels of body movement (Paxton \& Dale, in press). Often, work on body movement alignment incorporates elements of social psychology, like investigating how interpersonal alignment affects liking (Chartrand \& Bargh, 1999). Broadly speaking, these findings generally cast the phenomenon as a pervasive and relatively automatic process that can be enhanced with liking or rapport. However, limited research suggests that higher-level social factors may inhibit bodily alignment (Miles et al., 2010; Paxton \& Dale, under revision).

Individuals also align over numerous measures of speech. Over time, interacting individuals have been shown to use more similar acoustic features (Kousidis \& Dorran, 2008), sentence structures (Cleland \& Pickering, 2003), and even respiratory patterns (McFarland, 2001). The tendency toward alignment during interaction is so powerful that individuals even align to simulated partners (Krämer, Kopp, Becker-Asano, \& Sommer, 2012). These and related findings of interpersonal alignment in speech have led some to suggest that this is an automatic tendency driven in part by shared cognitive representations (Brennan et al., 2010).

These past findings point to a distinct temporal structure of speech and movement during interaction. Recently, researchers have begun to emphasize the importance of investigating interpersonal multimodal alignment on a large scale (e.g., Delaherche \& Chetouani, 2010; Louwerse et al., 2012). These questions allow researchers to more fully understand the complex, interdependent structure of communication channels during interaction.

## Dynamics of Interpersonal Alignment

Mechanistic models of body mechanics (e.g., interlimb coordination; Haken et al., 1985) have influenced recent work on the dynamics in interpersonal interaction (e.g., Miles et al., 2010). Researchers have begun to explore the forms and functions of alignment, going beyond earlier studies simply investigating its existence. Such work is dedicated to exploring the time course of alignment with the belief that-like many other phenomena-alignment is neither static nor uniform across contexts.

Like the work discussed above, research on interaction dynamics has also focused on speech and movement channels. From gaze patterns and postural sway (Shockley, Richardson, \& Dale, 2009) to speech production (Tilsen, 2009), researchers have found support for dynamical interpersonal and intrapersonal alignment, both unimodal and multimodal. Individuals' patterns of alignment change with task demands (Sebanz, Bekkering, \& Knoblich, 2006), social context (Miles, Lumsden, Richardson, \& Macrae, 2011), and even physical environment (Richardson et al., 2007), providing further support for claims of context dependence in alignment (Riley et al., 2011).

## The Present Study

Previous work has pointed to distinct patterns of organization of speech and body movement between and
within individuals, and recent trends have begun to situate this alignment within the context of multimodal interaction. Yet, so far, the dynamics of multimodality in alignment have remained relatively unexplored. Moreover, research on alignment thus far has sampled only a small percentage of the total space of human communicative contexts, focusing primarily on task completion or friendly interactions.

Our primary goal in the present study is to add to the growing literature on the dynamics of multimodal alignment. We aim to extend various elements of previous findings on unimodal and multimodal alignment, both interand intrapersonally. The present study explores participants’ speech patterns and their relation to body movement with three initial hypotheses. First, we hypothesize that individuals will align to one another's speech patterns but will not demonstrate in-phase synchrony of speech, due to the natural constraints of turn-taking. Second, we anticipate that individuals will exhibit multimodal intrapersonal synchrony, tending to move and speak at the same time. Third, although we anticipate that individuals will be most likely to move while speaking (and the reverse), we expect that analyses will reveal some evidence for interpersonal multimodal alignment (e.g., due to nodding).

The current project extends previous work on multimodal alignment further by situating the research within different conversational contexts, namely affiliation and argument. As part of a larger line of research investigating alignment in various contexts, the present research brings a focus on asymmetric contexts-interactions in which individuals have conflicting, differing, or opposing goals-to bear on questions of multimodal alignment. Previous research has demonstrated that conflict significantly decreases levels of interpersonal bodily synchrony (Paxton \& Dale, under revision). We continue to explore alignment during conflict in the present project. Compared to non-asymmetric contexts, we anticipate that argument will affect alignment in several ways: first, that individuals will demonstrate a more rigid turn-taking structure (possibly, e.g., to satisfy implicit social demands for reciprocity); second, that levels of intrapersonal multimodal synchrony will remain consistent; and third, that levels of interpersonal multimodal alignment will decrease. This pattern of results-balancing stable conversational structures with sensitivity to contextual factors-would reinforce claims of contextdependent, emergent properties of human interactions.

In addition to analyzing these data, the present study also hopes to begin work towards descriptive models of interpersonal and intrapersonal multimodal and unimodal alignment in different conversational contexts. After presenting our analyses, we highlight our findings in visualization networks of multimodal alignment dynamics.

## Method

## Corpus

The data presented here were collected by the authors as part of a larger corpus comparing interpersonal alignment
during argument and affiliation. The corpus comprised over 35 naïve participant dyads engaged in different conversational settings, collected from the University of Memphis and the University of California, Merced. As a further exploratory analysis building on previous findings (Paxton \& Dale, in press; Paxton \& Dale, under revision), the present analyses were performed on a subset of the participants from the University of California, Merced, based on uniformity of experimental conditions. The audio data had not yet been analyzed, separately or in conjunction with body movement.

## Participants

24 undergraduate participants (mean age $=20.14$ years) were recruited as 12 dyads ( 6 female, 6 mixed-sex) through the school's online subject pool system. Participants signed up independently and were unable to see their partner's identity beforehand. Only one dyad reported having known one another prior to participation. One mixed-sex dyad was dropped from present analyses because their opinions were too similar to achieve any argument during the experiment.

## Procedure

Upon arrival, participants were separated and individually completed a number of questionnaires prior to interacting with one another. One of the questionnaires was an opinion survey that included a number of sociopolitical (e.g., abortion, death penalty, legalization of marijuana) and university-specific (e.g., a campus rule forbidding freshmen students from bringing cars to campus) issues. The opinion survey posed the issues as open-ended, opinion-neutral questions. For each item, participants were given several lines to write their opinion and were directed to indicate the strength of that opinion on a Likert-style scale from 1 (feel very weakly) to 4 (feel very strongly).

Participants were randomly assigned to one of two conditions based on the order of the two target conversations that they were prompted to have. All dyads held a brief introduction conversation without the experimenter present ( $\sim 3 \mathrm{~min}$ ) and two target conversations (10min each). Half of the dyads were given an affiliative prompt first and an argumentative prompt second; half of the dyads experienced the reverse order. After each target conversation, participants were separated to complete postconversation measures. Participants were not informed in advance of the conversation topics. After holding both target conversations, participants were thanked and debriefed.

For the affiliative conversation, dyads were instructed to discuss popular media that both participants enjoyed. ${ }^{2}$ Experimenters identified the argumentative prompt for each dyad based on participants' responses to the opinion survey. The topic for which participants expressed

[^181]opposing views (e.g., one pro-life, the other pro-choice) and for which both participants indicated strong feelings was chosen. Up to two additional argumentative prompts were chosen using the same criteria and were given to participants if they could not continue the argumentative conversation on the first topic for the entire time.

## Materials

Movement data were collected automatically using a framedifferencing method (FDM; Paxton \& Dale, in press). Participants sat facing one another during their conversations and were captured in profile in a single frame on a high-definition camcorder (Canon VIXIA HF M31). ${ }^{3}$ The videos were downsampled at 8 Hz to a series of still frames. The FDM tracked movement by registering changes in pixels across frames (see Figure 1 for toy visualization) and applying a filter to remove extraneous pixel changes (e.g., due to fluctuations in light sources). For additional detail on the FDM, see Paxton and Dale (in press). See also Grammer, Honda, Jüette, and Schmitt (1999) for related methods.

Figure 1: Sample FDM sequence of interacting dyad, aggregated over multiple frames for visualization purposes.

Speech data were collected using individual lapel microphones (Audio-Technica ATR 3350) and a mixer (Azden CAM-3) so that each participant's audio was captured on a separate channel. The present research used on/off speech states as the measure for speech. On/off
speech states were obtained for each participant using the sound finder function in Audacity. Decibel cutoffs were individually determined for each dyad in order to maximize sensitivity and specificity.

Samples of data obtained from each interaction type are graphed in Figure 2. Each sample includes 250 sec of interaction. Taken from the same dyad, the figures graph changes in body movement as red and blue lines, with speech events depicted as boxes of corresponding color behind the lines.

## Results

The present analyses tested for unimodal and multimodal interpersonal and intrapersonal alignment. Crosscorrelations were calculated for interpersonal unimodal (e.g., participant A's movement to participant B's movement), interpersonal multimodal (e.g., participant A's speech to participant B's movement), and intrapersonal

[^182]

Figure 2: Sample body movement time series of a single dyad during 250s of interaction during an affiliative (left) and an argumentative (right) conversation. Speech data are represented as shaded boxes of corresponding colors.
multimodal (e.g., participant A's movement to participant A's speech) channels within a $+/-3000 \mathrm{~ms}$ range, yielding a series of cross-correlation
coefficients ( $r$ ). Using cross-correlation coefficients permitted us to investigate both in-phase synchrony and longer-phase alignment trends within the data.

The data were primarily analyzed using a series of linear mixed-effects models (Baayen, 2008), using dyad and condition as random effects unless otherwise noted. All main and interaction terms were standardized prior to being entered into the models. As standardized values, the crosscorrelation coefficients can be interpreted as beta weights, a measure of effect size (Keith, 2005).

## Unimodal Alignment

Movement Previous analyses of the corpus found evidence for in-phase bodily synchrony (Paxton \& Dale, under revision). ${ }^{4}$ To ensure that the subset analyzed here exhibited similar patterns, our first model predicted interpersonal body movement alignment ( $r_{\text {mov }}$ ) with conversation type (affiliative or argumentative) and time lag (125ms increments). Results confirmed that the subset of dyads conformed to broader patterns within the whole corpus. Increases in time lag (i.e., comparing movement further removed in time) significantly predicted a drop in $r_{\text {mov }}$ ( $\beta=-$ .25; $p<.0001$ ), providing evidence for in-phase interpersonal synchrony. Changes in $r_{\text {mov }}$ were also significantly predicted by conversation type ( $\beta=-.19 ; p<.0001$ ), with lower levels of movement synchrony in argumentative conversations. Interestingly, while only trending toward significance in analyses of the entire corpus, the interaction term between conversation type and time lag reached significance in this subset of the data ( $\beta=.14 ; p<.01$ ): Interlocutors' body movements were more tightly synchronized during affiliative conversations, reaching higher peak $r_{\text {mov }}$ and falling more sharply as time lag increased.

[^183]Speech The second model tested interpersonal speech alignment during different conversation contexts, using conversation type and time lag (125ms) to predict interpersonal speech alignment $\left(r_{\text {speech }}\right)$. As anticipated, increases in time lag predicted increases in $r_{\text {speech }}$ ( $\beta=.15$; $p<.0001$ ), while argumentative conversation type significantly predicted a decrease in $r_{\text {speech }}$ ( $\beta=-.44$; $p<.0001$ ). The interaction term was also significant ( $\beta=-.11$; $p<.001$ ). Together, these results suggest that interlocutors generally respected the turn-taking structure during all conversations but were more likely to exhibit overlapping speech during affiliative conversations.

To better situate these results, we performed complementary analyses comparing participants' speech patterns during different conversation types, accounting for condition, conversation number, speaker, and dyad membership as random effects. In a model predicting turn length with conversation type, argumentative conversations predicted slightly but significantly longer turn lengths compared with affiliative conversations ( $\beta=.04 ; p<.005$ ). Another model predicted total number of speech events in a conversation by both participants using conversation type and found that argumentative conversations had significantly fewer speech events than affiliative conversations ( $\beta=-.31 ; p<.0001$ ).

## Multimodal Alignment

Interpersonal Next, we predicted interpersonal multimodal cross-correlation coefficients ( $r_{\text {multi }}$ ) with conversation type and time lag. The main effect for conversation type was again significant, with argumentative conversations predicting a significant drop in $r_{\text {multi }}$ ( $\beta=-.21 ; p<.0001$ ). Neither time lag ( $\beta=-.02 ; p=.39$ ) nor the interaction term ( $\beta=.01 ; p=.76$ ) reached significance.

Intrapersonal Our final model predicted intrapersonal multimodal cross-correlation coefficients ( $r_{\text {self }}$ ) with conversation type and time lag. As predicted, we found no significant effect of conversation type on $r_{\text {self }}$ ( $\beta=.01$; $p=.75$ ), suggesting that intrapersonal alignment may be less
sensitive to conversation context than interpersonal alignment. Increases in time lag again significantly predicted decreases in $r_{\text {self }}$ ( $\beta=-.34 ; p<.0001$ ), suggesting that interlocutors were more likely to be moving when talking and vice-versa. As with unimodal body movement alignment, the significance of time lag as a main effect provided evidence for the existence of in-phase synchrony. The interaction term also reached significance ( $\beta=.09$; $p<.05$ ): Although participants exhibited in-phase multimodal intrapersonal synchrony, individuals' own body movements and speech events were more tightly connected during affiliative conversations.

## Network Visualizations of Interaction

To create the network visualizations of interpersonal interaction, we used body movement (M) and speech (S) time series data rather than cross-correlation coefficients. The networks were intended to capture relationships as they occur in time. We created two independent networks, one for affiliative interactions and the other for argumentative interactions (Figure 3). Connection strengths were presented as beta weights obtained through a series of linear mixedeffects models. ${ }^{5}$ All models used condition, conversation number, and dyad as random effects; the intrapersonal models ( $\mathrm{M}_{1}: \mathrm{S}_{1}$ and $\mathrm{M}_{2}: \mathrm{S}_{2}$ ) included participant as an additional random effect. Models used the nodes as predictors of other nodes, according to their connections (e.g., predicting $\mathrm{M}_{1}$ with $\mathrm{M}_{2}$ ).

## Discussion

While we often intuitively acknowledge that conversational contexts affect the course of an interaction, our results suggest that there are fundamental differences in interpersonal dynamics during different contexts. During conflict, interpersonal body movement synchrony diminishes. Interlocutors have a more rigid turn-taking structure with fewer and longer turns. Dyads use fewer instances of any overlapping speech, including events like laughter and verbal tracking. Interpersonal multimodal alignment-when one interlocutor is talking and the other is simultaneously moving-drops. Furthermore, in many of these cases, the effect size of conversation type on these measures is quite large, suggesting a very strong impact of context on these aspects of interaction.

On the other hand, some types of behavior exhibit relatively more stable properties across context. Interlocutors multimodally synchronize their own speech and movement, tending to move and speak at the same time regardless of conversational contexts. However, intrapersonal multimodal synchrony can still be affected by context through interaction effects. We believe this reinforces a view of interpersonal interaction as inherently

[^184]

Figure 3: Network visualizations for affiliative (top) and argumentative (bottom) interactions. Colors correspond to those used in Figure 2. Connection strengths are shown as beta weights obtained from a series of linear mixed-effects models and can be interpreted as effect sizes. All connections are significant ( $p<.001$ ).
context-dependent, although the effects may be quite small for some elements or in some contexts.

Our findings paint conversation as a highly complex interpersonal communication structure. While there are some relatively stable elements within it (e.g., intrapersonal multimodal alignment), other elements are very sensitive to conversational contexts (e.g., interpersonal bodily synchrony). While complementary behaviors align across interactions, argument as a conversation context appears to exhibit additional constraints on alignment patterns. Based on these exploratory analyses, interpersonal communicative structures appear to be self-organizing within the interaction and with strong regard to the overall context.

The corpus analyzed here provides a rich source of interaction data in multiple conversational contexts. We intend to continue to mine these data in order to better understand the nature of multimodal communication and interaction and to collect additional corpora on other conversation contexts. In doing so, we hope to more fully develop the interaction network presented here. Future directions will pursue the creation of more predictive models of interpersonal (e.g., Mehler, Lücking, \& Weiß, 2010) and intrapersonal (e.g., Tilsen, 2009) multimodal alignment that can shape additional experimental work as
models like the HKB (Haken et al., 1985) have shaped intrapersonal unimodal alignment.

## Acknowledgments

The authors would like to thank undergraduates J.P. Gonzales and Stephanie Frewen for their help in data collection and preparation, respectively. This research was supported partially by NSF grants BCS-0826825 and BCS0926670.

#### Abstract

In everyday communication, people not only use speech but also hand gestures to convey information. One intriguing question in gesture research has been why gestures take the specific form they do. Previous research has identified the speaker-gesturer's communicative intent as one factor shaping the form of iconic gestures. Here we investigate whether communicative intent also shapes the form of pointing gestures. In an experimental setting, twenty-four participants produced pointing gestures identifying a referent for an addressee. The communicative intent of the speakergesturer was manipulated by varying the informativeness of the pointing gesture. A second independent variable was the presence or absence of concurrent speech. As a function of their communicative intent and irrespective of the presence of speech, participants varied the durations of the stroke and the post-stroke hold-phase of their gesture. These findings add to our understanding of how the communicative context influences the form that a gesture takes.

Keywords: Pointing Gesture; Communicative Intent; Gesture Production; Action Planning; Deixis.

## Introduction

In everyday communication, people not only use speech but also meaningful hand gestures to convey information. One of the most intriguing questions in gesture research has been why such gestures take the physical form they do (Bavelas et al., 2008; Gerwing \& Bavelas, 2004; Krauss, Chen, \& Gottesman, 2000). The main focus so far in answering this question has been on gestures iconic in nature, i.e., gestures that in form and manner of execution visually resemble the simultaneously expressed meaning of the linguistic part of an utterance (McNeill, 1985), such as moving up and down
one's hand when talking about a basketball game. Typically, such studies have varied aspects of the communicative context, such as the visibility of gestures or the knowledge speaker and listener mutually share. Amongst other things, these studies have shown that speakers design their gestures for particular recipients and produce more (e.g., Alibali, Heath, \& Myers, 2001; Bavelas et al., 2008) as well as larger and more precise gestures when communicative intentions are enhanced (e.g., Gerwing \& Bavelas, 2004; Holler \& Stevens, 2007). Thus, iconic co-speech gestures seem closely linked to the speaker's specific communicative intent, and the particular form an iconic gesture takes depends on the context-bound communicative relation between speaker and addressee (see Holler \& Wilkin, 2011).

In contrast, it is unclear how the form of pointing gestures changes as a function of the gesturer's communicative intent. Pointing is a foundational building block of human communication (Kita, 2003) and allows us to directly connect our communication to the material world that surrounds us (Clark, 2003). Pointing has received much attention in the literature from an ontogenetic viewpoint because of its role in paving the way for the acquisition of language (Butterworth, 2003; Carpenter, Nagell, \& Tomasello, 1998; Tomasello, Carpenter, \& Liszkowski, 2007), as well as from a phylogenetic viewpoint with respect to declarative pointing being a uniquely human form of communication in a natural environment (Call \& Tomasello, 1994; Kita, 2003; Tomasello et al., 2007). In contrast, the exact form parameters that people vary in the production of pointing gestures in human adult communication remain largely unknown. Therefore, the present study aims at contributing further to our
understanding of why adults’ index-finger pointing gestures take the particular physical form they do in a communicative context.

There are some preliminary indications that suggest a relation between the form of a pointing gesture and the speaker's communicative intent. Cleret de Langavant et al. (2011) had participants repeatedly point to objects on a table in front of them. Two addressees were always sitting next to the table. At the onset of a communicative block, the participant was instructed to verbally address one of the addressees before the block started and was instructed before each trial of that block to point at a specific object for that addressee, who named the object after observing the participant's gesture. At the onset of a non-communicative block, the participant addressed nobody and was instructed before each trial to point at a specific object without having an addressee (and hence did not receive feedback from an addressee). Compared to the latter, non-communicative condition, the former condition yielded pointing gestures that had a trajectory and endpoint distribution that were tilted away from the addressee, arguably because the addressee's perspective on the target object was taken into account in the form of the gesture.

Everyday pointing gestures generally occur in a context in which two interlocutors share a joint attentional frame in which one person directs the attention of another person towards a location, event, or referent in the perceptual environment (Tomasello et al., 2007). An important prerequisite for a successful referential pointing gesture is that two interlocutors come to perceptually attend to the same entity or location and are mutually aware of the fact that they are both attending to the same thing (Clark, 1996). Therefore, instead of comparing a "communicative" situation (including addressing a listener and receiving verbal feedback) to a "non-communicative" situation (without addressing a listener and verbal feedback), as in Cleret de Langavant et al. (2011), we here compare two situations that are both communicative and differ only in the communicative intent of the speaker-gesturer. As a proxy of the communicative intent of the speaker-gesturer, we manipulate the degree of informativeness of the pointing gesture as a first factor in our design.

A second factor manipulated here is the presence of speech as a second modality. Pointing gestures often come with concurrent deictic speech such as spatial demonstratives (e.g., "this" and "that" in English). In the production of referring expressions, speech and gesture are tightly interconnected (Kendon, 2004; McNeill, 1992) and can be used independently or simultaneously to single out a referent (e.g., Bangerter, 2004), in contrast with iconic gestures that canonically come with speech. In the current study we manipulate the presence of such a second modality (speech) and explore the yet unaddressed question of whether the mere presence of speech as a second modality influences the form parameters people exploit in producing pointing gestures for their addressee, and whether the
presence of speech interacts with our manipulation of communicative intent.

The current study looks at different subcomponents (or: parameters) of the pointing gesture. We focus on the planning duration of the gesture, the duration of the stroke and the post-stroke hold-phase, as well as the point in time at which the apex is reached after the visual presentation of a referent (Levelt, Richardson, \& La Heij, 1985), and the amount of distance travelled by the pointing finger. Finally we also look at whether the synchronization of speech and gesture changes as a function of communicative intent.

## Method

## Participants

Twenty-four right-handed native speakers of Dutch (12 female; mean age 20.6), studying at Radboud University Nijmegen, participated in the experiment. They were compensated with $20 €$.

## Experimental Design and Set-up

Participants were seated at a distance of 100 cm from a computer screen that was placed back-to-back with another computer screen (henceforth: the back screen). Stimuli were four white circles in a horizontal line on the top of the screen, mirroring four circles on the back screen. The circles could light up either blue or yellow. A second participant (a confederate; henceforth: the addressee) looked at the back screen and the participant's pointing gesture via a camera. Figure 1 shows the view of the addressee via the camera (converted to a grayscale image). On all trials, participants referred to the circle that lit up. The addressee noted on a paper form to which of the four circles the participant

Figure 1: The addressee's view of the back screen and the pointing participant during a non-informative trial.
referred on each trial. In order to make the deictic act informative in one case but non-informative in the other, the following set-up was used. In both conditions, via a camera, the addressee observed the pointing gesture of the participant, as well as the circles at the back screen providing the corresponding view of the four circles the participant was seeing. This way, the addressee saw which of the four circles the participant pointed at, but without seeing which circle lit up on the participant's side of the screen, a crucial aspect in our manipulation (see below).

We manipulated the informativeness of the gesture (informative versus non-informative) as well as the modality of the deictic act (gesture-only versus gesture + speech) in a $2 x 2$ within participants design. In the informative condition, a circle turned blue or yellow only on the participants' screen but not on the back screen. Therefore the participant's pointing gesture was the only source of information on which the addressee had to base his decision in selecting the circle referred to by the participant. In the non-informative condition, the corresponding circles would light up on both the participant's and the addressee's screen. Thus, the participant's pointing gesture was non-informative, because the addressee saw one of the circles light up on the back screen at the same moment as the participant saw the corresponding circle light up (i.e., even before the onset of the participant's pointing gesture).

The modality factor was manipulated by having participants use either one or two modalities in referring to the circles. In gesture only blocks (G-only), participants pointed to a circle when it turned blue or yellow without producing speech. In gesture + speech blocks $(\mathrm{G}+\mathrm{S})$ participants pointed to the circle and said either die blauwe cirkel ("that blue circle") or die gele cirkel ("that yellow circle"), depending on the color of the circle. Note that, because on every trial only one circle turned blue or yellow, the speech was never informative (neither in the informative nor the non-informative blocks). The rationale for this was that we were interested in the possible effect of the mere presence of speech as a second modality, independently from the informativeness of the deictic act that was manipulated separately in the gesture.

Each trial started with a fixation cross, displayed for 500 ms , followed by the presentation of four white circles. After a jittered period of $500-1000 \mathrm{~ms}$, one of the circles turned yellow or blue. At this point, the participant was allowed to release her finger from a button, pointed to the blue or yellow circle, and named the circle (in the G+S blocks). The experiment consisted of 16 blocks of 20 trials each. Every condition in the experiment was represented by four blocks. The order of presentation of blocks was counterbalanced across participants. In half of the trials a circle lit up yellow, in the other half it lit up blue. The idea behind this was to create a slightly more complex and varied utterances to enhance the ecological validity in this very strictly controlled environment. Each block of 20 trials consisted of ten circles lighting up yellow and ten lighting up blue,
equally distributed over the four circles and the four conditions throughout the experiment, in a randomized way.

## Procedure

At the arrival of the participant, the experimenter explained that a second participant (i.e., the confederate addressee) would perform a behavioral task on the basis of the participant's gesture. The experimenter showed the participant the computer and form to be used by the addressee and demonstrated that the participant could be seen on the computer screen via a camera. Also, it was explained and shown to the participant that the addressee could only see the arm movement of the participant and the computer screen that was at the back of the computer screen that the participant saw. The addressee could not see the head of the participant, to avoid the participant from conveying information via the head and face. In order to keep participants motivated, it was emphasized that they were in a joint activity with the addressee and that the success of this joint activity depended on how well they worked together. The participant was then seated in a comfortable chair in the dimly-lit experiment room. The height of the screen was adjusted to the height of the eyes of the participant. The button used by the participant was placed at the height of the participant's elbow, 23 cm in front of the participant calculated from the vertical axis corresponding to the position of the participant's eyes. Participants were instructed to always rest their finger on this button, except when making the pointing gesture, which allowed calculating the duration and onset of the pointing gesture. A sensor was placed on the participant's right index finger nail to allow for motion tracking of the pointing movements. Participants’ electroencephalogram (EEG) was recorded continuously throughout the experiment. These results will be reported elsewhere.

After montage of the motion tracking sensor the experimenter picked up the addressee. The addressee was shown the room in which the participant performed the task, greeted the participant, and was seated in a chair in front of a computer in a room adjacent to the participant's room. In order to familiarize the participant with the different conditions and the task, thirty-two test-items (eight per condition) preceded the main experiment as a practice set. Participants received specific instructions to point with or without speech before each block. In addition, before each block, the participant was instructed whether the addressee could also see the same circles light up at the back screen or not during that block. Participants were asked to only move their hand and arm when pointing. During the experiment, participants were allowed to have a short break after every fourth block. Before and during the experiment, the communication between experimenter and addressee was minimal and fully scripted, in order to be constant across participants. After the experiment, the addressee was thanked for participation and left the room. Participants were debriefed, financially compensated, and thanked for participation.

## Kinematic recording and analysis

Behavioral and kinematic data were acquired throughout the experiment using experimental software (Presentation, Neurobehavioral Systems, Inc) and a 60 Hz motion tracking system and DTrack2 tracking software (both Advanced Realtime Tracking, Weilheim, Germany). For each trial, the Gesture Initiation Time (i.e. the moment the participant's finger left the button calculated from the moment a circle lit up) was calculated. This measure thus reflected the time it took to plan the pointing gesture. In addition, we collected for each trial the Apex Time (i.e. the moment of the endpoint of the gesture calculated from the moment a circle lit up). The endpoint of the gesture was defined as the point in time where the pointing index finger was at least 7 cm from the button and only moved forward less than 2 mm for two consecutive samples. The Stroke Duration was defined as the interval between the onset of the gesture (i.e., The Gesture Initiation Time) and the moment the apex was reached (i.e., the Apex Time). The Incremental Distance travelled by the pointing index finger was calculated for the complete stroke (similar to Levelt et al., 1985). Further, the Velocity of the hand movement was calculated for each trial on the basis of the Apex Time and the Incremental Distance. The Hold Duration of the pointing gesture was calculated by subtracting the Apex Time from the Retraction Time (i.e., the moment the index finger moved back in the direction of the button for at least 2 mm in two consecutive samples). In the G + S blocks, the Speech Onset Time was calculated from the moment one of the circles lit up. The Synchronization Time was defined as the difference between Apex Time and Speech Onset Time.

## Results

Trials on which the Gesture Initiation Time was below 100 ms or above 2000 ms were considered errors and excluded from all analyses ( $0.7 \%$ of total dataset). In addition, trials containing hesitations or errors in the participant's speech were removed from further analyses ( $0.2 \%$ of all data). Separate analyses of variance were performed for each
dependent variable with Informativeness (Informative versus Non-informative) and Modality (Gesture-only or Gesture+Speech) as within-subject factors.

A first analysis was performed on the Gesture Initiation Time. This analysis did not yield any significant main or interaction effect. Next, we analyzed the Stroke Duration. This analysis yielded a significant main effect of Informativeness, $F(1,23)=10.97, p=.003, \eta_{\mathrm{p}}{ }^{2}=.32$. This effect denoted that the duration of the stroke was significantly longer in the Informative condition ( $M=837$ ms ) than in the Non-informative condition ( $M=823 \mathrm{~ms}$ ). No significant main effect of Modality was found. There was no significant interaction between the two factors. Also an analysis on the Apex Time showed a significant main effect of Informativeness, $F(1,23)=8.15, p=.009, \eta_{\mathrm{p}}{ }^{2}=$ .26. This effect denoted that the apex was reached significantly later in the Informative condition ( $M=1379$ ms ) than in the Non-informative condition ( $M=1359 \mathrm{~ms}$ ). No significant main effect of Modality was found. There was no significant interaction between the two factors.

A further analysis was performed on the Incremental Distance. No significant main or interaction effect was found. Because the same amount of distance was travelled across conditions, but the apex was reached later in the Informative condition than in the Non-informative condition, the velocity of the pointing gesture must have been lower in the Informative condition compared to the Non-informative condition. Indeed, an analysis on the mean Velocity yielded a significant main effect of Informativeness, $F(1,23)=5.75, p=.025, \eta_{\mathrm{p}}^{2}=.20$. The velocity of the pointing gesture was significantly lower in the Informative condition ( $M=38.2 \mathrm{~cm} / \mathrm{s}$ ) than in the Noninformative condition ( $M=38.7 \mathrm{~cm} / \mathrm{s}$ ). Again, no significant main effect of Modality or interaction between the two factors was found. Another analysis, performed on the Hold Duration, yielded a significant main effect of Informativeness, $F(1,23)=10.17, p=.004, \eta_{\mathrm{p}}{ }^{2}=.31$. The Hold Duration was significantly longer in the Informative condition ( $M=1235 \mathrm{~ms}$ ) compared to the Non-informative condition ( $M=1143 \mathrm{~ms}$ ). No significant main effect of

Table 1: Overview of the results per condition in the experiment. Duration in ms is displayed for the Gesture Initiation Time (GIT), Stroke Duration (Stroke), Apex Time (Apex), Hold Duration (Hold), Speech Onset Time (SOT), and Synchronization Time (Sync). Further, the Incremental Distance in cm (Dist) and Velocity in $\mathrm{cm} / \mathrm{s}$ (Velocity) are provided. The standard error of the mean is indicated between parentheses.

| Condition | GIT | Stroke | Apex | Dist | Velocity | Hold | SOT | Sync |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
|  |  |  |  |  |  |  |  |  |
| Informative |  |  |  |  |  |  |  |  |
| Gesture-only | $534(21)$ | $834(30)$ | $1368(42)$ | $51(1)$ | $38.5(1)$ | $1252(135)$ |  |  |
| Gesture + Speech | $550(22)$ | $840(27)$ | $1389(39)$ | $51(1)$ | $37.8(1)$ | $1219(121)$ | $1385(65)$ | $4(54)$ |
|  |  |  |  |  |  |  |  |  |
| Non-informative | $532(22)$ | $819(29)$ | $1351(41)$ | $51(1)$ | $39.0(1)$ | $1138(116)$ |  |  |
| Gesture-only | $841(24)$ | $826(27)$ | $1367(40)$ | $51(1)$ | $38.5(1)$ | $1149(106)$ | $1351(66)$ | $16(54)$ |
| Gesture + Speech |  |  |  |  |  |  |  |  |

Modality was found. There was no significant interaction between the two factors.

In the $\mathrm{G}+\mathrm{S}$ conditions, participants referred linguistically to the circle on the screen while pointing. An analysis on the Speech Onset Time with Informativeness as the only withinsubject factor revealed a significant main effect, $F(1,23)=$ 6.79, $p=.016, \eta_{\mathrm{p}}^{2}=.23$. This effect reflected that the speech onset on average took place significantly later in the Informative condition ( $M=1385 \mathrm{~ms}$ ) than in the Noninformative condition ( $M=1351 \mathrm{~ms}$ ). An analysis on the Synchronization Time did not show a significant main effect of Informativeness ( $p=.16$ ), indicating that the onset of the speech and the apex of the gesture were aligned similarly and independently from the informativeness of the gesture. Table 1 summarizes all results.

## Discussion

Research investigating the production of iconic gestures has found that the form of such gestures changes on the basis of the communicative intent of the speaker-gesturer. Importantly, here we show that also in the case of pointing gestures speaker-gesturers exploit different form parameters as a function of their communicative intent. First, the duration of the stroke of pointing gestures was longer in the informative condition, which led to a gesture with a lower velocity and delayed the moment at which the apex was reached. Presumably participants did this in order to be as precise as possible in pointing to a target, which could be achieved by pointing more slowly. An additional benefit would then be that the addressee would have more time to identify towards which referent the gesture was heading. Second, the post-stroke hold-phase of the gesture was maintained longer, presumably in order to assure that the addressee had enough time to identify which referent the speaker pointed to. The form parameters under investigation here were not affected by the presence of deictic speech. Nevertheless, the onset of speech was synchronized with the moment at which the pointing gesture reached its apex.

A previous study compared a communicative to a noncommunicative situation and found that people may modify the trajectory and endpoint location of their pointing gesture to single out a referent for their addressee (Cleret de Langavant et al., 2011). The current study takes this research a step further by comparing two situations that are both communicative and identical except for the communicative intent of the gesturer. Cleret de Langavant et al. (2011) did not find a difference in the duration of the pointing gesture when comparing their communicative to their non-communicative condition. Here we did find an effect of communicative intent on the duration of the stroke and the post-stroke hold-phase. Thus, in addition to varying the endpoint location and trajectory of a pointing gesture (as in Cleret de Langavant et al., 2011), people may also use the duration of different sub-components of the pointing gesture in order to communicate effectively.

Participants temporally aligned the onset of the deictic linguistic expression with the moment the pointing gesture
reached its apex, regardless of whether the gesture was informative or not. This finding is in line with previous studies showing such temporal alignment of pointing and speech (e.g., Levelt et al., 1985; McNeill, 1992) and with models of speech and gesture production that underline the synchronization of speech and gesture (e.g., De Ruiter, 2000; Krauss et al., 2000). Here we show that this temporal synchrony between deictic speech and gesture is maintained irrespective of the speaker-gesturer's communicative intent.

We found a similar effect of communicative intent in situations where people only used gesture to communicate, compared to situations where speech and gesture were concurrently produced (Clark, 1996; Kendon, 2004). However, in our study, speech was purposefully never informative and very similar across trials, and there is indeed evidence that deictic speech can interact with the form of a simultaneously produced gesture (e.g., Gonseth, Vilain, \& Vilain, 2012). It is therefore possible that whenever speech itself is informative enough to single out a referent, speaker-gesturers no longer design their concurrent gesture to be maximally informative. Future research needs to shed more light on the influence of speech-gesture interaction on the form of deictic gesture and speech while manipulating the informativeness of the speech.

In general, the results of our study fit well with models of speech and gesture production that allow for a role of the speaker-gesturer's communicative intent in modulating the exact form of a gesture, such as the Sketch model (De Ruiter, 2000) and the Interface model (Kita \& Özyürek, 2003). Conversely, our data would argue against models of speech and gesture production that question whether the speaker’s communicative intent plays a role in determining the form of a gesture (e.g., Krauss et al., 2000). In our study, participants had the communicative intention of producing a pointing gesture towards a referent, either accompanied with referential speech or not. The Sketch model, which explicitly describes the production of pointing (in addition to other types of gesture), underlines that upon the intention to produce a pointing gesture, conventions such as which hand shape and finger to use can be retrieved from a knowledge store (called a "gestuary" by De Ruiter, 2000) in memory. This representation of the pointing gesture in the gestuary is only a template or abstract motor program, and there are a number of degrees of freedom that can be varied depending on the context in which the pointing gesture is performed. According to this model, in our study, participants retrieved a pointing gesture template from memory and subsequently exploited the duration of both the stroke (and as such the velocity and the moment the apex was reached) and the post-stroke hold-phase of the gesture as free parameters. Our study thus suggests that duration is a free parameter that people use to vary the execution of their pointing gesture, and further specifies in which specific components of the gesture duration is indeed varied.

The form a pointing gesture takes not only depends on the gesturer's communicative intent. Research has shown that it also depends on physical factors such as the spatial location
of a referent. For instance, people may raise their pointing arm and hand higher when a referent is more distant (Wilkins, 2003). Furthermore, the form of a gesture depends on cultural factors. In different cultures, different body parts are used for pointing (Kita, 2003; Wilkins, 2003). Finally, it may depend on socio-pragmatic factors. In a corpus study on Lao speakers, Enfield, Kita, and De Ruiter (2007) observed a distinction between relatively big points in which the whole arm is outstretched and relatively small points in which the hand is the main articulator. They argue that this difference in form is related to the pragmatic function of the utterance a gesture occurs in. Big points would do the primary work of an utterance, such as pointing out the location of an object, whereas small points would occur in utterances in which speech is central, adding a background modifier on the basis of social factors such as the common ground between interlocutors (p. 1738). Future studies could investigate interactions between such different physical, cultural, socio-pragmatic, and communicative factors.

To conclude, our study showed that people exploit the duration of the stroke (and as such its velocity and the moment the apex is reached) and the post-stroke hold-phase of their pointing gesture to communicate effectively. Thus, the form of a pointing gesture varies as a function of the speaker-gesturer's communicative intent. Similarly to iconic gestures, the form of pointing gestures is dependent, among other factors, on the context-bound communicative relation between speaker-gesturer and addressee.

# Comprehending with the body: Action compatibility in sign language? 

Pamela Perniss (p.perniss@ucl.ac.uk), David Vinson (d.vinson@ucl.ac.uk),<br>Neil Fox (neil.fox@ucl.ac.uk), Gabriella Vigliocco (g.vigliocco@ucl.ac.uk)<br>Department of Cognitive, Perceptual and Brain Sciences, 26 Bedford Way, WC1H 0AP London, UK

#### Abstract

Previous studies show that reading sentences about actions leads to specific motor activity associated with actually performing those actions. We investigate how sign language input may modulate motor activation, using British Sign Language (BSL) materials, some of which explicitly encode direction of motion, vs. written English, where motion is only implied. We find no evidence of action simulation in BSL comprehension, but replicate effects of action simulation in comprehension of written English. The results suggest that the perception of motor articulation in the language input interferes with mental simulation involving the motor system.

Keywords: embodiment; sign language; motor system; action-compatibility effect

## Introduction

There is now a body of evidence for an embodied view of language, according to which language comprehension is based in our bodily experience of the world and involves the same systems necessary for bodily experience. The grounding of language in perception and action has been evidenced in a wide range of behavioral and neuroscientific studies (e.g. Barsalou, Barbey, Simmons \& Wilson, 2003; Barsalou, 2008; Beauchamp \& Martin, 2007; Gallese \& Lakoff, 2005; Glenberg \& Kaschak, 2002; Glenberg \& Gallese, 2012; Zwaan \& Kaschak, 2008). For example, Stanfield and Zwaan (2001) have shown that sentence comprehension involves the activation of specific imagery related to the perceptual and action properties of an event. Participants were faster to verify that a pictured object (e.g. nail) appeared in a preceding sentence when the orientation of the object (e.g. horizontal vs. vertical) in the picture matched that implied in the sentence (e.g. John hammered the nail into the wall). Neuroscientific studies have likewise pointed to specific involvement of motor areas in understanding language related to action. For example, as found by Tettamanti, Buccino, Saccuman, Gallese et al. (2005) in an fMRI study, reading sentences describing actions using specific body parts (e.g. I bite the apple, I kick the ball) activates the area in the motor cortex related to physical use of that body part (e.g. mouth for bite, foot for kick) (see also Hauk, Johnsrude \& Pulvermüller, 2004).

The Action-Sentence Compatibility Effect (ACE), first demonstrated by Glenberg and Kaschak (2002), provides further compelling evidence that we involve our sensorimotor system in language comprehension by mentally simulating the actions and events encoded in language. In the Glenberg and Kaschak (2002) study, participants were presented visually with written sentences that implied either motion toward (Andy delivered the pizza to you) or away
from (You delivered the pizza to Andy) the body. Participants were asked to judge sentence sensibility by responding with a button press that required movement of the arm either toward or away from the body - i.e. in a direction congruent or incongruent with the direction of motion implied by the sentence. Participants were faster to respond to sentences when the implied motion was congruent with the response direction. This was true of sentences implying transfer in both the concrete and abstract domains (e.g. You communicated the message to Adam). In a related study, Borreggine and Kaschak (2006) provided evidence for the ACE when the same English sentences were presented to participants auditorily, unfolding in real time. The Action-Sentence Compatibility Effect suggests that sentence comprehension involves a dynamic mental simulation of the event, in this case, a motor simulation of performing the described action.

As the evidence supporting sensori-motor system involvement in language comprehension accumulates, we must also address the question of how this embodiment comes about. How does language come to be grounded in our bodily experience and what are the mechanisms by which language processing engages the sensori-motor system (cf. Perniss, Thompson \& Vigliocco, 2010)? Moreover, there is much debate about how embodiment effects may be modulated by context (cf. Willems \& Casasanto, 2011), and how effects may be constrained by different properties of language.

In this context, the strong role of action/motor simulation in sentence comprehension demonstrated by the ACE effect raises an interesting question with respect to the modality of language presentation. Neither the written visual nor the spoken audial presentation of sentences involves the physical use of the motor system. This situation is very different, however, in the case of sign languages. In sign languages, the natural languages of deaf people, meaning is encoded through movement of the hands and arms through the space on and in front of the body. The visual medium of sign language moreover affords a high degree of iconicity, or resemblance between linguistic form and meaning. This potential is exploited particularly for encoding sensorimotor information, such that meanings related to action and motion are expressed in highly iconic linguistic forms. Thus, many sign language verbs encoding transfer of the type studied by Glenberg and Kaschak (2002) explicitly realize directionality of motion in the event through a corresponding movement of the hands through space (i.e. toward or away from the body).

To date, embodiment effects have been studied looking at spoken/written language. Extending the investigation of
embodiment to language expressed in the visual modality, where the same motor articulators that perform nonlinguistic actions are used to encode actions linguistically, is an important step to understanding the nature of embodiment, and the conditions under which embodiment effects come about. The simulation effects observed in action sentence comprehension may well be modulated or constrained by inherent properties of language, particularly related to language modality and the potential for iconic representation. To address this question, we ask here how the iconic and motor properties of visual language may affect action simulation in sign language sentence comprehension?

One possible outcome is that we find an effect of action simulation in sentence comprehension consistent with what has been shown for English. The perception of motor action in language, where the linguistic (i.e. phonological) expression of action verbs is realized through directional motion, could boost the involvement of motor simulation in sentence comprehension. In this case, participants should be faster to respond in a direction corresponding to the event (and its realization in sign language), compared to when the response direction is incongruent with the event. It is also possible, however, that we observe an effect in the opposite direction, as the interpretation of the signed sentences may involve mentally taking the perspective of the signer producing them, as we discuss below.

An alternative outcome is that motor simulation of the encoded event in comprehension may be reduced or eliminated by the involvement of the motor system in the articulation of the action. Because viewing sign language means viewing physical movement of the same articulators necessary for the action simulation (here, arms and hands), the simulation itself may be blocked or even unnecessary. Thus, a contrasting prediction is that viewing sentences presented in a sign language would not yield an ACE effect.

To test these contrasting predictions, we investigate ACE effects in deaf users of British Sign Language (BSL).

## Experiment 1

We sought to replicate the Glenberg and Kaschak (2002) study using close translations of the original English sentences into BSL. All of the experimental sentences in this study implied directional motion, with equal numbers of sentences referring to motion toward the body and motion away from the body. Within these, half referred to concrete transfer events (as in You delivered the pizza to Andy) and half to abstract transfer events (as in You communicated the message to Adam).

The BSL sentences not only preserved the specific events described by the English sentences but also their $2^{\text {nd }} / 3^{\text {rd }}$ person reference structure. In BSL, as in other sign languages, person reference is achieved by directing signs at locations in space associated with the entities being talked about. Second person (you) is associated with a location directly opposite the signer, the canonical location of an
addressee. ${ }^{1}$ Third person (he/she/it) is associated with a location to the right or left of the signer. The body of the signer, specifically a location at the center of the signer's chest, is associated with first person ( $I$ ). Points to the appropriate locations indicate the arguments, e.g. subject and object, of a verb. In addition, verb signs themselves -so-called directional predicates - can indicate arguments by physically moving between the locations associated with the arguments. ${ }^{2}$

This is illustrated in the BSL example sentence shown in Figure 1, which corresponds to English James awarded the degree to you. In the example, $3^{\text {rd }}$ person reference to James is achieved in stills 2-3 of the figure, consisting of a sign for the letter ' J ' (for James), in still 2, followed by a pointing sign to a $3^{\text {rd }}$ person location to the right of the signer's body, in still 3. The predicate in the final still conveys the meaning he awards to you by moving from the $3^{\text {rd }}$ person location associated with James to the $2^{\text {nd }}$ person location - outward from and opposite the signer's body - associated with the participant/addressee viewing the sentence. Thus, in the BSL version of James awarded the degree to you, participants see the predicate move toward them, in the same way as the actual event would involve movement toward them. In the experiment, participants perceived directional verbs like award-to moving either toward or away from them, congruent with the direction of the event.

Figure 1: Glossed example of BSL sentence. (English translation: James awarded the degree to you.) The sentence includes a directional verb that moves from $3^{\text {rd }}$ to $2^{\text {nd }}$ person. The perceived motion in viewing the sentence is thus toward the participant's/addressee's body.

Not all predicates in BSL are directional, however, in this way. Translation of the set of verbs that appears in the original Glenberg and Kaschak (2002) study ignores a crucial contrast between directional vs. non-directional verb types in BSL. In non-directional predicates, the form of the verbs is the same regardless of the direction of the event (e.g. in the verb write, the hands represent writing at a location in front of the body regardless of who is writing to whom). Only directional predicates encode the direction of the event by moving between the locations associated with their arguments. (See the schematizations of verb types and direction used across experiments provided in Figure 2.)

[^185]A second set of sentences was designed to address this issue. This set encoded semantically similar events from those of Glenberg and Kaschak (2002), but using different verbs, in order to manipulate the number of directional vs. non-directional verbs that appeared in the sentences. This is important because the ACE effect hinges on the simulation of directional motion, and may be influenced here by the congruence of perceived phonological motion with the motion entailed by the event itself.

Figure 2. Schematization of verb types, person reference, and direction used across Experiments 1 and 2.

## Method

Participants 16 deaf adult signers of BSL were recruited from the greater London area. BSL age of acquisition ranged from $0-13$ years (mean 3.13; with 9 native signers who acquired BSL from birth). Participant age ranged between 19-59 years (mean age 34.69). All participants had normal or corrected to normal vision.

Materials For Experiment 1a, the original English sentences (Glenberg \& Kaschak, 2002) were translated into BSL by a native deaf BSL signer, and proficient BSLEnglish bilingual. BSL sentences were videotaped and edited into single sentence clips. All sentences depicted transfer from $2^{\text {nd }}$ to $3^{\text {rd }}$ or from $3^{\text {rd }}$ to $2^{\text {nd }}$ person, corresponding with direction of motion toward or away from the body, respectively (see Figure 1). 20 abstract and 20 concrete events were included, with two sentences depicting each event (one toward the body, one away). 40 nonsense sentences were also filmed, again closely resembling those used by Glenberg and Kaschak (2002). Different test lists were created so that each participant saw only one sentence referring to a given event, with equal numbers of abstract/concrete, toward/away sentences. Sentences were randomly ordered for each participant.

For Experiment 1b, we constructed BSL sentences around events involving 16 directional verbs and 13 non-directional verbs. ${ }^{3}$ For each verb we created four sentences, two sensible sentences (one toward the body, one away from the

[^186]body) and two nonsense sentences (one toward, one away). Each participant saw all four sentences involving a given verb, with materials divided into four blocks so that each verb occurred only once per block and so that conditions were approximately balanced within each block. Order of blocks and order of trials within a block were randomly ordered for each participant. In both experiments, we treated nonsense sentences as fillers, only analyzing the effects of implied directional motion in sentences depicting real events.

Procedure Participants sat directly opposite a computer screen with a response box oriented sagittally in front of them, and were told they would see BSL sentences addressed to them. Participants were prompted to press and hold the middle of three buttons on the response box upon the appearance of a fixation cross in the middle of the screen. Upon pressing the button, a video clip of a BSL sentence began to play, and continued to play as long as the middle button was held down. Participants judged the sensibility of the sentence by moving their finger to press a button either away from or toward their body from the middle button (i.e. to the near or far button on the response box). Participants were told to respond as quickly and accurately as possible. We measured the time it took for participants to release the central button, thus tapping into the motor planning necessary to make their responses (see Borreggine \& Kaschak, 2006). Participants came for two sessions, which differed only in the direction of the response for sensible sentences (toward vs. away from the body), with the order of response per session counterbalanced across participants. Experiments 1 a and 1 b were carried out separately in each session, again with the order counterbalanced across participants.

## Results

We analyzed only responses for sensible sentences, excluding errors and using button release latencies as the dependent measure. We analyzed Experiment 1a using $2 \times 2$ ANOVA (sentence direction $\times$ response congruence). The main effect of sentence direction was not significant; $F(1,15)=3.260, p=.091$ : a tendency for faster responses for transfer toward the body. Neither the main effect of response congruence and interaction were significant ( $F<1$ ).
For Experiment 1 b we conducted $2 \times 2 \times 2$ ANOVA also including the factor of verb type (directional vs. nondirectional). There was a main effect of sentence direction $\left(F(1,15)=6.772, \quad p=.020, \quad \eta_{\text {partial }}^{2}=0.311\right)$; the sentences moving toward the body were faster than those moving away from the body. There was also a main effect of verb type $\left(F(1,15)=124.933, p<.0001, \eta_{\text {partial }}^{2}=0.891\right)$; sentences with non-directional verbs were much faster than sentences with directional verbs (2091 vs. 2271 msec respectively), likely due to differences in sentence durations (e.g. directional verbs may take longer on average to execute than non-directional verbs). There was also an interaction between verb type and sentence direction $(F(1,15)=10.442$,
$p=.006, \eta_{\text {partial }}^{2}=0.410$ ), again presumably related to differences in verb durations. Crucially, the main effect of congruence was not significant $(F<1)$, nor were any of the interactions involving congruence (congruence $\times$ direction $F(1,15)=1.453, p=.247$; congruence $\times$ verb type, $F<1$; 3way interaction $F(1,15)=3.702, p=.074)$. See Figure 3.

We found no ACE effect: there was no main effect of response congruence, nor any interactions involving it. ${ }^{4}$

Figure 3: Results of Experiment 1a (left: BSL replication of Glenberg \& Kaschak, 2002) and 1 b (right: BSL $2^{\text {nd }} / 3^{\text {rd }}$ person comparing directional/non-directional verbs). We report correct button release times to sensible sentences as a function of sentence direction (Away (from) or Toward the body) and whether the response direction is congruent or incongruent with the directional event being described. Error bars reflect standard error of the mean (by subjects).

## Discussion

In Experiments 1a and 1 b we did not find an ACE effect; responses were not faster when the sentence implied an event moving in the same direction as the hand action required to make a sensibility decision. Furthermore, in Experiment 1 b there was no difference in response times between when the direction of motion entailed by the action was encoded phonologically (directional verbs) vs. when it was not (non-directional verb). This implies that the lack of action simulation - and thus lack of motor system involvement - may be related to perceiving sign language, which is produced by means of motor movement of the same articulators involved in the actual action event.

However, it may be the case that ACE requires that the direction of the button press converge with the direction of the event. In the $2{ }^{\text {nd }} / 3^{\text {rd }}$ person transfer used in Experiments 1 a and 1 b , the BSL directional verbs move diagonally, offset approximately $45^{\circ}$ from the center of the producer's body and offset approximately $45^{\circ}$ from the participant's direction of response (see Figure 2). If sentence compatibility effects require close directional convergence between the sentence judgment response and the simulated event, this discrepancy could reduce or eliminate ACE effects. Finally, if the lack of an effect in Experiments 1a and 1 b is due to the use of sign language in the task, we should be able to observe an ACE effect in the same

[^187]participants when they are reading English sentences. Obtaining an ACE effect using English is especially important in the face of the null effects we have reported here, showing that our procedure is sound and our participant number large enough to find evidence for ACE, if it were there.

## Experiment 2

Experiment 2a assesses whether the lack of convergence between the direction of motion encoded in the event and the response direction modulates simulation effects. We use BSL sentences that imply transfer between $1^{\text {st }} / 2^{\text {nd }}$ person, thereby maximizing the overlap in directionality. Sentences that encode transfer between $1^{\text {st }} / 2^{\text {nd }}$ person (e.g. I awarded the degree to you) involve phonological movement between the signer's body ( $1^{\text {st }}$ person) and a location opposite the signer's body ( $2^{\text {nd }}$ person). Thus, directional verbs move along the central axis, straight toward or away from the body. This modification of person reference in verbs creates complete directional convergence with the direction of button press response and with the direction of motion entailed by the actual action event. We otherwise used exactly the same materials and procedures as in Experiment 1b, where directional vs. non-directional verbs are compared.

Experiment 2 b assesses whether the lack of an effect in Experiment 1 is indeed specific to the use of sign language. The same (BSL-English bilingual) participants who took part in Experiment 2a, also carried out the original experiment by Glenberg and Kaschak (2002) with visual presentation of written English sentences.

## Method

Participants A new group of 16 deaf adult BSL-English bilinguals ${ }^{5}$ were recruited from the greater London area. BSL age of acquisition ranged from 0-11 years (mean 3.85; with 7 native signers who acquired BSL from birth). English age of acquisition ranged from 0-5 years (mean 2.19). Ages ranged between 18-59 years (mean age 30.75). All participants had normal or corrected to normal vision.

Materials BSL materials for Experiment 2a were the same as for Experiment 1 b , but all sentences depicted transfer from $1^{\text {st }}$ to $2^{\text {nd }}$ or from $2^{\text {nd }}$ to $1^{\text {st }}$ person. For the written English experiment, we used the original set of sentences from Glenberg and Kaschak (2002). List creation, task order etc. were the same as in Experiment 1.

Procedure The procedure was the same as in Experiment 1. For English sentences (Experiment 2b), participants saw the written English sentence appear in the middle of the screen.

[^188]
## Results

As in Experiment 1 we analyzed only the responses for sensible sentences, excluding error trials and using button release latencies as our dependent measures. We analyzed Experiment 2 a using $2 \times 2 \times 2$ ANOVA also including the factor of verb type (sentence direction $\times$ response congruence $\times$ verb type). None of the main effects reached significance (congruence $F<1$; direction $F(1,15)=2.299$, $p=.150$; verb type $F(1,15)=2.681, p=.122$ ), nor did any of the interactions (congruence $\times$ verb type, $F(1,15)=1.246$; $p=.282$; three-way interaction $F(1,15)=3.082, p=.1001$; all other $F<1$ ). As in Experiments 1a and 1b we found no ACE effect in BSL. ${ }^{6}$
We analyzed Experiment 2 b using $2 \times 2$ ANOVA. Here we found a main effect of congruence $(F(1,15)=10.888, p=.005$, $\left.\eta_{\text {partial }}^{2}=0.421\right)$ : an ACE effect in written English. There was a marginal main effect of sentence direction $(F(1,15)=4.353$, $p=.054$ ) and no interaction $(F<1)$. See Figure 4.

Figure 4: Results of Experiment 2a (left: BSL $1^{\text {st }} / 2^{\text {nd }}$ person comparing directional/non-directional verbs) and $2 b$ (right: English replication of Glenberg \& Kaschak, 2002 with BSL signers). We report correct button release times to sensible sentences as a function of sentence direction (Away (from) or Toward the body) and whether the response direction is congruent or incongruent with the directional event being described. Error bars reflect standard error of the mean (by subjects).

## Discussion

As in Experiment 1a and 1b, we find no ACE effect in Experiment 2a: responses to BSL sentences are no faster when the direction of response is congruent with the event depicted by a sentence. But we find reliable ACE effects in English (Experiment 2b), replicating the original Glenberg and Kaschak (2002) study with exactly the same participants as in Experiment 2a. Finding an ACE effect in English vs. no such effect in BSL, in the same population, suggests that action simulation is involved in language comprehension when visually perceiving written language, but not when perceiving signed language.

[^189]
## General Discussion

We assessed whether the same effects of action simulation observed during comprehension of English directional sentences can be observed in the comprehension of BSL directional sentences. The ACE effect has been argued to demonstrate that sentence comprehension relies on simulation of the actions encoded in the sentences. Specifically, the ACE effect shows that sentence comprehension is facilitated when the action implied by a sentence is directionally congruent with the action required to judge sentence sensibility.

Operating in the visual-spatial modality, sign language necessarily involves motor movement and utilizes the high potential for action iconicity that the medium affords. These properties of sign language led us to propose two possible outcomes regarding the role of action simulation in sign language comprehension: the action simulation is either boosted or blocked.

We found no evidence for an ACE effect in BSL sentence comprehension across three experiments ( $1 \mathrm{a}, 1 \mathrm{~b}, 2 \mathrm{a}$ ). The results thus suggest that viewing sign language does not engage the motor system in comprehension in the way that has been found for written and spoken presentation of English sentences. These results do not come about because of lack of power: we observed an ACE effect with the same participants when presented with English written sentences. This finding also indicates that it is not knowing a sign language per se that modulates the use of action simulation in sentence comprehension (i.e. in a second language).

The results further suggest that it is not the iconicity between the direction of motion of the action signs and the actual actions that blocks the involvement of action simulation in comprehension, as there was no difference found between directional vs. non-directional verbs.

Why then do we fail to see an ACE effect in BSL? A first possibility is that the lack of involvement of the motor system in comprehension may be related to perceiving the physical engagement of the motor articulators. This engagement would block the system from engaging in sentence simulation. It is also possible that the involvement of our sensori-motor systems in language comprehension depends on the format in which language is presented. The ACE effect has been found previously, and replicated here, only for language presented in a unichannel format - the written or the spoken word. These unichannel formats are not directly evocative of the events encoded in the sentences, they have no explicit visual correspondence to the events being described. They are impoverished in this sense compared to the rich, depictive event representations provided by the visual modality of signed language. Thus, it may be that an "impoverished" unichannel language representation relies on action simulation in comprehension, while a richer, multichannel language presentation - particularly involving depictive, iconic representation - does not. The action may not need to be "filled in" or simulated in the context of a rich, depictive representation of the event.

We cannot rule out, however, that the iconic properties of sign language action predicates play a role in affecting the involvement of the motor system. Even the non-directional verbs, which do not overtly encode the direction of motion of the action, were often iconic of the action in some way (e.g. BSL pour which resembles pouring a liquid, but does not vary in its direction depending on who is doing the pouring). Such iconic properties may engage the same effectors in simulation, perhaps with other aspects of the event such as hand configuration and orientation being more salient than generic aspects of directional motion. Our results also do not rule out the possibility that the perception of motor movement at all, and particularly non-iconic movement, may block the involvement of the motor system in comprehension.

Finally, there are a number of further modality-related differences between English and BSL that might have played a role in our study. First, the temporal unfolding of the event is different. Secondly, word order differences may play a role. While the English sentences follow a rigid Subject-Verb-Object order, the BSL sentences typically had the verb in final position (a word order common to many sign languages). Future research on ACE effects in spoken languages with verb-final word order, e.g. Japanese or Turkish, would be illuminating in this regard.

Another issue that bears further investigation relates to perspective-taking in sign language comprehension. Specifically, though participants were informed that they would see BSL sentences addressed to them, sentence comprehension may have involved mentally taking the signer's perspective. If participants mapped their own body onto that of the sign model producing the sentences, mentally imitating the sign model's motor production, this would create a conflict between the congruence between sentence direction and response direction. However, if this were the case, it is likely that we would have seen an ACE effect in the opposite direction. As no effect whatsoever was observed in the BSL versions of the experiments, we do not assume this to have played a role.

Thus, our research suggests that the involvement of action simulation in language comprehension is dependent on the format and modality of language presentation. This is important to our understanding of the conditions under which and the degree to which language comprehension involves simulation. The idea that the use of action simulation may be contextually dependent is in line with previous observations that contextual variables (e.g. abstract vs. concrete contexts) modulate effects of embodiment in terms of differential activation of sensori-motor representation in language processing (Mahon \& Carramazza, 2007; Willems \& Casasanto, 2011 for a review). Context dependency of the degree to which embodiment (i.e. the involvement of sensori-motor systems) is evident in language comprehension demonstrates a fundamental flexibility, rather than rigidity, of the architecture of language processing.

#### Abstract

Eye gaze and behavioral mimicry are important foundations of social interaction. Inspired by recent studies on eye-gaze mediated spontaneous behavioral mimicry of gestures, we studied the effect of eye gaze direction on vocal mimicry. Participants were instructed to repeat digits spoken by a virtual agent with a direct or averted eye gaze. As a measure of imitation, the vocal pitch was recorded and analyzed in order to determine if and to what extent vocal mimicry was modulated by eye gaze. The results showed that eye gaze direction affects vocal mimicry as measured by pitch slope. That is, when participants were exposed to an agent that gazed at them directly, they accommodated their intonation more to that of the agent, than when they were exposed to an agent that averted its gaze. These results suggest that in social interaction with a virtual agent, humans mimic vocal intonation and that the degree of mimicry depends on the eye-gaze direction of the agent. The implications for studies of social interaction are discussed.

Keywords: Eye Gaze; Vocal Mimicry; Virtual Agent

## 1. Introduction

In social interaction, eye gaze direction and behavioral mimicry are powerful nonverbal social signals (Stass \& Willis Jr, 1967; Kendon, 1967; Scherer, 1974; Cook \& Smith, 1975; Fukayama, Ohno, Mukawa, Sawaki, \& Hagita, 2002; Mason, Tatkow, \& Macrae, 2005; Baaren, Janssen, Chartrand, \& Dijksterhuis, 2009; Wang, 2012). Among different types of nonverbal cues, vocal pitch mimicry appears to play a fundamental role. The results of a range of experimental studies suggest that speakers effortlessly imitate and converge to the phonetic properties of recently heard speech (Delvaux \& Soquet, 2007; Gentilucci \& Bernardis, 2007; Natale, 1975; Pardo, 2006; Shockley, Sabadini, \& Fowler, 2004), including pitch (Babel \& Bulatov, 2012; Goldinger, 1998; Gorisch, Wells, \& Brown, 2012). Pitch - the perceptual correlate of fundamental frequency $\left(F_{0}\right)$ - is, arguably, the most important vocal source of information regarding emotions, stands and attitudes of the speaker. The $F_{0}$ region thus provides acoustic information for imitation exploited in promoting social convergence and status accommodation (Gregory, 1983; Gregory, Webster, \& Huang, 1993; Gregory \& Webster, 1996; Gregory, Dagan, \& Webster, 1997; Haas \& Gregory, 2005; Pardo, 2006) and expressing ingroup-outgroup bias (Babel, 2009; Pardo, Gibbons, Suppes, \& Krauss, 2012).

According to the Communication Accommodation Theory (CAT), in social interaction, people adjust their vocal characteristics to accommodate to each other (Giles, Coupland, \& Coupland, 1991). Support for CAT came from a study by (Gregory \& Webster, 1996), who analyzed Larry King Live television interviews. The results revealed that depending on the relative status of the interviewed guest, Larry King mimicked the vocal characteristics of his guests (in case of high status guests) or the guests mimicked the vocal characteristics of Larry King (in case of low status guests). In general, speakers who are perceived as attractive, likable and/or dominant influence listeners' pitch output, and pitch convergence can be seen as an indicator of cooperative behavior in communication dyads (Okada, Lachs, \& Boone, 2012). Pitch divergence, on the other hand, suggests that speakers may wish to be viewed as dissimilar and increase social distance between themselves (Babel, 2009).

Interestingly, empirical studies have shown that in social interactions, the direction of eye gaze influences the degree of behavioral mimicry (Kleinke \& Pohlen, 1971; Chartrand \& Bargh, 1999). A striking demonstration of the direct link between eye gaze direction and behavioral mimicry is due to Wang, Newport, and Hamilton (2011). In their study, participants were presented with a movie of an actress that either looked directly at the camera or averted her gaze from the camera. In both conditions there were movies of the actress opening her hand and movies in which she closed her hand. At the beginning of each trial, participants were instructed to either open or close their hand. The instructed hand movements could be congruent or incongruent with the displayed hand movements of the actress. After receiving the instruction, participants had to make the hand movement as quickly as possible. They were not instructed to mimic the hand movement of the actress. Not surprisingly, participants were significantly faster in making congruent hand movements than in making incongruent ones. Interestingly, though, the congruent hand movements in the direct gaze condition were considerably faster than those in the averted gaze condition, whereas for the incongruent hand movements gaze direction had no effect. These findings reveal that eye contact has a quick and specific effect on action mimicry.

Inspired by these results, we expect eye-gaze modulated mimicry in other response modalities, such as the vocal modality. Although vocal mimicry is a well-known phenomenon, the modulating effect of eye gaze has not yet been explored experimentally. The aim of this study is to investigate if vocal mimicry is modulated by eye gaze direction.

Instead of exploring the effect of eye gaze on reaction times, we determined its effect on the degree of vocal mimicry. We employed an experimental setting in which a virtual agent with either an averted or direct gaze utters single words with one of three pitch contours. The participants were instructed to repeat the words, but were not instructed to mimic the pitch contours (instead, they were distracted with another task).

## 2. Experiment

## Participants and Design

Forty-seven Dutch native speakers ( 24 male; mean age $21 ; 4$ ) were recruited from the Tilburg University student population. The experiment had a one-way within-subjects design with Eye Gaze Direction (direct, averted) as the independent variable and Vocal Mimicry as the dependent variable.

## Material

The stimulus material consisted of 8 visually presented words during which we measured speakers' baseline pitch, followed by 48 videos ( 16 experimental trials +32 distractors). Eight of the 16 experimental trials involved direct gaze of the agent (top figure 1), during the other 8, the agent either averted his gaze left or right (4 times each). In half of the distractor movies and only in these movies, the agent blinked his eyes; the ratio of gaze directions was 8:4:4 for direct:left:right in the blinking distractor group as well as in the no-blinking distractor group. In every stimulus, the agent expressed a single word (all Dutch monosyllabic digits between 0-10, in order to prevent possible emotional associations to the stimuli that might affect the speaker's pitch), followed by a blank screen.

The virtual agent was created with Poser (Smitch Micro Software inc, Aliso Viejo, California, U.S.), see Figure 1. The agent's lip movements were matched to the pre-recorded words and subtle head and eye movements were added to enhance the realism and to prevent the agent from being perceived as threatening (Ellsworth, 1975; Cook \& Smith, 1975; Argyle, Lefebvre, \& Cook, 1974). A film strip of a sample movie is shown in Figure 2.

The sound files used for the agent's voice were prerecorded in a sound attenuated booth by the second (male) author. His pitch values represented average vocal values for an adult male speaker in the Netherlands (i.e., in the 70-250 Hz range). Three different intonations were used in these recordings (a falling, a rising, and a late-rising tune, see Figure 3). Each movie lasted approximately 5 s , including a 0.5 s fade-from-black and fade-to-black to (i) smooth the transition between consecutive movies, (ii) mark the beginning and end of each stimulus, and (iii) avoid an unnatural and potentially
threatening gaze duration.

## Procedure

The experiment was set up in E-Prime (Psychological Software Tools Inc, Pittsburgh, Pennsylvania, USA) and presented with the help of a Dell Latitude E5510 laptop and a Trust HS-2100 headset. The distance between the participant's mouth and the headset's microphone was kept constant. For the baseline recordings, participants were presented with a random sequence of eight consecutive digits displayed

Figure 1: Impression of the virtual agent used in the experiment. From top to bottom: direct gaze, right averted gaze (while blinking in a distractor movie), and left averted gaze (while speaking).

Figure 2: Film strip of a sample movie as used in the experiment.
in white against a blue background. They were instructed to read each word out loud. Subsequently, they were shown a randomized sequence of videos in which the agent pronounced a digit and were instructed to repeat it. In order to ensure that the participants fixated the agent's eye region and did not focus on the imitation task, they were given the additional instruction to press the space bar whenever the agent blinked. The full length of the experiment was 10 minutes on average.

Figure 3: Graphical representations of the three different intonation patterns of the spoken digits as pronounced by the EIA (second experimenter's voice). From top to bottom: falling intonation, rising intonation, and late-rising intonation (in Hz ).

## Measurements

The experimental audio files collected during the experiment (1128 in total) were manually preprocessed to remove unvoiced speech and silent segments. After establishing the appropriate pitch threshold and ceiling for each individual voice, by auditory and visual inspection of the audio file and spectrogram, respectively, we extracted the pitch contour using the standard autocorrelation-based pitch detection function of Praat (Boersma, 2001). The frequency values were converted to semitones to allow for a comparison of male and female speakers (Borden \& Harris, 1980). For each audio file, we determined the values of two measures of pitch contour: pitch slope $\left(P_{\text {deriv }}\right)$ and pitch regression $\left(P_{\text {regline }}\right)$. The pitch slope is defined as the average difference of adjacent frequencies in the pitch contour. The pitch regression is defined as the slope of the linear regression line through the points making up the pitch contour.

Our measure of vocal mimicry is based on two variables. The first variable $\Delta_{P_{\text {baseline }}}$ is the absolute difference between the agent's pitch, $P_{\text {agent }}$ and the participant's baseline pitch, $P_{\text {baseline }}$, i.e., the pitch of the participant before repeating the agent.

$$
\begin{equation*}
\Delta_{P_{\text {baseline }}}=\left|P_{\text {agent }}-P_{\text {baseline }}\right| \tag{1}
\end{equation*}
$$

The second variable $\Delta_{P_{\text {rep }}}$ is the absolute difference between the agent's pitch and the participant's pitch while repeating the agent, $P_{\text {rep }}$.

$$
\begin{equation*}
\Delta_{P_{\text {rep }}}=\left|P_{\text {agent }}-P_{\text {rep }}\right| \tag{2}
\end{equation*}
$$

By subtracting the values of $\Delta_{P_{\text {baseline }}}$ and $\Delta_{P_{\text {rep }}}$, we obtain our measure of vocal mimicry $M_{V}$.

$$
\begin{equation*}
M_{V}=\Delta_{P_{\text {baseline }}}-\Delta_{P_{\text {rep }}} \tag{3}
\end{equation*}
$$

A positive value of the vocal mimicry $M_{V}$ indicates vocal mimicry, whereas a negative value indicates vocal complementarity. The value of vocal mimicry was calculated both for the pitch slope and the pitch regression separately.

## 3. Results

We start by reporting the vocal mimicry results regardless of eye gaze direction. Subsequently, we report the gazedependent vocal mimicry results. Non-parametric tests were used for data that were not normally distributed.

## Vocal Mimicry Results Independent of Gaze Direction

A Wilcoxon Signed-rank test was performed to establish if vocal mimicry occurred. Effect size estimates were computed using $r(=|Z / \sqrt{N}|)$, where $N$ equals the number of samples. The results for $P_{\text {deriv }}$ and $P_{\text {regline }}$ indicated a significant difference between the baseline and the experimental trial measurements, with a shift in the direction of the agent's pitch (see Table 1). Figures 4 and 5 illustrate the results: Both figures show the median values of the absolute differences between the agent's and the participant's pitch in the baseline and the repetition trial, with the results for males and females plotted separately.

Table 1: Results of Wilcoxon Signed-rank test for mimicry regardless of eye gaze direction (pitch measurements reported in semitones).

|  | $\Delta_{P_{\text {baseline }}}$ | $\Delta_{P_{\text {rep }}}$ | $Z$ | $r$ | $p$ |
| :--- | :--- | :--- | :--- | :--- | :--- |
| $P_{\text {deriv }}$ |  |  |  |  |  |
| Females | 41.473 | 37.926 | -2.829 | 0.417 | 0.005 |
| Males | 41.012 | 38.252 | -2.543 | 0.367 | 0.011 |
| Total | 41.813 | 37.926 | -3.852 | 0.397 | $<0.001$ |
| $P_{\text {regline }}$ |  |  |  |  |  |
| Females | 0.837 | 0.301 | -3.041 | 0.448 | 0.002 |
| Males | 0.847 | 0.255 | -3.114 | 0.449 | 0.002 |
| Total | 0.841 | 0.668 | -4.360 | 0.450 | $<0.001$ |

Figure 4: Plot of the results obtained for $P_{\text {deriv }}$ absolute differences with error bars ( $95 \% \mathrm{CI}$ ).

Figure 5: Plot of the results obtained for $P_{\text {regline }}$ absolute differences with error bars ( $95 \% \mathrm{CI}$ ).

These results indicate that participants accommodated the slope and regression line of their pitch contours to that of the agent. On both measures, when the dataset was split by gender, male and female participants showed similar effects.

## Vocal Mimicry Results Dependent on Gaze Direction

The results of the Wilcoxon Signed-rank test (Table 2) show a significant effect of gaze: compared to the participant's baseline, the slope of the pitch contour in the participant's repetition is more similar to that of the agent gazing towards the participant, than when the agent averted its gaze. A split-file analysis by gender showed a significant effect for male participants only. The medians of $P_{\text {deriv }}$ are visually presented in Figure 6, indicating cases of divergence in the condition with averted gaze in the male participant group.

Table 2: Results of Wilcoxon Signed-rank test for mimicry as measured by $P_{\text {deriv }}$ depending on eye gaze direction.

|  | Median | Median |  |  |  |
| :--- | :--- | :--- | :--- | :--- | :--- |
|  | $M_{V}$ | $M_{V}$ |  |  |  |
|  | Direct | Averted | $Z$ | $r$ | $p$ |
| $P_{\text {deriv }}$ |  |  |  |  |  |
| Females | 6.339 | 2.203 | -1.612 | 0.238 | 0.107 |
| Males | 5.013 | 2.394 | -1.971 | 0.285 | 0.049 |
| Total | 5.754 | 2.203 | -2.529 | 0.261 | 0.011 |

The results of a mixed within-between analysis of variants as measured by $P_{\text {regline }}$ are listed in Table 3. The results indicate no significant main effect of either gaze or gender, as well as no interaction effect of the two variables.

To explore possible individual variations in mimicry (taking pitch slope as the representative measure), we computed

Figure 6: The median values of $P_{\text {deriv }}$ absolute differences between the agent's and the participant's pitch for direct and averted gaze including error bars ( $95 \% \mathrm{CI}$ ).

Table 3: Results of ANOVA test for mimicry as measured by $P_{\text {regline }}$ depending on eye gaze direction.

|  | df | $F$ | $p$ | $\eta_{p}^{2}$ |
| :--- | :--- | :--- | :--- | :--- |
| $P_{\text {regline }}$ |  |  |  |  |
| Gender | 1 | 0.083 | 0.775 | 0.002 |
| Gaze | 1 | 1.772 | 0.190 | 0.038 |
| Gender $\times$ Gaze | 1 | 0.386 | 0.537 | 0.009 |

for each participant the average difference between $M_{V}$ in the averted gaze condition and $M_{V}$ in the direct gaze condition. The resulting scores reflect the individual effect of gaze on vocal mimicry; positive scores are associated with vocal mimicry, negative scores with vocal complementarity. Figure 7 is a graphical display of the scores, sorted from smaller to larger scores. Each bar represents a participant, and the height of the bar represents the magnitude of mimicry (positive) or complementarity (negative).

Figure 7: Individual differences in vocal mimicry
To sum up, we found that participants exhibit verbal mimicry as measured by $P_{\text {deriv }}$ and $P_{\text {regline }}$ and that at least in the case of $P_{\text {deriv }}$, the mimicry effect is stronger when the agent gazes at the participant. In addition, we observed individual varia-
tions in the degree of vocal mimicry. The implications of our findings are discussed in the next section.

## 4. General Discussion and Conclusion

Pitch is arguably the most important source of information regarding emotions, stances and attitudes of the speaker (Juslin \& Laukka, 2003) and pitch mimicry plays an important role in human interaction in that it reflects the closeness of the social bond between two individuals. Our findings indicate that pitch mimicry in social interactions may be modulated by eye gaze. The results of our experiment extend and generalize the findings obtained by Wang et al. (2011) for the visual (gesture) modality. The existence of eye-gaze modulated vocal mimicry underscores the importance of eye gaze as a social signal and lends further support to the close relation of eye contact and behavioral mimicry in social interaction.

The potential impact of eye gaze on the social bond between virtual agents and humans is of relevance to the development of future human-computer interfaces that display an interactive embodied agent and sense vocal and visual cues of the human interacting with the agent. Software controlling an interactive embodied agent, may confirm the establishment of a social bond with the human by instructing the agent to eye gaze and vocally address the human and subsequently sense the concomitant vocal mimicry.

In our experiment, participants were instructed to repeat the digit pronounced by the agent. It is not clear to what extent the mimicry observed depends on the type of instruction. Future work may experiment with alternative types of responses. For instance, participants could be instructed to complete a partial sentence uttered by the agent or to respond to a statement. In this way the dependency between an explicit instruction to repeat an utterance and behavioral mimicry can be determined.

Our use of a male human voice and a male virtual agent, may have caused gender effects that can be further explored in future studies. According to the CAT (Giles et al., 1991), talkers modify their speech to reinforce valued and socially meaningful differences between themselves and their interaction partners. Since male voices are lower pitched than female voices (Sachs, Lieberman, \& Erickson, 1973), females possibly reinforced the gender difference between themselves and the agent by deviating from the agents relatively low pitched voice and produce a higher pitched voice. Another issue to be explored in the future concerns the effect of joint attention. As well known, interlocutors are likely to follow each others gaze direction. It remains to be seen if contexts eliciting joint attention support vocal and other types of behavioral mimicry.

#### Abstract

In a series of experiments conducted with Dutch native speakers, we explored systematic size/power sound-symbolic associations in novel and existing words. In Experiment $1(N=64)$, participants associated vowel-intrinsic fundamental frequency with size/power, disregarding the modality of stimuli presentation (spoken, written), but depending on the lexical status of the stimulus (more strongly for novel then for existing words). In Experiment $2(N=56)$, we explored the idea that the order of vowels in a word affects soundsymbolic associations, as pitch contours emerge from a sequence of vowel-intrinsic fundamental frequencies. Participants perceived stimuli with 'rising' combinations of front-back vowels as less powerful than stimuli with 'falling' combinations. This finding indicates that even in non-tonal languages, sound symbolism is not bound to a single segment (phoneme). We compared the effect to the perception of tones in a tonal language, which we explored in Experiment 3 with Mandarin native speakers $(N=96)$ judging the perception of power in monosyllabic novel brand names with four different tones (rising, falling, level and fall-rise). In Experiment 4 ( $N=146$ ), we examined the effect of vowel-intrinsic intensity, which has previously remained un-noted. The results showed that like fundamental frequency, also intrinsic intensity influences size/power-symbolic associations.

Keywords: Sound Symbolism; Cross-modal Correspondence; Form-Meaning Arbitrariness; Frequency Code; Intrinsic Intensity; Intrinsic Fundamental Frequency.

## Introduction

A series of relatively recent experiments has shaken one of the most fundamental postulates about human language, namely the arbitrariness assumption regarding the relation between the sound structure of a word and its meaning. Originating with de Saussure, it has long been presumed that the number of pictorial, imitative, or onomatopoetic words in any language is very small (Hockett, 1958; de Saussure, 1916/1959). However, in violation of de Saussure's arbitrariness assumption, many studies confirm that both existing words and non-words in different languages evoke connotations based on their sound structure (Klink, 2000, 2001, 2003; Yorkston \& Menon, 2004; Lowrey \& Shrum, 2007; Shrum et al., 2012; Kovic et al.,

2010; Coulter \& Coulter, 2010; Aveyard, 2012; Parise \& Spence, 2012; Spence, 2011; Baxter \& Lowrey, 2011). The sound-meaning link appears to facilitate both L1 and L2 learning (Nygaard et al., 2009; Imai et al., 2008) by helping to solve the "cross-modal correspondence problem" (which stimuli to link to link together across the senses; Spence, 2011; Bremner et al., 2012) and has been claimed to hold universally (Ultan, 1978; Ramachandran \& Hubbard, 2005).

On the one hand, languages encode crossmodal relationships by mapping phonemes to specific shapes. For example, by virtue of the so-called "Bouba-Kiki" effect, round vowels are typically linked to rounded objects, whereas high-pitched un-round vowels bring to mind angularity (Köhler, 1929; Ramachandran \& Hubbard, 2001; Westbury, 2005; Bremner et al., 2012). The effect seems to hold for children as young as 2-2.5 years and concerns both objects and visual actions (Maurer, Pathman, \& Mondloch, 2006; Imai et al., 2008). On the other hand, sound-symbolic phenomena might give rise to a visual size/power association (Sapir, 1929). In various languages, words containing vowels with high intrinsic fundamental frequency, the acoustic correlate of pitch, (e.g., front vowels such as /ı, i, $\varepsilon /$; Lehiste \& Peterson, 1961; Whalen \& Levitt, 1995) are perceived as referring to lighter, thinner, smaller, less powerful and more feminine entities/individuals and, possibly, prickly, sour taste (Crisinel \& Spence, 2009) as opposed to words containing vowels with low intrinsic fundamental frequency (e.g., back vowels such as $/ \tau, o, \rho /$ ). A similar effect can be achieved by using different types of consonants that can influence fundamental frequency either directly, or by raising the frequency of the accompanying vowel (cmp. voiceless vs. voiced consonants, fricatives vs. plosives). The effect has primarily been observed for nonwords (e.g., invented brand names; Klink, 2000, 2001, 2003; Yorkston \& Menon, 2004; Lowrey \& Shrum, 2007; Shrum et al., 2012) but appears to hold for existing words as well, at least in limited domains: In a study in the area of consumer psychology, Coulter \& Coulter (2010) reported that vowel pitch in numerals can influence the perception of price discounts in English and Chinese.

The association between pitch and size/power can, for the most part, be explained by the mechanism of the Frequency Code (Ohala 1994; Gussenhoven, 2004), a psycholinguistic principle primarily used to account for interpretational effects of rising and falling utterance contours in different languages (Chen, 2004). According to the Frequency Code, high pitch is linked to smaller immature speakers (with thinner, smaller vocal folds and shorter vocal tracts producing higher fundamental frequency) and, hence, utterances carrying high and/or rising pitch are interpreted as less dominant, more uncertain, friendlier and questioning. Presumably, the effects of the Frequency Code can be translated from the suprasegmental domain (utterance prosody) to the micro-prosodic, segmental domain, and affect meaning with the help of motor-imitative mechanisms associated with speech perception.

## Current Study

In our current study, we attempted to explore further the effect of phonetic segment-intrinsic properties on interpretation of words and non-words. Surprisingly, past research of the sound-referent cross-modal mappings mostly involved written presentation of stimuli. Given that the Frequency Code is grounded in principles of speech production, the question arises what role the modality of presentation plays in the sound-size association. Are sound symbolic effects stronger if words are presented aurally rather than visually? Moreover, according to most models of reading (Coltheart, 2006; Coltheart, 2012), unlike existing words, pseudo-words and non-words can only be pronounced with the help of a system that associates visual segments (i.e., graphemes) with sounds. Are soundsymbolic effects stronger for pseudo-words and non-words than for existing words? We addressed these two questions in Experiment 1 conducted with Dutch native speakers.

Existing research in the area of phonetic symbolism has, so far, disregarded the possibility that not just individual phonemes, but also their sequences, might create meaningful associations between phoneme-intrinsic fundamental frequency and meaning, by virtue of producing a micro-prosodic contour. For example, in words consisting of two syllables, a sequence of high-low vowels (e.g., /CiCo/) produces a "falling contour", while the opposite sequence (/CoCi/) produces a "rising contour". In accordance with the predictions of the Frequency Code (Gussenhoven, 2004; Chen, 2004), these two contours should receive different interpretations (big/powerful and small/powerless, respectively). Do sound-symbolic associations vary with different sequencing of high- and low-pitched phonemes in a word? We explored the issue in Experiment 2 and compared the outcomes collected for a non-tonal language (Dutch) with perceptions of lexical tones in a tonal language (Mandarin Chinese) in Experiment 3.

The last issue raised in the current study concerns the effect of other segment-intrinsic prosodic features apart from fundamental frequency, in particular, segment-intrinsic intensity (Lehiste \& Peterson, 1959). As observed in
prosodic studies of interpersonal influence, intensity (loudness) is positively associated with judgments of dominance and potency (Scherer, 1974; Aronovitch, 1976; Buller \& Burgoon, 1986). If size/power-symbolic relations arise by transfer from the suprasegmental to the segmental domain, we might expect sounds with intrinsically higher intensity to have an effect comparable to that of low intrinsic fundamental frequency. To our knowledge, soundsymbolic associations of intrinsic intensity have not been explored in the past. Given the frequent co-occurrence of high intrinsic intensity and low intrinsic pitch, it might, in fact, be the case that at least some of the sound-meaning associations reported in the literature might be due to intrinsic intensity, rather than intrinsic fundamental frequency. Therefore, we also examined the interplay of the two acoustic features in Experiment 4.

To sum up, in our study, we addressed the following research questions:

1. Are sound symbolic effects stronger if words are presented aurally rather than visually? Are they stronger for pseudo-words than for existing lexemes? (Experiment 1)
2. Do sound-symbolic associations vary with different sequencing of high- and low-pitched phonemes in a word? (Experiment 2 and 3)
3. Are sound-symbolic associations affected by segmentintrinsic intensity? (Experiment 4)

## Experiment 1

In the first experiment, we addressed the question whether or not the modality in which stimuli are presented can affect sound-symbolic interpretation of vowel-intrinsic fundamental frequency. Given that most studies of crossmodal correspondences make use of non-words and pseudowords, we were also interested to find out if the effect is weaker (or perhaps absent) for items with denotative components.

## Participants and Design

Sixty-four native speakers of Dutch ( 32 male; $M_{\text {age }}=25.3$, $S D=10.5$ ) participated in the experiment on a voluntary basis. The experiment had a $2 \times 2 \times 2$ mixed withinbetween design. The between-participant variable was Modality in which participants perceived the stimuli (reading or listening). The participants were randomly assigned to the reading or listening condition (32 in each). The within-participant variables were Denotation (stimuli consisting either of existing words or pseudo-words) and Vowel-Intrinsic Fundamental Frequency (High or Low). The dependent variable was Perceived Power/Size.

## Material

The stimuli were either pseudowords consisting of phoneme and syllable combinations that are possible in Dutch but meaningless (e.g., Boloem, Wabboelan, Piripi and Kenep) or pseudowords composed of meaningful morphemes (e.g., Zondaar, Godenbad, Tinteling or Kietelkit). In total, 160 biand tri-syllabic stimuli were systematically divided into four
variants, resulting in lists of 40 items ( 20 existing words or compounds, 20 pseudo-words). For the listening condition, the stimuli were recorded in a soundproof booth by a native Dutch female speaker ( 50 y ) without any detectable dialect or speech habits.

## Procedure and Instrumentation

The experiment was cast as a marketing study of brand names for a generic type of shampoo. In the listening condition, the stimuli were presented on a Philips Go Gear MP4 with a headset. In the reading condition, the participants filled out a pen-and-paper form. Each experimental session lasted 6-10 minutes. Participants indicated their perception of the brand names on 4 VAS scales each 7.5 cm long (male/female, big/small, dominant/not dominant and unfriendly/friendly). The Cronbach's alpha coefficient of the four scales was .8 and the scales were reduced to a single Perceived Power/Size measure.

## Results

A mixed analysis of variance was used to explore the effect of the independent variables on the Perceived Power/Size. Stimuli with low intrinsic vowel frequency scored higher on the Power/Size scale than stimuli with high frequency vowels, $F(1,62)=326.77, p<.001, \eta_{p}{ }^{2}=.79$. The interaction effect of Denotation and Vowel-Intrinsic Fundamental Frequency was also significant, $F(1,62)=$ 41.29, $p<.001, \eta_{\mathrm{p}}{ }^{2}=.40$; the interpretation of pseudowords was more sensitive to the intrinsic vowel properties and their size/power-symbolic associations. Than the interpretation of existing words. There was no effect of modality of presentation.

## Discussion

The results of the first experiment show that the perception of pseudowords consisting of both meaningful and meaningless morphemes is influenced by vowel-intrinsic fundamental frequency: in accordance with the predictions of the Frequency Code, front vowels are associated with less power/smaller size than back vowels. The effect was found to be independent of the modality in which stimuli were presented. The effect was stronger for meaningless pseudowords than for those composed of existing morphemes, suggesting that the phoneme-to-grapheme route (Coltheart, 2006; Coltheart, 2012) might play a role.

## Experiment 2

In the second experiment, we addressed the question of the scope of vowel-intrinsic fundamental frequency effects: Are they bound strictly to the individual phonemes or can they combine into tones with different sound-symbolic interpretations, akin to lexical tones in tonal languages?

## Participants and Design

The experiment was conducted among 56 participants ( 25 male, $M_{\text {age }}=35.9, S D=13.0$ ), all native speakers of Dutch,
taking part on a voluntary basis. The independent variable was Vowel-Intrinsic Fundamental Frequency (High, Low, Falling and Rising and the dependent variable was perceived Power/Size of the stimulus (brand name).

## Materials

The stimulus list contained 32 meaningless pseudowords, 16 experimental and 16 fillers. The experimental items consisted of 8 bisyllabic and 8 monosyllabic meaningless pseudowords with either the sequence front vowel - back vowel or the opposite, or just a front or a back vowel, with a systematic variation of voiced and voiceless plosives and fricatives (see Table 1).

## Procedure and Instrumentation

The experiment was cast as a marketing study for a new product name and presented online via the LimeSurvey platform. The stimuli were presented in a visual modality only. Participants evaluated the stimuli on four 7-point scales (male/female, big/small, thick/thin and heavy/light). The mean Cronbach's alpha coefficient was .8 and for the purpose of the statistical analyses, the scales were thus reduced to a single Power/Size measure.

Table 1: Examples of experimental stimuli.

|  |  | High | Low | Falling | Rising |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  |  |  |  |
| C-Type | Voicing |  |  |  |  |
| Plosive | - | $T i$ | To | Tito | Toti |
|  | + | $B i$ | Bo | Bibo | Bobi |
| Fricative | - | Vie | Voe | Vievoe | Voevie |
|  | + | Soe | Sie | Siesoe | Soesie |

## Results

A repeated-measures ANOVA showed a significant effect of Vowel-Intrinsic Fundamental Frequency on the Perceived Power/Size of the novel product name, $F_{l}(3,165)=47.59$, $p<.001, \eta_{\mathrm{p}}{ }^{2}=.46, F_{2}(3,31)=4.23, p<.05, F_{\text {min }}^{\prime}(3,37)$ $=3.88, p<.05$. A post-hoc analysis indicated that the frontback (intrinsically falling) sequence was evaluated as more powerful ( $M=4.23, S D=.74, p=.017$ ) than the back-front (intrinsically rising) sequence ( $M=3.92, S D=.68, p<$. 001 ) and monosyllabic front-vowel stimuli (intrinsically high; $M=3.00, S D=.66, \mathrm{p}<.001$ ). The monosyllabic backvowel stimuli (intrinsically low) were perceived as the most powerful product names $(M=4.33, S D=.66)$ compared to the other three types $(p<.001)$.

## Discussion

In the second experiment, we tested the interpretation of vowel-intrinsic $F_{0}$ in combinations of two syllables, using the dimensions 'front-back' (/I-9/ and /i-u/). The vowel order had a large significant effect on the perception of Power/Size. Stimuli with 'rising' combinations of front-back vowels (e.g., /kuki/) were perceived as less powerful than stimuli with 'falling' combinations (e.g., /kiku/); they were
also judged as being less powerful than monosyllabic stimuli with a high (front) vowel. This finding indicates that sound symbolism that arises due to vowel-intrinsic fundamental frequency is not bound to a single phoneme but may be the result of combining the acoustic values for sequences of syllables.

## Experiment 3

In the third experiment, we explored sound-symbolic interpretations of tones in a tonal language (Mandarin Chinese). In spite of the long tradition of phonetic and phonological research into tone perception and use in tonal languages, no experimental studies have laid an explicit link between the Frequency Code and lexical tones (for a general overview, see Lapolla, 1994).

## Participants and Design

Ninety-six graduate and undergraduate Chinese students (39 male) from a university in Beijing participated in the study, 11 participants were excluded from the analysis due to incomplete data caused by server problems. The study was conducted in Mandarin Chinese and had a $2 \times 4$ design mixed within-between participant design. The withinparticipant variable was Tone (Tone 1 in high pitch height (H) - Level, Tone 2 in half-high pitch height (LH) - Rising, Tone 3 in half-low pitch height $(\mathrm{L}(\mathrm{H})$ ) - Low-Rising, and Tone 4 in low pitch-height (HL) - Falling; Gussenhoven, 2004; Wiedenhof, 2004). The between-participant variable was the writing system (Chinese characters or Pinyin); participants were randomly divided into one of the two conditions ( 45 in the character-written group and 40 in the Pinyin-written group).

## Material

Sixteen non-existent brand names (pseudowords) were written in matched Chinese characters and in Pinyin with four different tones (e.g., lū, lú, lǔ and lù). A pretest conducted with the Pinyin transcriptions showed that Chinese readers (same population, different group than the participant group) did not have any meaningful associations with the stimuli outside of the context of the experiment.

## Procedure and Instrumentation

Participants evaluated the visually presented stimuli on a 7point scale using the anchors "not powerful at all" (1) and "very powerful" (7). The study was conducted online with help of the Qualtrics platform.

## Results

There was a significant main effect of the type of tone on the average perceived power of brand names, $F(1.88$, 156.71) $=79.297, p<.001, \eta_{\mathrm{p}}{ }^{2}=.49$, with degrees of freedom corrected using Huynh-Feldt estimates of sphericity. Post-hoc comparisons revealed that the Tone 4 (Falling) was more powerful than the other three Tones. Tone 2 (Rising) and Tone 3 (Low-Rising) were more powerful than Tone 1 (Level/High); the perception of Tone 2
was not different from the perception of Tone 3, see Fig. 1. The writing system used for the presentation of stimuli did not have a significant effect.

Figure 1: Perception of Chinese lexical tones in novel brand names.

## Discussion

The results of the experiment show that the lexical tones in Mandarin Chinese are interpreted in a similar way as segmental and suprasegmental pitch (fundamental frequency) in non-tonal languages. Along the lines predicted by the Frequency Code, high (level) and rising tones are associated with less powerful brand names than falling tones.

## Experiment 4

In the fourth experiment, we identified another intrinsic acoustic property of vowels, namely intensity, as a feature that might play a role in cross-modal relationships. Given that the two acoustic values often correlate, it could be that at least some of the sound-symbolic effects discussed in the literature are caused by perceptions of intensity. Therefore, we were interested in a possible interplay of the two acoustic properties.

## Participants and Design

The participants were 146 native Dutch speakers ( 84 male, $\left.M_{\text {age }}=40.39, S D=13.5\right)$ who took part in the experiment on a voluntary basis. The experiment had a $2 \times 2$ withinparticipant design, with Fundamental Frequency (High, Low) and Intensity (High, Low) as independent variables and Perceived Power/Size as the dependent variable.

## Material

We used 40 fictitious brand names (pseudowords) as stimulus material. The brand names were constructed in accordance with the measurements of intrinsic fundamental frequency and intrinsic intensity of vowels (Lehiste \& Peterson, 1959; 1961) and within the limits of the Dutch
phonemic inventory in the following way: we selected four vowels as the most extreme representatives of the two acoustic dimensions (/u/ ~ [+ Fundamental Frequency, + Intensity], $/ \mathrm{i} / \sim$ [ Fundamental Frequency, - Intensity], /a/ $\sim$ [- Fundamental Frequency, + Intensity] and $/ \mathrm{I} / \sim$ [Fundamental Frequency, - Intensity]), see Fig. 2. The four vowels were systematically combined with both voiced and voiceless consonants in bi-syllabic non-words ("company names"), e.g. Manan, Doedoer, Tipit and Liediel.

Figure 2: Intrinsic fundamental frequency and intrinsic intensity of vowels (after Lehiste \& Peterson, 1959, 1961).

## Procedure and Instrumentation

The material was presented visually via the LimeSurvey platform as a part of a marketing study conducted on behalf of a foreign company in the Netherlands. Participants evaluated possible company names on four 5 -point scales: male/female, big/small, dominant/submissive and strong/weak. On the basis of the Cronbach's alpha (. 9 on average), the measures were reduced to a single scale.

## Results

The results of a repeated measures ANOVA show a significant effect of Fundamental Frequency, $F_{( }(1,145)=$ $223.44, p<.001, \eta_{\mathrm{p}}{ }^{2}=.61, F_{2}(1,36)=73.75, p<.001$, $F_{\text {min }}^{\prime}(1,62)=55.45, p<.001$, and a slightly weaker significant effect of Intensity, $F_{l}(1,145)=155.17, \mathrm{p}<.001$, $\eta_{\mathrm{p}}{ }^{2}=.52, F_{2}(1,36)=49.47, p<.001, F_{\min }^{\prime}(1,61)=37.51$, $p<.001$, as well as a trend of an interaction effect, $F_{l}(1$, $145)=26.66, p<.001, \eta_{p}{ }^{2}=.17, F_{2}(1,36)=3.76, p<$. $001, F_{\text {min }}^{\prime}(1,47)=3.30, p=.08$ on the perceived Power/Size, see Table 2.

Table 2: Mean Perceived Power/Size.

| Fundamental <br> Frequency | Intensity | $M$ | $S D$ |
| :---: | :---: | :---: | :---: |
| High | High | 2.34 | .75 |
|  | Low | 2.01 | .58 |
| Low | High | 3.00 | .65 |
|  | Low | 2.43 | .60 |

## Discussion

The results of Experiment 4 indicate that sound-size/power correspondence can arise not just thanks to vowel-intrinsic fundamental frequencies but also as a result of intrinsic intensity. Given that the two acoustic values appear to be in a negative correlation, it was not possible to pry apart their effects using written stimuli. In a follow-up study, their contribution could be explored in detail with the help of artificially synthesized stimuli. Another issue to explore in the future concerns individual differences in vowel pronunciation. As noted by Lehiste \& Peterson (1959, 1961), different speakers, in fact, vary in their use of the vowel space. The question thus arises if the sound-symbolic effects found in various studies are linked to speakers' own prototypical production targets or based on previous perceptual experience.

## General Discussion and Conclusion

In our study, we addressed a number of important questions regarding cross-modal correspondences in the auditory domain. We conducted a series of experiments under the assumption that the size/power sound-symbolic relations are due to intrinsic acoustic properties of phonemes captured by the psycholinguistic principle of the Frequency Code, rather than by idiosyncratic mechanisms akin to weak synaesthesia (see Parise \& Spence, 2012, for a discussion). The results of the experiments indicate that sound symbolic effects are not necessarily stronger when words are presented aurally rather than visually, however, the cross-modal sound-size correspondences are stronger for pseudo-words than for existing words. The intrinsic fundamental frequency effects are not bound to individual phonemes but can combine into tones with different sound-symbolic interpretations. In a sense, non-tonal languages thus resemble tonal languages where different lexical tones appear to be interpreted differently (at least on pseudo-words). Finally, other acoustic features apart from fundamental frequency may codetermine the cross-modal sound-based associations: in particular, intrinsic intensity seems to play a significant role.

## Acknowledgments

The authors would like to thank Jill Meijer, Milou Steenvoorden, Xiaohan Wang and Stijn Gimbrère for their help with collecting experimental data.

# Justified True Belief Triggers False Recall of "Knowing"

#### Abstract

Philosophers traditionally held that knowledge is justified true belief. Gettier (1963) challenged this view with thought experiments in which someone has a justified and true belief, but an element of luck is involved that disqualifies the belief from counting as knowledge. We examined laypeople's concept of knowledge using a semantic integration paradigm modeled after that of Gentner (1981). Participants read stories in which a character 'thought' something was true. On a subsequent recall task, readers sometimes falsely recalled the verb 'thought' as 'knew,' implicitly indicating that the reader had attributed knowledge to the character. False recall of 'knew' occurred more frequently when the story described a justified true belief than an unjustified belief. Justified true belief triggered these recall errors even in a so-called "Gettier case". The present findings suggest that semantic integration provides an empirical paradigm suitable for investigating lay notions about knowledge.

Keywords: belief; knowledge; semantic integration; false memory; experimental philosophy

People's beliefs are the primary drivers of their actions, yet these beliefs are often uncertain-the products of limited information about the world and interconnections between other (often uncertain) beliefs. For this reason, a capacity for evaluating the status of different beliefs is important for individuals in directing their own rational behavior, and for predicting the behavior of others. Understanding these processes requires an analysis of the concept of knowledge: the distinction between what is known versus what is merely believed, imagined, hoped for, or assumed. Research on metacognition has examined how people assess their confidence in their own beliefs (e.g., Klayman et al., 1999; Tsai, Klayman \& Hastie, 2008), and research on theory of mind (Premack \& Woodruff, 1978) has examined how beliefs are attributed to others (e.g., Birch, 2005) but there
has been very little psychological research examining the self-assessment and attribution of knowledge.

Making a decision about when to attribute knowledge, either to oneself or to another, hinges on one's conception of knowledge: it is a decision about whether or not the concept applies in a particular instance. Although other factors may play into this decision process, understanding the exact nature of the concept itself is essential to understanding the overall process of knowledge attribution. Philosophers have long contemplated the nature of knowledge, and have also developed a variety of methods for studying concepts. A common method involves using thought experiments.

One of the most influential of these thought experiments was proposed by Edmund Gettier (1963). Named for their progenitor, "Gettier cases" challenge the traditional conception of knowledge. Prior to the 1960s, most philosophers thought that knowledge should be analyzed as justified true belief. Today, many philosophers see Gettier cases as counterexamples to that analysis. Gettier cases are situations in which an agent has a true belief that is justified, but an element of luck is involved that disqualifies their cognitive state from being considered knowledge. To illustrate such a case, suppose that at $3: 34 \mathrm{pm}$ an agent comes to believe it is $3: 34 \mathrm{pm}$ by looking at her normally reliable watch. Suppose also that unbeknownst to the agent, her watch had been stopped for exactly 24 hours-she just happened to glance at her watch at the correct time. The agent's belief is not only true, but is also justified (since looking at one's normally reliable watch is a good way to form veridical beliefs about time of day). However, most philosophers judge that this agent does not know that it is $3: 34 \mathrm{pm}$, because her belief is true only by luck. If this judgment is correct, then this case is a counterexample to the traditional thesis that knowledge is justified true belief. It remains an open question whether philosophers' conceptions of knowledge are shared by laypeople. Recently,
experimental philosophers have sought to empirically investigate laypeople's intuitive judgments about philosophical thought experiments (for a review, see Knobe et al., 2012). In particular, researchers have turned their attention to examining whether philosophers' Gettier judgments are shared by laypeople (Weinberg, Nichols \& Stich, 2001; Turri, in press). Starmans and Friedman (2012) investigated laypeople's evaluations of Gettier cases by presenting participants with short vignettes that described agents forming beliefs under different circumstances. Three different versions of each scenario were created: the agents in the vignettes either formed a false belief, formed a justified true belief, or were "Gettiered"-the belief they formed was both justified and true, but was true only by luck. Starmans and Friedman then asked participants to judge whether the agents "knew" or "only believed" the proposition in question, and to rate how confident they were in their judgment. Participants attributed knowledge to agents in Gettier cases almost as readily as they did in cases of non-Gettiered justified true belief, suggesting that laypeople's concepts of knowledge may differ from those held by many philosophers. Their findings led Starmans and Friedman to conclude that laypeople view knowledge as justified true belief, in accord with the more traditional philosophical view.

However, the survey-based methodology used by Starmans and Friedman (2012) has limitations. Answers on such surveys may be influenced by demand characteristics (Orne, 1962). For example, if participants form some interpretation of the experimenter's hypothesis, they may attempt to confirm or disconfirm this hypothesis. In addition, participants commonly display apprehension about being evaluated (Weber \& Cook, 1972). This may lead them to give responses they perceive as either socially desirable, or likely to be considered "correct," irrespective of their actual attitudes or answers. For research on folk concepts, this type of evaluative apprehension might be manifested as a sort of amateur philosophizing, or attempts to avoid being "tricked" by the experimenter.

A further concern with survey-based methods is that asking participants to make knowledge attributions fails to isolate their knowledge concepts from other decision processes that could influence their judgments downstream. This is a general problem for survey-based methods, one that applies not only to investigations of concepts for knowledge, but also to investigations of lay concepts in general. Recently, social psychologists and experimental philosophers have investigated such concepts as intentional action (e.g., Knobe et al., 2012), causation (e.g., Livengood \& Machery, 2007), and explanation (Braverman et al., 2012), but thus far their methods have been primarily survey-based. In fact, almost all work in experimental philosophy utilizes these methods.

Here we propose and test a new method for examining people's concepts, based on psychological research related to semantic integration. Semantic integration is the cognitive process by which smaller units of semantic
information are combined to form larger meaningful structured representations, or "discourse meanings," during language processing. Many researchers in cognitive psychology and psycholinguistics have investigated how these structured representations are formed and how they are stored in memory. Early research by Sachs (1967) revealed that memory for the meaning of sentences is more robust than memory for their specific wordings. During language processing, the original form of presented material is stored only temporarily, just long enough to be comprehended. Once comprehended, the material's meaning is then encoded into long-term memory. Bransford and Franks (1971) reasoned that if semantic information is integrated during language processing, and it is the meaning of a passage that is actually encoded into memory, then human memory ought to exhibit productivity. That is, it should be possible for exposure to several basic, interrelated propositions to produce false verbatim memory for more complex propositions that express their combination, even when these propositions were never themselves experienced. These sorts of productive memory errors have been taken as evidence for semantic integration across a variety of language comprehension contexts (Flagg, 1976; Owen, Bower \& Black, 1979; Gentner, 1981; Sulin \& Dooling, 1974; Thorndyke, 1976).

To explain such findings, Gentner (1981) proposed a model of language processing in which linguistic propositions are considered both individually and in the broader context of the story in which they appear. Her model assumes that when a sentence is read within the context of a larger passage, the discourse meaning that a reader forms may incorporate information not contained in the original sentence.

In evaluating this model, Gentner (1981) focused her investigations on a relatively well-analyzed area of linguistics, the meanings of verbs. She was able to make specific predictions about how manipulations of the contextual information given in a passage of text would affect later recall for verbs within that passage. To illustrate, consider the relationship between the general verb 'give' and the more specific verb 'pay'. An informal analysis suggests that 'to give' some item is to take some action that transfers ownership of that item to a recipient. 'Paying' is a more specific form of giving, in which the giver owes the recipient. In her experiments, Gentner (1981) asked her participants to read paragraph-long stories that each featured a critical sentence containing some key verb of interest. For instance, one of these stories contained the critical sentence, "Max finally gave Sam the money." Two versions of this story were created, one that contained additional context explaining that Max owed Sam money, and a control story that lacked this information. After reading one version of the story, Gentner's participants performed a recall task, in which they were shown the critical sentence with the word 'gave' removed, and asked to fill in the word that had appeared in the story. In support of her predictions, Gentner found that participants who had been provided with the
additional contextual information were more likely to falsely recall the more specific verb 'paid' as having appeared in the critical sentence than participants who had read the control story.

We aimed to turn this methodology on its head: Whereas Gentner (1981) used a false recall paradigm to examine how known semantic structures are integrated during language processing, we used a similar paradigm to examine the semantic structure of the concept 'knowledge'. Following Gentner (1981), we constructed stories containing the generic cognition verb 'thought', and used false recall of the more specific verb 'knew' as a measure of the extent to which different contexts instantiate the semantic structure of 'knowledge'. By incorporating the relevant contextual information into our stories, we can examine whether the different scenarios imagined in various thought experiments differentially activate people's concept of knowledge.

Gentner's (1981) paradigm has several qualities that are desirable for our present purposes, relative to other semantic integration tasks. First, the use of free recall makes its results more compelling than tasks that rely on recognition judgments. Participants' responses to recognition tasks can be influenced by both true recollection as well as feelings of familiarity (Tulving, 1985). In contrast, explicit recall of the word 'knew' provides strong evidence for the semantic activation of the concept. Second, this paradigm focuses responses onto a single specific word of interest, whereas other semantic integration paradigms often ask participants to evaluate larger semantic units, such as phrases or sentences. This specificity may help reduce ambiguity in investigations of individual concepts.

Experiment 1 served as a proof of concept, demonstrating that semantic integration can be used to investigate laypeople's concept of knowledge. In Experiment 2 we examined the more controversial issue of how Gettier cases activate people's concept of knowledge.

## Experiment 1

## Method

In Experiment 1 we constructed two similar stories about a detective investigating a crime. In the first story, the detective forms the justified true belief (JTB condition) that his suspect is guilty: the omniscient narrator reveals that the detective's suspect committed the crime, and the detective uncovers evidence that his suspect is guilty. In the second story, the detective forms the unjustified belief (UB) that his suspect is guilty: he cannot find any useful evidence linking his suspect to the crime, and the narrator does not reveal whether the suspect is guilty. Following Gentner (1981), each story included a critical sentence with a critical word (italics added here for emphasis): "Whatever the DA's reservations, Dempsey thought Will was guilty." The critical word in both stories was 'thought', a generic cognition verb that could plausibly be recalled as 'knew', should the right conditions be met. This critical sentence was later presented with a blank in place of the critical word,
and participants were asked to recall the word that appeared in the story.

Based on prior research involving semantic integration and false recall paradigms (Gentner, 1981), we predicted that participants who read the story in which Dempsey's belief is justified and true would be more likely to falsely recall the word "knew" than participants who read the story in which Dempsey's belief is unjustified. Of course, it will not come as a surprise if a justified true belief more closely resembles people's concept of knowledge than an unjustified belief. Experiment 1 examined this simple case in order to demonstrate the potential of the semantic integration paradigm.

Participants This experiment was conducted online, with 147 participants ( 91 female) recruited from Amazon's Mechanical Turk (mTurk). The mean age of the participants was 34 years. They were all paid $\$ 0.50$ for their participation.

Procedure Participants were randomly assigned to the JTB and UB conditions, and were asked to read the corresponding story about the detective. Then, participants completed a distraction task, reading an approximately 1000 -word selection from a fictional article on gamma ray bursts (taken from Waskan et al., under review). Timing controls ensured that participants spent an adequate amount of time attending to each section of the experiment.

In the recall task, participants were shown five sentences from the detective story, each missing one word that was replaced with an underscored blank space. They were instructed to type in the word that originally appeared in the story. The critical sentence was always presented first.

After the recall task, participants were asked a direct question to assess their understanding of whether Dempsey had knowledge or not. Following Starmans and Friedman (2012), they were asked: "Would you say that Dempsey knew Will was guilty, or only thought Will was guilty?" They indicated their choices as 'knew' or 'thought,' and then rated their confidence on a 1-5 Likert scale.

## Results and Discussion

Recall task Participants' responses during the recall task were classified as either 'thought'-type responses or 'knew' responses. Words and phrases synonymous with 'thought' but neither stating nor implying knowledge were grouped together as 'thought'-type responses. In an effort to remain conservative, only the word 'knew' was counted toward the tally of 'knew' responses. Responses that were nonsense (i.e., were not verbs, were random letters typed in the blank, etc.) were excluded from analysis. After these exclusions, 64 participants remained in the JTB condition and 65 participants remained in the UB condition.

As predicted, participants recalled the word 'knew' significantly more often when they were assigned to the JTB condition than when they were assigned to the UB condition ( $39 \%$ vs. $18 \% ; X^{2}(1)=5.72, p=.016$ ). This
finding demonstrates that participants semantically integrated contextual information, specifying that Dempsey's belief was both true and justified, with the generic cognition verb 'thought,' leading to false recall of the more specific verb 'knew.'

Knowledge survey question Following Starmans and Friedman (2012), participants' 'knew' and 'thought' responses were assigned scores of 1 and -1 respectively, and these values were multiplied by the confidence ratings participants reported to produce a knowledge rating score. Knowledge ratings from participants in the JTB condition (-1.40) were significantly higher than in the UB condition $(-3.66), t(127)=6.94, p<.001$.

## Experiment 2

## Method

In Experiment 2 we used the semantic integration paradigm to examine a more substantive question about knowledge. Specifically, we investigated the extent to which Gettier cases activate people's concept of knowledge. Experiment 2 used three stories, adapted from the detective stories of Experiment 1.

In the first story, one character "Will" is guilty of a crime and "Dempsey," the detective in the story, finds authentic evidence of his guilt, forming the justified true belief that he is guilty (JTB condition). Meanwhile, another character "Beth", who is Will's girlfriend, observes the sequence of events that unfold and result in Dempsey thinking that Will is guilty. In the second story, Will is innocent of the crime, but is framed by his girlfriend Beth because she suspects that he is cheating on her. Dempsey finds evidence planted by Beth, and as a result forms the false belief that Will is guilty of the crime (FB condition). Finally, in the third story, Will is guilty of the crime, but he has eliminated all the authentic evidence of his crime. Beth, as part of a ploy to seek reprisals against Will, plants evidence that implicates him in the crime. Dempsey finds this evidence and forms the belief that Will is guilty. In this case, Dempsey's belief is both justified and true, but is only true by chance (Gettier condition). In each of these stories, the critical sentence read, "Whatever the ultimate verdict would be, Dempsey thought Will was guilty" (italics added here for clarity).

Importantly, the evidence Dempsey uncovered was the same in each version of the story. Moreover, the structure and wording of the stories was identical-save for the relevant manipulations-and the stories were closely matched in overall length.

Participants Experiment 2 was also conducted online, with 304 participants ( 164 female) recruited from mTurk. The mean age of participants was 31 years. All participants were paid $\$ 0.50$ for their participation.

Procedure Participants were randomly assigned to one of the three conditions, and were asked to read the
corresponding story about the detective. The distractor and recall tasks for Experiment 2 were the same as those in Experiment 1. After the recall task, participants were asked the same question about Dempsey's knowledge as in Experiment 1, and were also asked, "Should Dempsey have arrested Will?" Participants rated their confidence for both responses. After these questions, participants answered a pair of comprehension questions to ensure they had attended to central details of the story.

## Results and Discussion

Recall task Some participants were excluded from analysis after failing the reading comprehension check. Others gave ambiguous free recall responses that did not fit into either the 'knew' or 'thought' response categories. After these exclusions, 259 participants remained in the final analysis. Participants' recall responses were classified according to the same criteria as in Experiment 1. Figure 1 shows the proportion of 'knew' responses in the three conditions.

False recall of 'knew' was observed significantly more often in the JTB ( $42 \%$ ) and Gettier ( $47 \%$ ) conditions as compared with the FB ( $23 \%$ ) condition $\left(X^{2}(1)=5.94, p\right.$ $=.015$, and $X^{2}(1)=9.63, p<.01$, respectively). No significant difference was found between the frequencies of 'knew' recall in the JTB and Gettiered conditions ( $X^{2}(1)$ $=.20, p=.66)$. Participants thus seemed to believe that agents in Gettier cases possess knowledge, and apparently drew no distinction between Gettier cases and non-Gettier cases of justified true belief. This finding agrees with that reported by Starmans and Freidman (2012), and stands in contrast to how philosophers have understood the implications of Gettier cases.

Survey questions Participants' knowledge rating scores were calculated as in Experiment 1. This same procedure was also employed with the "arrest" question to calculate an action rating score, where a positive score indicated that participants endorsed Dempsey's arresting Will.

Figure 1: Percent false recall of 'knew' in critical sentence across conditions

Participants' knowledge ratings differed significantly between conditions, $F(2,256)=18.12, p<.001$. Post hoc tests using Bonferroni corrections indicated that participants' knowledge ratings in both the JTB (0.62) and Gettier conditions ( -0.11 ) were higher than those in the FB condition ( $-2.56 ; p<.001$ ), but that knowledge ratings did not differ significantly between the JTB and Gettier conditions ( $p=.65$ ). This finding is consistent with the results of the recall task, and replicates the pattern of results reported by Starmans and Friedman (2012). It is worth noting, however, that participants' actual knowledge rating scores are considerably lower in the present experiment than in that reported by Starmans and Friedman. This is likely due to the different experimental materials used, and in particular the quality of evidence depicted in the different stories: Starmans and Friedman's vignettes feature direct perceptual evidence, whereas our materials describe weaker physical and testimonial evidence.

Significant differences between conditions were also found for action ratings, $F(2,256)=52.81, p<.001$, where planned comparisons revealed the same pattern as for knowledge ratings: participants action ratings differed between the JTB (3.26) and FB ( -0.12 ) conditions ( $p<.001$ ), and between the Gettier (3.80) and FB conditions ( $p<.001$ ), but not between the JTB and Gettier conditions ( $p=.69$ ). Interestingly, participants endorsed Dempsey's action (arresting Will) even when Dempsey had been Gettiered. A number of philosophers hold that knowledge is intimately connected to action (Hawthorne \& Stanley, 2008). In particular, they hold that it is intuitive that if a person knows some proposition, then it is acceptable for them to use that proposition in reasoning and in action. Our result is consistent with this thesis: in conditions where participants say that Dempsey knows Will is guilty, they also tend to say that he should have arrested Will.

## General Discussion

## Summary

Experiment 1 provided a proof-of-concept that semantic integration tasks can be used to examine people's concept of knowledge. As expected, a story in which a character forms a justified true belief activated people's concept of knowledge more strongly than a story in which this same character forms an unjustified belief, as evidenced by an increase in false recall of the verb 'knew' in place of 'thought.'

The results of Experiment 2 corroborate Starmans and Friedman's (2012) findings on laypeople's reactions to Gettier cases, while avoiding alternative interpretations that might be raised with survey-based methods. As our participants believed they were completing a memory task, it is very unlikely that their responses were affected by unwanted demand characteristics, or are indicative of some sort of performance error (Kauppinen, 2007; Cullen, 2010). Rather, their responses presumably reflect their concept of knowledge, which apparently differs from the concept
developed by philosophers who have considered Gettier cases.

These results have important implications for philosophical research. Most philosophers have accepted that Gettier cases are not instances of knowledge, and thus that knowledge is not equivalent to justified true belief. At the same time, many of them also assume that when they analyze the concept of knowledge, they are investigating a concept that is shared by laypersons (or at least that lay judgments inform philosophical theories of knowledge). In light of our findings, as well as those of Starmans and Friedman (2012), it appears that philosophers may need to reconsider their assumptions (but see Nagel, San Juan \& Mar, 2013, for evidence that different variants of Gettier cases may yield divergent findings).

The present study demonstrates that semantic integration tasks provide a promising methodology for empirically investigating lay concepts, avoiding many of the pitfalls associated with survey-based methods. Semantic integration tasks minimize the likelihood that participants' responses are affected by demand characteristics, and make it possible to isolate the activation of concepts from downstream decision processes.

## Directions for Future Research
